22 Abstract

23 The Amazon and Congo basin are the two largest continuous blocks of tropical forest with a central
24 role for global biogeochemical cycles and ecology. However, both biomes differ in structure and
25 species richness and composition. Understanding future directions of the response of both biomes
26 to environmental change is paramount. We used one elevational gradient on both continents to
27 investigate functional and stoichiometric trait shifts of tropical forest in South America and Africa.
28 We measured community-weighted functional canopy traits and canopy and topsoil $\delta^{15}\text{N}$
29 signatures. We found that the functional forest composition response along both transects was
30 parallel, with a shift towards more nitrogen conservative species at higher elevations. Moreover,
31 canopy and topsoil $\delta^{15}\text{N}$ signals decreased with increasing altitude, suggesting a more conservative
32 N cycle at higher elevations. This cross-continental study provides empirical indications that both
33 South-American and African tropical forest show a parallel response with altitude, driven by
34 nitrogen availability along the elevational gradients, which in turn induces a shift in the functional
35 forest composition. More standardized research, and more research on other elevational gradients
36 is needed to confirm our observations.

37

38

39

40 Introduction

41 A good understanding of the future response of tropical forest ecosystems to global change is
42 required because of their vital role in global biogeochemical cycles and ecology. However, due to
43 the long turnover times in forest ecosystems, it is hard to acquire insight in these future responses.
44 As a result, empirical research has since long turned to studying ecosystems along natural
45 gradients, which can greatly advance our understanding of ecosystem ecology and function in
46 response to environmental shifts. Elevational gradients in particular offer open-air space-for-time
47 experiments. Contrary to latitudinal gradients or elevational gradients in the higher latitude zones,
48 they are not complicated by changes in seasonality, and with careful interpretation can offer great
49 insights in tropical forest functioning (Körner, 2007; Malhi et al., 2010; Sundqvist et al., 2013).
50 Hence, elevational transects have been postulated as a viable and useful setup to assess long-term
51 ecosystem responses to environmental changes, and serve as an empirical tool to assess future
52 trajectories of forest ecosystems under global change (Malhi et al., 2010; Sundqvist et al., 2013).
53 This has invoked research efforts on transects in South America, but no such studies have been
54 carried out in central African forests, leaving the second-largest continuous block of tropical forest
55 understudied. Nevertheless, recent work has shown that African and South-American tropical
56 forest currently show important differences in structure (Banin et al., 2012) and species richness
57 and composition (Slik et al., 2015). These differences call for cross-continental empirical research
58 in both the Amazon and the Congo basin (Corlett and Primack, 2006), and in this context we can
59 raise questions about the universality of tropical forest biogeochemistry and functioning across
60 both continents, and subsequently their response to future global change scenarios. Additionally,
61 due to the central role of nutrient availability that drives both net ecosystem productivity (NEP)

62 and ecosystem carbon use efficiency (CUE_e) (Fernandez-Martinez et al., 2014), the effect of
63 climatic gradients on nutrient availability should be better understood.

64
65 Indeed, recent efforts have shown that biosphere-atmosphere carbon exchange in forests is
66 regulated by nutrient availability (Fernandez-Martinez et al., 2014) and therefore, changes in
67 nutrient bio-availability induced by global change need to be accounted for. Canopy chemical traits
68 are proxies that are relatively easy to assess, and from which ecosystem functioning and
69 biogeochemistry can be inferred (Asner et al., 2015; Wright et al., 2004). Nutrient ratios and
70 concentrations in leaves, along with specific leaf area (SLA), are traits that are known to cluster
71 around the leaf economic spectrum, which expresses a trade-off in photosynthetic efficiency and
72 leaf turnover. Indeed, canopy nutrients play key roles in photosynthesis, and are hence vital for
73 carbon exchange processes at the leaf level (Evans, 1989; Reich et al., 2009). Consequently,
74 species with high SLA, N and P are associated with high photosynthesis rates (Poorter et al., 2009;
75 Reich et al., 1997; Wright et al., 2004), but have an ‘expensive’ nutrient economy (fast leaf
76 turnover). Previous work has shown that these traits vary systematically with landscape
77 biogeochemistry (Asner et al., 2014, 2015) and hence the functional canopy signature of forests
78 across gradients express the ecological response to changes in nutrient availability. Canopy
79 chemistry has received increasingly more attention because of its inherent link to the plant strategy.
80 Nevertheless, and as rightfully noted by Asner and Martin (2016), there are only limited surveys
81 on canopy functional signatures in the tropics, while this information is vital for a landscape-scale
82 understanding of tropical forest assembly. In addition to leaf traits, both leaf and soil $\delta^{15}\text{N}$ are
83 known integrators of the local N cycle and analysis of natural abundance of stable N isotope ratios
84 is a powerful and extensively studied proxy for N cycling in ecosystems (Högberg, 1997). Previous

