16 **Abstract**

17 Climate, fire and soil nutritional limitation are important elements that affect the vegetation
18 dynamics in areas of forest-savanna transition. In this paper, we use the dynamic vegetation model
19 INLAND to evaluate the influence of inter-annual climate variability, fire and phosphorus (P) limitation
20 on the Amazon-Cerrado transitional vegetation structure and dynamics. We assess how each
21 environmental factor affects the net primary production, leaf area index and aboveground biomass (AGB),
22 and compare the AGB simulations of observed AGB map. We used two regional datasets – the 1961-
23 1990 average seasonal climate and the 1948 to 2008 inter-annual climate variability, two datasets of total
24 soil P content in soil, based on regional (field measurements) and global data and the INLAND fire
25 module. Our results show that inter-annual climate variability, P limitation and fire occurrence gradually
26 improve simulated vegetation types and these effects are not homogeneous along the
27 latitudinal/longitudinal gradient showing a synergistic effect among them. In terms of magnitude, the
28 effect of fire is stronger, and is the main driver of vegetation changes along the transition. The nutritional
29 limitation, in turn, is stronger than the effect of inter-annual climate variability acting on the transitional
30 ecosystems dynamics. Overall, INLAND typically simulates more than 80% of the AGB variability in
31 the transition zone. However, the AGB in many places is clearly not well simulated, indicating that
32 important soil and physiological factors in the Amazon-Cerrado border, such as lithology and water table
33 depth, carbon allocation strategies and mortality rates, still need to be included in the model.

34 **1 Introduction**

35 The Amazon and Cerrado are the two largest and most important phytogeographical domains in
36 South America. The Amazon forest has been globally recognized and distinguished not only for its
37 exuberance in diversity and species richness, but also for playing an important role in the global climate
38 by regulating water (Bonan, 2008; Pires and Costa, 2013) and heat fluxes (Shukla et al., 1990; Rocha et
39 al., 2004; Roy et al., 2002). The Cerrado is recognized worldwide for being the richest savanna in the
40 world (Myers et al., 2000; Klink and Machado, 2005). It is characterized by different physiognomies,
41 ranging from sparse physiognomies to dense woodland formations, and the latter are commonly mixed
42 with Amazon rainforest forming transitional areas. The Amazon-Cerrado transition extends for 6270 km
43 from northeast to southwest in Brazil, and the ecotonal vegetation around this transition is a mix of the
44 characteristics of the tropical forest and the savanna (Torello-Raventos et al., 2013).

45 Gradients of seasonal rainfall and water deficit, fire occurrence, herbivory and low fertility of the
46 soil have been reported as the main factors that characterize the transition between forest and savanna
47 globally (Lehmann et al., 2011; Hoffman et al., 2012; Murphy and Bowman, 2012). However, few studies
48 have evaluated the individual and combined effects of these factors on Brazilian ecosystems ecotones
49 (Marimon-Junior and Haridasan, 2005; Elias et al., 2013; Vourtilis et al., 2013).

50 It is challenging to assess the degree of interaction among these various environmental factors in
51 the transitional region and to infer how each one influences the distribution of the regional vegetation. In
52 this case, Dynamic Global Vegetation Models (DGVMs) can be powerful tools to isolate the influences
53 of climate, fire and nutrients, therefore helping to understand their large-scale effects on vegetation
54 (House et al., 2003; Favier et al., 2004; Hirota et al., 2010; Hoffman et al., 2012).

55 Previous modelling studies using DGVMs that investigate climate effects in the Amazon indicate
56 that the rainforest could experience changes in rainfall patterns which would either transform the forest
57 into an ecosystem with more sparse vegetation – similar to a savanna, what has been called as the
58 "savannization of the Amazon" (Shukla et al., 1990; Cox et al., 2000; Oyama and Nobre, 2003; Betts et
59 al., 2004; Cox et al., 2004; Salazar et al., 2007) - or to a seasonal forest (Malhi et al., 2009; Pereira et al.,
60 2012; Pires and Costa, 2013). These studies had great importance to the improvement of terrestrial
61 biosphere modeling, but they neglect two important processes in tropical ecosystem dynamics: fire
62 occurrence and nutrient limitation, particularly the Phosphorus (P) limitation.

63 In tropical ecosystems, fire plays an important ecological role and influences the productivity, the
64 biogeochemical cycles and the dynamics in the transitional biomes, not only by changing the phenology
65 and physiology of plants, but also by modifying the competition among trees and lower canopy plants
66 such as grasses, shrubs and lianas. Fire occurrence, depending on its frequency and intensity, may increase
67 the mortality of trees and transform an undisturbed forest into a disturbed and flammable one (House et
68 al., 2003; Hirota et al., 2010; Hoffmann et al., 2012). Fires also affect the dynamics of nutrients in the
69 savanna ecosystem, changing mainly the N:P relationship and P availability in the soil (Nardoto et al.
70 2006).

71 Studies suggest that P is the main limiting nutrient within tropical forests (Malhi et al., 2009;
72 Mercado et al., 2011; Quesada et al., 2012) unlike the temperate forests. Phosphorus is a nutrient that is
73 easily adsorbed by soil minerals due to the large amount of iron and aluminum oxides in the Amazon
74 and Cerrado acidic and strongly weathered soils (Dajoz, 2005; Goedert, 1986). In the tropics, the warm
75 and wet climate favors the high biological activity in the soil and the litter decomposition, not limiting

76 the nitrogen for plant fixation. In Cerrado, higher soil fertility is related to regions with greater woody
77 plants abundance and less grass cover, similarly to the features found in the Amazon rainforest (Moreno
78 et al., 2008; Vourtilis et al., 2013; Veenendaal et al., 2015). However, the phosphorus limitation is often
79 neglected by DGVMs. which usually assume unlimited P availability and consider nitrogen as the main
80 limiting nutrient. However, N is not a limiting nutrient for trees in the tropics (Davidson et al. 2004),
81 while P availability affects the trees dynamics.

82 In principle, in transitional forests, where the climate is intermediate between wet and seasonally
83 dry, the heterogeneous structure and phenology make it difficult to represent these forests in models. The
84 Amazon-Cerrado border is the result of the expansion and contraction of the Cerrado into the forest (see
85 Marimon et al., 2006; Morandi et al., 2016), especially in the Mato Grosso state, where extreme events,
86 such as intense droughts, influence the vegetation dynamics (Marimon et al., 2014) and the nutrient
87 (Oliveira et al., 2017) and carbon cycling (Valadão et al., 2016).

88 Currently, no model has demonstrated to be able to accurately simulate the vegetation transition
89 between Amazon and Cerrado. In general the DGVMs simulate evergreen forest along the Amazon-
90 Cerrado border and neglect savanna occurrence (Botta and Foley, 2002; Bond et al., 2005; Salazar et al.,
91 2007; Smith et al., 2014). This difficulty may be due to absence or not well represented disturbances such
92 as fire, nutritional limitation or soil proprieties. Thus, we need a better understanding of the drivers on
93 transitional vegetation to determine the parameters and establish relations between the environmental and
94 transitional vegetation physiognomies.

95 In this paper we use the dynamic vegetation model INLAND (Integrated Model of Land Surface
96 Processes) to evaluate the influence of inter-annual climate variability, fire occurrence and P limitation

97 in the Amazon-Cerrado transitional vegetation dynamics and structure. We assess how each element
98 affects the net primary production (NPP), leaf area index (LAI) and aboveground biomass (AGB) and
99 compare the model simulated AGB to observed AGB data. The results presented here are important to
100 build models that accurately represent the transition vegetation, and show the need to include the spatial
101 variability of eco-physiological parameters in these areas.