85 efforts have shown that shifts towards lower $\delta^{15}\text{N}$ values indicate a more closed N cycle with lower
86 N availability, and *vice versa* (Brookshire et al., 2012; Craine et al., 2015; Houlton et al., 2006).
87 This shift in isotopic ratios is caused by increased rates in fractioning processes such as
88 denitrification, where ^{14}N is preferentially consumed, leaving the source pool enriched with ^{15}N
89 (Hobbie and Ouimette, 2009). Hence $\delta^{15}\text{N}$ values have been used to infer shifts in N openness
90 across natural gradients (Martinelli et al., 1999; Menge et al., 2011; Vitousek et al., 1989), and
91 subsequently, combining both leaf traits and $\delta^{15}\text{N}$ values is an interesting approach to assess
92 ecosystem responses to environmental gradients.

93

94 In this study we address the existing lack of standardized cross-continental research and assessed
95 shifts in nutrient availability and forest functional composition along two similar transects in
96 Ecuador and Rwanda. We assessed these shifts through indicative (I) community-level functional
97 traits and (II) nitrogen isotope ratios in topsoil and canopy. We hypothesized that (I) both these
98 community-level traits and stable isotope signals would indicate a shift in nitrogen availability
99 with altitude, and that (II) these shifts would be similar on both continents in terms of direction
100 and magnitude, given a standardized research protocol and a similar adiabatic lapse rate.

101 Materials and Methods

102 **Field inventories, sampling and trait analyses**

103 We selected plots at different altitudes on the West flank of the Andes in Ecuador (ranging
104 from 400-3200 masl) and in the Nyungwe national Park Rwanda (1600-3000 masl), in the
105 Southern Great Rift Valley (figure S1 and Table S1 for location and overview maps). Due to
106 reduced accessibility, the gradient in Rwanda was shorter than the South-American transect. We
107 delineated and inventoried plots following an international standardized protocol for tropical forest

108 inventories (RAINFOR, Malhi et al. 2002), with an adapted plot size of 40 by 40 m. In each plot,
109 the diameter of all live stems with a diameter larger than 10 cm was measured at 1.3 m height and
110 the trees were identified to species or genus level. Besides diameters also tree heights were
111 measured, in order to estimate the aboveground carbon storage (AGC) using pan-tropical
112 allometric relationships (Chave et al., 2014). The canopy of every plot was characterized by
113 selecting the most abundant tree species, aiming at a sampling percentage of 80% of the basal area
114 of the plots. For the selected species of all plots, we sampled mature leaves of a minimum of three
115 individuals per species per plot using tree climbers. For most of the individuals we sampled fully
116 sunlit leaves, but this was not always possible for the safety of the climbers, in which case we
117 sampled partly shaded leaves under the top canopy. Previous work on elevational transects has
118 shown that the vertical profile of leaves within a canopy has little effect on the trait values (Fisher
119 et al., 2013). Additionally, composite samples of the topsoil (0-5 cm) were collected at five
120 different places within each plot, and mixed per plot prior to drying. Soil and leaf samples were
121 dried for 48 hours at 60°C. Roots were picked out of the soil samples before grinding and
122 subsequently carbon (C), nitrogen (N) content and $\delta^{15}\text{N}$ of plant and soil samples were analyzed
123 using an elemental analyzer (Automated Nitrogen Carbon Analyser; ANCA-SL, SerCon, UK),
124 interfaced with an Isotope Ratios Mass Spectrometer (IRMS; 20-20, SerCon, UK). Leaf samples
125 were dry-ashed at 550°C for 5.5 hours; the ash was dissolved in 2M HCl solution and subsequently
126 filtered through a P-free filter. The aliquots were then analyzed for total P by AAS method No.G-
127 103-93 Rev.2 (Multitest MT7/MT8; Ryan and others 2001). SLAs were calculated by dividing the
128 leaf areas of all the sampled leaves per individual by their summed dry mass. Leaf areas were
129 determined by either photographing leaves with on white paper with a reference scale or by drawing
130 leaf contours and scanning the drawings. Both the scans and the pictures were processed using the

131 ImageJ software (Schneider et al., 2012). For one abundant species of the higher altitudes on the
132 Rwandan transect (*Podocarpus latifolius* (Thunb.) R.Br. ex Mirb.) we could not obtain good area
133 estimates, so we adopted SLA figures from literature (Midgley et al., 1995).