102 **2 Materials and methods**

103 **2.1 Study Area**

104 The present study focuses on the Amazon-Cerrado transition (Figure 1). We use the official
105 delimitation of the Brazilian biomes proposed by IBGE (2004), and define five transects along the
106 transition border with $1^\circ \times 1^\circ$ grid size (the terms “transition”, “Amazon-Cerrado transition” and “Forest-
107 Savanna transition” are used interchangeably with the same meaning throughout this
108 manuscript). Transects 1 to 4 are established considering approximately 330 km into the Amazon and 330
109 km into the Cerrado domain, while Transect 5 is 880 km long on the southern Amazon-Cerrado border.
110 The transects are located as follows: Transect 1 (T1, 44° - 50° W; 5° - 7° S), Transect 2 (T2, 46° - 51° W; 7° -
111 9° S), Transect 3 (T3, 48° - 54° W; 9° - 11° S), Transect 4 (T4, 49° - 55° W; 11° - 13° S), and Transect 5 (T5,
112 52° - 60° W; 13° - 15° S) (Figure 1).

113 **2.2 Description of the INLAND Surface Model**

114 The Integrated Model of Land Surface Processes (INLAND) is the land-surface component of the
115 Brazilian Earth System Model (BESM). INLAND is basically a revision of the IBIS model (Integrated
116 Biosphere Simulator, described by Foley et al., 1996; Kucharik et al., 2000), through assembly and

117 standardization of different IBIS versions, and improvements in software engineering. We used the
118 version described by Senna et al. (2009) as starting point for INLAND. No changes in tuning were done
119 since that paper, except the addition of the P parameterization, described below. Code is available from
120 <http://www.biosfera.dea.ufv.br/en-US/download-inland>.

121 The model considers changes in the composition and structure of vegetation in response to the
122 environment and incorporates important aspects of biosphere-atmosphere interactions. The model
123 simulates the exchanges of energy, water, carbon and momentum between soil-vegetation-atmosphere.
124 These processes are organized in a hierarchical framework and operate at different time steps, ranging
125 from 60 minutes to 1 year, coupling ecological, biophysical and physiological processes. The vegetation
126 structure is represented by two layers: upper (arboreal PFTs) and lower (no arboreal PFTs, shrubs and
127 grasses) canopies, and the composition is represented by 12 plant functional types (PFTs) (e.g., tropical
128 broadleaf evergreen trees or C4 grasses, among several others).The photosynthesis and respiration
129 processes are simulated in a mechanistic manner using the Ball-Berry-Farquhar model (details in Foley
130 et al., 1996). The vegetation phenology module simulates the processes such as budding and senescence
131 based on drought phenology scheme for tropical deciduous trees. The dynamic vegetation module
132 computes the following variables yearly for each PFT: gross and net primary productivity (GPP and NPP),
133 changes in AGB pools, simple mortality disturbance processes and resultant LAI, thus allowing
134 vegetation type and cover to change with time. The partitioning of the NPP for each PFT resolves carbon
135 in three AGB pools: leaves, stems and fine roots. The LAI of each PFT is obtained by simply dividing
136 leaf carbon by specific leaf area, which in INLAND is considered fixed (one value) for each PFT.

137 INLAND has eight soil layers to simulate the diurnal and seasonal variations of heat and moisture.
138 Each layer is described in terms of soil temperature, volumetric water content and ice content (Foley et
139 al., 1996; Thompson and Pollard, 1995). Furthermore, all of these processes are influenced by soil texture
140 and amount of organic matter within the soil profile.

141 Considering these aspects of vegetation dynamics and soil physical properties the model can
142 simulate plant competition for light and water between trees, shrubs and grasses through shading and
143 differences in water uptake (Foley et al., 1996). These PFTs can coexist within a grid cell and their annual
144 LAI values indicate the dominant vegetation type within a grid cell. For example, the dominant vegetation
145 type is a Tropical Evergreen Forest if the PFT tropical broadleaf evergreen tree has an annual mean upper
146 canopy LAI (LAI_{upper}) above $2.5 \text{ m}^2 \text{ m}^{-2}$. On the other hand, the dominant vegetation type is a Tropical
147 Deciduous Forest if the tropical broadleaf drought-deciduous tree has an annual mean LAI_{upper} above
148 $2.5 \text{ m}^2 \text{ m}^{-2}$. Where total tree LAI (LAI_{upper}) is between 0.8 and $2.5 \text{ m}^2 \text{ m}^{-2}$, dominant vegetation type is
149 savanna, and LAI_{upper} values smaller than $0.8 \text{ m}^2 \text{ m}^{-2}$ characterize a grassland vegetation type.

150 We assume that the vegetation types Tropical Evergreen Forest and the Tropical Deciduous Forest
151 in INLAND represents the Amazon rainforest, while Savanna and Grasslands represent the Cerrado.
152 Savanna would be equivalent to the Cerrado physiognomies *Cerradão* and *Cerrado sensu strictu*, while
153 Grasslands would be equivalent to the physiognomies *Campo sujo* and *Campo Limpo* (*sensu* Ribeiro and
154 Walter, 2008).

155 The soil chemical properties are represented by the carbon, nitrogen and phosphorus. The carbon
156 cycle is simulated through vegetation, litter and soil organic matter, where the biogeochemical module is
157 similar to the CENTURY model (Parton et al., 1993; Verberne et al., 1990). The amount of C existing in

158 the first meter of soil is divided into different compartments characterized by their residence time, which
159 can vary in an interval of hours for microbial AGB and organic matter to several years for lignin. The
160 model considers only the soil N transformations and carbon decomposition, but the N cycle is not fully
161 simulated and N does not influence the vegetation productivity, i.e., there is a fixed C:N ratio. The P cycle
162 also is not fully implemented, instead the P-limitation is spatially parameterized through the linear relation
163 developed by Castanho et al. (2013) to limit the gross primary productivity. A map of total P available in
164 the soil (P_{total}) is used by the model to estimate the maximum capacity of carboxylation by the Rubisco
165 enzyme (V_{max}) for each grid using Equation (1) :

$$166 \quad V_{max} = 0.1013 P_{total} + 30.037 \quad (1)$$

167 where V_{max} and P_{total} are given in $\mu\text{molCO}_2 \text{ m}^{-2} \text{ s}^{-1}$ and mg kg^{-1} , respectively. This equation has been based
168 on data for tropical evergreen and deciduous trees, and is applied only to these two PFTs, the other PFTs
169 are unaffected.

170 INLAND also contains a spatial fire module, based on the Canadian Terrestrial Ecosystem Model
171 CTEM (Arora and Boer, 2005). In this module, three aspects of the fire triangle are considered – the
172 availability of fuel to burn, the flammability of vegetation, and the presence of an ignition source. Each
173 is represented daily by an independently calculated probability and the product of the three is the
174 probability of fire occurrence, calculated daily. Availability of fuel to burn depends on biomass,
175 flammability depends on soil moisture and ignition depends on a random lightning occurrence and a
176 constant anthropogenic ignition probability. The daily fire occurrence probability is equal to the daily
177 AGB burned fraction. The AGB burned fraction is accumulated throughout the year and its ratio is applied
178 at the end of each year to the grid cell area, reducing the leaf, wood and root biomass pools.

179 2.3 Observed data

180 2.3.1 Phosphorus databases

181 We used two P databases to estimate V_{\max} (Equation 1): one regional (referred to as PR) and one
182 global database referred to as PG). In addition, a control P map (PC) represents the unlimited nutrient
183 availability case, equivalent to a V_{\max} of $65 \mu\text{molCO}_2 \text{ m}^{-2} \text{ s}^{-1}$, or 350 mg P kg^{-1} soil, according to Equation
184 1.

185 The PR database was developed from total P in the soil for the Amazon basin published by
186 Quesada et al. (2011) plus 54 additional available P samples (P extracted via Mehlich-1 extractor,
187 $P_{\text{mehlich-1}}$) (Figure 2a). We used the $P_{\text{mehlich-1}}$ and clay contents measured in a forest-savanna transition
188 region in Brazil (Mato Grosso state) to estimate P_{total} and expand the coverage area of the P data (Section
189 S1). These 54 samples were gridded to a $1^\circ \times 1^\circ$ grid to be compatible with the spatial resolution used by
190 INLAND, resulting in 12 additional pixels with observed total P content (Figure 2a). For pixels without
191 observed P_{total} , the P_{total} was assumed to be 350 mg P kg^{-1} soil, similarly to the PC conditions.