134

135 **Statistical analysis**

136 Average leaf trait values as specific leaf area (SLA), leaf nitrogen content on mass basis
137 (LNC), leaf phosphorus content on mass basis (LPC), $\delta^{15}\text{N}$, C:N and N:P ratio were calculated for
138 every selected species, based on the sample values for the different individuals of the species.
139 Subsequently, to calculate community-level traits and leaf $\delta^{15}\text{N}$ per plot, we calculated a basal area
140 weighted-average canopy value and standard deviation using the species composition and the
141 species averages, following Asner et al. (2016b). Hence:

$$142 \quad \bar{x}_w = \frac{\sum_{i=1}^N w_i \cdot x_i}{\sum_{i=1}^N x_i}$$

143 with x_w the weighted value for trait x , x_i the mean trait value for species i and w_i the basal-area
144 based weight of that species in the specific plot. Subsequently for the weighted standard deviations
145 (σ_w):

146

147

$$148 \quad \sigma_w = \sqrt{\frac{\sum_{i=1}^N w_i \cdot (x_i - \bar{x}_w)^2}{(N - 1) \sum_{i=1}^N w_i}}$$

149 with N the number of nonzero weights.

150 The structure of the trait datasets was assessed qualitatively using Pearson correlation statistics
151 after log-transforming the trait data for normality. Finally, we studied the relations between the

152 different leaf traits and elevation using mixed effects models for the different traits, with a random
153 error structure. The plots were spatially clustered around four altitudes on both transects, hence we
154 introduced these elevational clusters as a random effect, and treated altitude and transect as fixed
155 effects. Models were then fitted using maximum likelihood methods in the ‘lme4’ package in R
156 (Bates et al., 2007). P-values of the fixed effects –elevation, transect and their interaction - were
157 determined based on the denominator degrees of freedom calculated with the Satterhwaite
158 approximation, in the lmerTest package (Kuznetsova et al., 2014). The P-values for the interaction
159 term, along with the Akaike Information Criterion (AIC) for models with and without this
160 interaction term were used to decide whether or not to exclude the interaction term. For reasons of
161 linearity we used the inverse C:N (hence rather N:C) in these analyses. Models for $\delta^{15}\text{N}$ were
162 assessed for each transect, using mixed effects models, with elevational cluster as a random effect.
163 To explicitly determine divergence and convergence of plant and soil $\delta^{15}\text{N}$ with altitude,
164 compartment (i.e. canopy leaves or topsoil) was introduced as a fixed effect and the interaction
165 term was left in the model. For the statistical analysis, the R-software was used (R Core Team,
166 2014).

167

168 Results

169 The pooled trait datasets from both transects showed a consistent and similar correlation structure
170 (Fig. S2), with both the separate and the pooled data showing significant correlations between all
171 traits, except SLA and N:P. The structural vegetation parameters on both transects showed
172 important differences: for the same altitude range, we found a higher stem density, but less species
173 on the Rwandan transect (Table 1). Tree height and basal area were comparable, and the carbon
174 stocks showed high variability along both transects. Climatic conditions were similar, with a highly

175 consistent temperature gradient (Fig. S3, Table 1), and similar mean annual precipitation in the
176 concurring elevational ranges. The linear mixed effects models with altitude as fixed effect, were
177 able to explain a significant proportion of variation in all traits. This is reflected by both the
178 marginal (m) and conditional (c) R^2_{adj} , respectively proxies for the variation explained by the fixed
179 effects, and the random and fixed effects together (Schielzeth and Nakagawa, 2013) (Table 2). The
180 interaction term was not significant in any case, hence the trait responses to altitude were parallel
181 on both continents. LNC, N:C, LPC and N:P significantly decreased with altitude ($R^2_{adj,m}$ of
182 respectively 0.83, 0.87, 0.68 and 0.60), with the Rwanda transect showing higher overall values.
183 SLA also decreased significantly, but with a slightly higher intercept for the Ecuadorian transect
184 ($R^2_{adj,m} = 0.83$). $\delta^{15}N$ decreased on both continents with altitude, with a similar effect on both
185 continents (Table 3). There was a significant divergence between slope and soil $\delta^{15}N$ along the
186 Ecuadorian transect, while Rwanda showed a significant convergence ($R^2_{adj,m} = 0.93$ and 0.55 for
187 respectively Ecuador and Rwanda).

188

189 Discussion

190 Elevational transects are viable setups to assess long-term ecosystem responses to environmental
191 gradients. We assessed canopy chemistry, functional composition and $\delta^{15}N$ signals along one
192 elevational gradient in South-America and one in Central Africa. The measured traits are indicative
193 proxies for the underlying biogeochemistry of the forest ecosystems. The shifts of these proxies
194 along both transects were parallel in both setups. They indicated a lowering N availability with
195 increasing altitude, with a subsequent parallel shift in functional forest composition on both
196 continents.

197

198 The vegetation structure was varying differently along both transects. The high variability in the
199 stem number, basal area and carbon stocks is potentially caused by the relatively small plot size.
200 Other research efforts, targeting these variables in specific, use plot sizes of 1 hectare, as set
201 forward by the RAINFOR protocol, in tropical forests worldwide (Phillips et al., 2009). As such,
202 the differing carbon stocks probably do not integrate important stochastic events (e.g. tree fall)
203 from the forest along both slopes. However, interestingly enough we found a lower average carbon
204 stocks and higher number of trees in the upper two Rwandan clusters in comparison to the
205 Ecuadorian forests. This contrasts to what has been reported from large scale forest monitoring
206 networks across the lowland forests of Amazon and the Congo basin (Lewis et al., 2013). More
207 research in larger plots, including dynamics and productivity should validate if this is a consistent
208 observation in highland forest on both continents. On the other hand, the lower species number on
209 the African transect fits well within the recent findings of a pantropical study, reporting a lower
210 tree species diversity in the African tropical forest (Slik et al., 2015).

211
212 Different environmental variables are influenced by altitudinal changes, i.e. atmospheric pressure,
213 temperature, cloudiness, moisture, etc. (Körner, 2007). Accordingly, elevation is an indirect proxy
214 for the related changes in these variables. In this view, the air temperature decrease with elevation
215 was highly similar on both transects, which means that we can validly assess similar temperature-
216 driven responses of both forest functional composition and the underlying nutrient dynamics. The
217 high collinearity in the trait datasets corresponds well to known trade-offs described as the “leaf
218 economics spectrum” (LES); basically a leaf-level trade-off between leaf construction cost, i.e.
219 low specific leaf area (SLA), leaf nitrogen content (LNC) and leaf phosphorus content (LPC); and
220 photosynthetic efficiency, i.e. high SLA, LNC and LPC (Wright et al., 2004). LNC, LPC and SLA

221 showed a highly significant decrease with altitude (Fig. 1 and Table 2), indicating a functional
222 shift towards more nutrient conservative species communities at higher altitudes on both transects.
223 Indeed, leaves at lower altitudes with high LNC, LPC and SLA and hence a more efficient
224 photosynthetic apparatus and rapid turnover, are replaced by leaves with low LNC, LPC and SLA
225 values at higher altitudes. We've added previous published work of South America and South-
226 East Asia, with similar temperature gradients by Asner et al, Kitayama and Aiba and Van de Weg
227 et al. to our transects (Asner et al., 2016b; Kitayama and Aiba, 2002; Van de Weg et al., 2009; Fig.
228 S3) to assess the consistency of our observed trends. We added the limited amount of studies where
229 community-weighted means were reported along one 'single mountain range system', hence
230 neglecting a recent and relevant contribution from Asner et al. (Asner and Martin, 2016). Our
231 comparison showed that the decreasing trend in LNC was consistent with the other studies from
232 South-America (Asner et al., 2016b; Van de Weg et al., 2009), but not with South-East Asia where
233 no significant trend was found (Kitayama and Aiba, 2002). However, leaf mass area (LMA; the
234 inverse of SLA) of all studies showed a similar, increasing trend with elevation. LPC shows a
235 strong and significant trend along both transects in this study, while the other studies report no
236 significant trend. This is consistent with the meta-analysis presented by Tanner et al., which shows
237 consistent negative LNC trends on 'same mountain' studies and inconsistent LPC trends (Tanner
238 et al., 1998). A recent effort on a larger scale in Peru has shown that LES trade-off between LNC-
239 LPC or SLA-LPC is indeed decoupled by climatic and geophysical filters, while the leaf SLA-
240 LNC trade-off is more robust (Asner et al., 2016a). Regarding the studies we included for
241 comparison (Fig. S3), only Van de Weg et al. assessed N:P ratio. Although no significant trend
242 was found, they reported that N:P ratio was lowest in the highest sites (Van de Weg et al., 2009).
243 Additionally, decreasing N:P ratios have also been reported on other transects on the Andes (Fisher

244 et al., 2013; Soethe et al., 2008), and recently in Peru using airborne imaging spectroscopy (Asner
245 et al., 2016a).