192 A global dataset of P_{total} (Figure 2b) was also used to estimate V_{\max} . This global data set is part of
193 a database containing six global maps of the different forms of P in the soil (Yang et al., 2013). The P_{total}
194 was estimated from lithologic maps, distribution of soil development stages, fraction of the remaining
195 source material for different stages of weathering using chronosequence studies (29 studies), and P
196 distribution in different forms for each soil type based on the analysis of Hedley fractionation (Yang and
197 Post, 2011), which are part of a worldwide collection of soil profile data. The uncertainties and limitations
198 associated with this database are restricted to the Hedley fractionation data used, which are 17% for low
199 weathered soils, 65% for intermediate soils and 68% for highly weathered soils (Yang et al., 2013).

200 **2.3.2 Above-Ground Biomass (AGB) database**

201 The AGB database used was created by Nogueira et al. (2015) and considered undisturbed (pre-
202 deforestation) vegetation existing in the Brazilian Amazonia. This database was compiled from a
203 vegetation map at a scale of 1:250000 (IBGE, 1992) and AGB averages from 41 published studies that
204 had conducted direct sampling in either forest (2317 plots) or non-forest or contact zones (1830 plots).
205 We bi-linearly interpolated the AGB (dry weight) for each transect considering $1^\circ \times 1^\circ$ to ensure
206 compatibility of the observed and simulated data.

207 Five longitudinal transects (Figure 1) were individually used to characterize AGB in the Amazon-
208 Cerrado border (Figures 3a and 3b). In T1, T2, T3 and T4, the higher AGB values in the west and lower
209 values in the east are consistent with the transition from a dense and woody vegetation (the Amazon
210 forest) towards a sparse vegetation with lower AGB (the Cerrado). However, T1 shows a more gradual
211 reduction of AGB along the west to east gradient, while in T2, T3 and T4 where the transition is more
212 abrupt. In T5 no west-east gradient is present with high AGB heterogeneity and predominant low AGB
213 across the transect (Figure 3b).

214

215 **2.4 Simulations**

216 The model was forced with the prescribed climate data based on the Climate Research Unit (CRU)
217 database (Harris et al., 2014). Two climate boundary conditions were used: the first is referred to as the
218 monthly climatological average (CA) that represents the average climate for the period 1961-1990. The
219 second climate boundary condition is the historical dataset, for the continuous period between 1948 and
220 2008, thus considering interannual climate variability (CV). For both boundary conditions, the variables

221 used are rainfall, solar radiation, wind velocity and maximum and minimum temperatures. The CRU
222 database is developed from observations at meteorological stations across the world's land areas and has
223 been widely used by the scientific community in case studies to evaluate El Niño–Southern Oscillation
224 (ENSO) effects and other modes of interannual climate variability (Foley et al., 2002; Marengo, 2004;
225 Wang et al., 2014), because these data preserve the spatial mean of the rainfall data, although they do not
226 provide adequate representation of the precipitation variance (Beguería et al., 2016). The dataset has a 1-
227 degree spatial resolution and a monthly time resolution.

228 Soil texture data is based on the IGBP-DIS global soil (Global Soil Data Task 2000) (Hansen and
229 Reed, 2000). In the CV group of runs, the model was spin-up by cycling the 1948-2008 climate data (61-
230 year) seven times, totaling 427 years. In the CA group of runs, the annual mean climate data was cycled
231 427 times. In both cases, CO₂ varied from 278 to 380 ppmv, according to observations in the period,
232 updated annually. In both cases, only the model results of the last 10 years were used to analyze the
233 results.

234 The experiment design is a factorial combination of the climate scenarios (CA, monthly
235 climatological average, 1961-1990; CV, monthly climate time series, 1948-2008), the nutrient limitation
236 on V_{max} (PC, no P limitation (V_{max} = 65 μmolCO₂ m⁻² s⁻¹); PR, regional P limitation; PG, global P
237 limitation) and the occurrence of fire (F) or not (Table 1). The 12 combinations in Table 1 allow the
238 evaluation of individual and combined effects of climate, soil chemistry, and the incidence of fire on the
239 variables: Net Primary Production (NPP), tree AGB, and LAI of the upper and lower canopies (LAI_{upper},
240 LAI_{lower}).