246
247 In addition to the above community-level functional traits, the decreasing $\delta^{15}\text{N}$ values on both
248 continents (Fig. 1) are another strong indication of the decreasing N availability in the upper
249 forests. Along the transects, both topsoil and canopy leaves showed decreasing $\delta^{15}\text{N}$ values with
250 increasing altitude (Fig. 1), indicating a more closed N cycle with lower N availability at the higher
251 altitudes of both transects. It has been shown that lowland tropical rainforests exhibit high values
252 of $\delta^{15}\text{N}$ mainly caused by the high gaseous nitrogen losses via denitrification, a strongly
253 fractionating process (Houlton et al., 2006). The decreasing trends with altitude are interesting and
254 seem to support the existing paradigm that tropical forests shift from P to N limitation in transition
255 from lowland to montane tropical forest (Townsend et al., 2008). This is also reflected in the
256 stoichiometric shifts, as canopy N:P is decreasing with increasing elevation (Fig. 1). Hence plants
257 incorporate relatively less N compared to P in canopies at higher altitudes. The higher soil $\delta^{15}\text{N}$
258 values along the lower part of the Rwanda transect suggests a more open N-cycle compared to the
259 lower part of the Ecuadorian transect. This corroborates with a recent finding of very high N losses
260 at 1900 masl at the Rwanda site (Rütting et al., 2014), and the observation of high retention
261 potential of bio-available N in Chilean Andisols (Huysens et al., 2008). Further research is needed
262 to explain the notable divergence in soil and foliage $\delta^{15}\text{N}$ along the Ecuadorian transect, mainly
263 driven by the highest elevational cluster. As previously reported this can be due to different degrees
264 of dependence upon ectomycorrhizal fungi (EcM) (Hobbie et al., 2005), different mycorrhizal
265 association types (Craine et al., 2009) or shifts in the uptake of different forms of nitrogen (Averill
266 and Finzi, 2011; Kahmen et al., 2008). EcM-associated plant species are expected to show more

267 depleted isotopic ratios, due to isotope fractionation during N transfer to the host plant. This effect
268 is obscured in lowland N rich tropical forests and might just not be detectable at lower altitudes,
269 but might become apparent in N poorer environments such as the higher altitude forests (Mayor et
270 al., 2014). Secondly, a study from a temperate elevational transect has shown that plants
271 increasingly switch to organic N sources with decreasing temperature, without fractionation upon
272 N transfer from EcM to plants (Averill and Finzi, 2011). Resulting from that, they found a
273 convergence rather than divergence of $\delta^{15}\text{N}$ soil – canopy along altitude, because plants draw N
274 increasingly from a source pool close to the bulk isotopic signature. We have no data on EcM
275 colonization or $\delta^{15}\text{N}$ of sporocarps in the study plots, so we are not able to disentangle both
276 mechanisms. However, by characterizing both community functional traits and canopy and soil
277 $\delta^{15}\text{N}$, the data of these transects is consistent with a decreasing availability of soil N as elevation
278 increases. We suggest the reduced N availability to be caused by an indirect temperature effect on
279 the N-cycle, consistent with observations from a direct fertilization experiment (Fisher et al.,
280 2013). Lower temperatures slow down depolymerization and N mineralization processes, hence
281 also N bio-availability, thereby invoking changes in the functional plant communities along the
282 transects (Coûteaux et al., 2002; Marrs et al., 1988). Future global change will most likely distort
283 N availability both directly via increased reactive N deposition (Galloway et al., 2008; Hietz et al.,
284 2011) and indirectly via a temperature effect on N mineralization in forest soils. This raises
285 questions on the future of plant species within the already threatened montane tropical forest
286 biome, where higher N availability and temperature increase might distort the existing ecological
287 niches and in turn also increase N losses. Further research should therefore focus on process-based
288 knowledge of N and P cycle dynamics along such transects to further assess if the availability is
289 actually limiting the ecosystems. These observations also have repercussions for carbon fluxes:

290 since nutrient availability exerts a stronger control on NEP than on gross primary production (GPP)
291 (Fernandez-Martinez et al., 2014), it is likely that the CUE_e will be lower at higher altitudes. It has
292 been hypothesized that this decrease in CUE_e is due to an increased investment of photosynthates
293 to non-biomass components, such as root symbionts for nutrient mining and root exudates, in
294 expense of net primary production (NPP) (Vicca et al., 2012). However, recent empirical evidence
295 has shown for one transect in the Andes, that a decrease in GPP with increasing altitude is not
296 accompanied by a trend in CUE (Malhi et al., 2016). More work on carbon budgets along
297 elevational transects is needed to fully understand the role of N and P availability and its interaction
298 with climate gradients for the tropical forest carbon cycle.