241 We consider that the subtraction between the simulations (CV+PC) and (CA+PC) represents the
242 isolated effect of inter-annual climate variability without P limitations. The same logic is applied to isolate
243 other factors such as fire and P in different climate scenarios. For example, the fire effect under average
244 climate without P limitation case is calculated by the difference between CA+PC+F and CA+PC.
245 Similarly, the isolated effect of fire under a climate with inter-annual variability scenario without
246 influence of P limitation is calculated by the difference between CV+PC+F and CV+PC. The different
247 combinations of climate scenarios with and without fire effects and with and without P limitations are
248 described in Table 2.

249 **2.5 Statistical analysis and determination of the best model configuration**

250 The statistical analysis is divided in four parts. First, we present maps of the isolated effects for
251 all simulated area calculated as the average of last ten years of simulated spatial patterns. The statistical
252 significance of the isolated effects on NPP, LAI and AGB are determined using the t-test with $p < 0.05$.
253 The results are tested in each pixel, for all the simulated domain ($n = 10$).

254 Second, we present an analysis of variance using the one-way ANOVA and the Tukey-Kramer
255 test in the transition zone. We consider all 31 pixels which fall in transects T1 to T5 (n_{pixels}). The results
256 presented are based on the set of last 10 years of simulation (1999-2008, n_{years}) for the 12 combinations
257 ($n_{\text{simulation}}$) in Table 1. Moreover, we grouped treatments according to climate regardless of P limitation,
258 presence or absence of fire, where all sets with CV vs CA are tested (Group 1, $n=1860$, ($n_{\text{pixel}} \times n_{\text{year}} \times$
259 ($n_{\text{simulation}}/2$)). Similarly, in Group 2 we tested if PC, PR or PG were significantly different from each other
260 regardless the F or climate used (Group 2, $n=1240$, ($n_{\text{pixel}} \times n_{\text{year}} \times (n_{\text{simulation}}/3)$). In Group 3 we tested if
261 fire introduced a significant effect regardless of climate and P limitation (Group 3, $n=1860$, ($n_{\text{pixel}} \times n_{\text{year}}$

262 $\times (n_{\text{simulation}}/2)$). Finally, all treatments were tested to each simulation assessing their individual effects on
263 NPP, LAI and AGB ($n_{\text{pixel}} \times n_{\text{year}} = 310$).

264 Third, a correlation coefficient between the simulated and observed values for AGB was
265 calculated for each transect. The simulated variables are averaged for the last 10 years of simulations
266 (1999 - 2008) and compared to AGB from Nogueira et al. (2015) within a grid cell.

267 Finally, we evaluate INLAND's ability to assign the dominant vegetation type by analyzing 10
268 years of probability of occurrence. If the dominant vegetation type (evergreen tropical forest, or deciduous
269 forest for the Amazon rainforest, and savanna or grasslands for Cerrado) in a pixel is the same in more
270 than 90% of the simulated years (9 out of 10), then the simulated vegetation type is defined as "very
271 robust" for that pixel; if it occurs in 70 - 90% of the simulated years, the simulated result is considered to
272 be "robust". If the dominant vegetation occurred in less than 70% of simulated years, the pixel is
273 considered "transitional" vegetation.

274 **3 Results**

275 **3.1 Influence of climate, fire and phosphorus in the Amazon-Cerrado transition region**

276 **3.1.1 Spatial patterns**

277 Overall, the inclusion of inter-annual climate variability (CV) resulted in a decrease in the
278 simulated average tree biomass (TB) by 3.8% in the entire Brazilian Amazonia, and by 8.7% in the entire
279 Cerrado in comparison to average climate (CA), values obtained by difference $CV+PC - CA+PC$ (Figure
280 4a). The spatial differences between CV and CA for TB simulations are statistically significant and range
281 from -3 kg-C m^{-2} to $+2 \text{ kg-C m}^{-2}$. The state of Pará, with higher influence of the El Niño phenomenon,

282 experienced the highest decrease in TB in the CV simulation. In the state of Roraima, on the other hand,
283 there was an increase of about 2 kg-C m^{-2} in TB when CV was considered. Bolivia and southwest of Mato
284 Grosso state also presented, in some grids points, a significant increase in AGB higher than 2 kg-C m^{-2} .