299

300 **Conclusions**

301 Altogether, this study evidences parallel functional shifts with a similar direction and magnitude
302 along two comparable elevation gradients, in tropical forests on two different continents. The data
303 suggests, in two different ways, that this shift is caused by temperature-driven response of nutrient
304 availability. With the first data on an elevational transect in Central Africa, this work adds to the
305 existing set of elevational transects in the tropics. However, more transects are needed, especially
306 in Africa, to validate a universal response of tropical forests to environmental change.
307 Furthermore, work on process-based nutrient dynamics is important to unravel the importance of
308 different global change factors for both forest basins.

536

537

538 **Table 2** Fixed effects estimates (altitude in km asl) for the different canopy-level response
539 variables; leaf nitrogen content (LNC), inverse C:N ratio, specific leaf area (SLA), leaf phosphorus
540 content (LPC) and N:P ratio, along with the estimated marginal (m) and conditional (c) R^2_{adj} (sensu
541 Nakagawa and Schielzeth (5)). The interaction term for altitude x transect was not significant in
542 any case, and was hence not retained in any model.

543

Response	Effect	Estimate	SE	P-value	$R^2_{adj,m}$	$R^2_{adj,c}$
LNC (%)	Ecuador intercept	3.04	0.131	<0.001	0.80	0.85
	Rwanda intercept	3.65	0.115	0.003		
	Altitude	-0.59	0.000	<0.001		
SLA (cm ² g ⁻¹)	Ecuador intercept	175.28	14.107	<0.001	0.77	0.95
	Rwanda intercept	172.55	12.504	0.835		
	Altitude	-36.24	0.007	0.002		
N:C	Ecuador intercept	0.07	0.003	<0.001	0.83	0.91
	Rwanda intercept	0.07	0.003	0.033		
	Altitude	-0.01	0.000	<0.001		
LPC (%)	Ecuador intercept	0.16	0.012	<0.001	0.60	0.88
	Rwanda intercept	0.17	0.011	0.247		
	Altitude	-0.02	0.000	0.009		
N:P	Ecuador intercept	20.66	1.055	<0.001	0.54	0.74

545

546

547

548 **Table 3** Fixed effects estimates (altitude in km asl) for $\delta^{15}\text{N}$ in both canopy and topsoil
 549 (compartment) on both transects, along with the estimated marginal (m) and conditional (c) R^2_{adj}
 550 (sensu Nakagawa and Schielzeth (5)).

Response	Effect	Estimate	SE	P-value	$R^2_{\text{adj,m}}$	$R^2_{\text{adj,c}}$
$\delta^{15}\text{N}$ Ecuador(‰)	Canopy intercept	3.96	0.406	<0.001	0.93	0.94
	Soil intercept	5.19	0.440	0.009		
	Altitude	-2.59	0.000	<0.001		
	Altitude x compartment	1.53	0.000	<0.001		
$\delta^{15}\text{N}$ Rwanda (‰)	Canopy intercept	6.83	3.193	0.21103	0.55	0.82
	Soil intercept	12.37	1.749	0.004		
	Altitude	-2.02	0.001	0.310		
	Altitude x compartment	-1.37	0.001	0.074		

551

552 **Fig. 1. Trends in community-level functional traits and leaf (full line, closed circles) and topsoil (dashed line, open circles) $\delta^{15}\text{N}$**
 553 **of the elevation transects in Ecuador (red) and Rwanda (blue).** Leaf nitrogen content (LNC), leaf phosphorus content (LPC), specific
 554 leaf area (SLA), and leaf N:C, P:C and N:P ratio decrease with increasing altitude on both transects. Both transect showed decreasing
 555 values of $\delta^{15}\text{N}$, providing additional evidence for a more closed N-cycle with increasing altitude. Lines represent the fixed altitude
 556 effects in the respective statistical models for both Ecuador (red, 400-3200 masl) and Rwanda (blue, 1600-3000 masl).