285 On average, P acts as a limiting factor in the simulated TB, decreasing by 13% in regional P (PR)
286 simulation and 15% in global P (PG) simulation. In PR, TB decreased mainly in the southeastern
287 Amazonia (between Pará and northeastern Mato Grosso states) and northwestern Amazonas state (Figure
288 4b). In PG, the largest TB decline occurred in central Amazonia, northeastern Pará and northeastern Mato
289 Grosso (Figure 4c). In Cerrado, on the other hand, TB declined by 2% for PR and 9% for PG with respect
290 to the control simulation. In PR, the few pixels in the Cerrado that have P limitation showed a significant
291 decrease in TB (Figure 4b), while in PG the TB reduction was statistically significant for most of the
292 Cerrado domain, except in southern Tocantins state (Figure 4c).

293 The tree biomass reduction due to fire events is much higher in magnitude more than due to P
294 limitation or inter-annual climate variability (Figure 4d). The small or null fire effect in the Central
295 Amazon rainforest is related the greater water availability on the Amazonia, which makes the forest
296 naturally not flammable as well as a gradient towards seasonally dryer climate increases the intensity and
297 magnitude of fire effects towards the Cerrado (Figure 4d). The fire effect on TB over the Amazon domain
298 was 21-24% of the P limitation effect (range for PR and PG cases), while the fire effect on TB over the
299 Cerrado was more than 250% of the P limitation effects in CV simulations, which is due to quick growth
300 of grasses after fire occurrence in the latter.

301 **3.1.2 Influence of climate, fire and phosphorus in the transects**

302 Results of the ANOVAs and Tukey-Kramer test indicate that the inclusion of CV, limitation by P
303 (PR and PG) and fire in INLAND led to significantly different averages of NPP, LAI and AGB in the
304 transition zones. This influence of climate, P and fire are shown separately in Tables 3 to Table 5 and
305 combined in Table 6.

306 The effects of climate and P on productivity show that CV reduces the NPP from
307 $0.68 \text{ kg-C m}^{-2} \text{ yr}^{-1}$ to $0.64 \text{ kg-C m}^{-2} \text{ yr}^{-1}$ (Table 3) and the P effect results in NPP decline from
308 $0.71 \text{ kg-C m}^{-2} \text{ yr}^{-1}$ to $0.64 \text{ kg-C m}^{-2} \text{ yr}^{-1}$ (both PR and PG) (Table 4). The fire effect, moreover, has a
309 positive effect on NPP from $0.66 \text{ kg-C m}^{-2} \text{ yr}^{-1}$ when fire is off to $0.67 \text{ kg-C m}^{-2} \text{ yr}^{-1}$ when fires is on. This
310 difference, albeit low, is statistically significant (Table 5).

311 In addition CV and P limitation reduce the $\text{LAI}_{\text{total}}$ in the canopy (Table 3 and Table 4), increasing
312 three times $\text{LAI}_{\text{lower}}$ and decreasing $\text{LAI}_{\text{upper}}$ (Table 5). The magnitude of fire effect on AGB (46.7%,
313 Table 5) is greater in relation to the CV (5%, Table 3) and P (14%, Table 4) limitation effects.

314 Even though CV effects on NPP and AGB for each simulation is not statistically significant, the
315 effects of fire and P limitation (regardless of phosphorus map) are. Fire effects are significant only for
316 structural variables as AGB, $\text{LAI}_{\text{total}}$, $\text{LAI}_{\text{upper}}$ and $\text{LAI}_{\text{lower}}$. It presents an increase of LAI total of
317 $1.52 \text{ m}^2 \text{ m}^{-2}$ in CV+PG+F in relation to CV+PG, and of $1.32 \text{ m}^2 \text{ m}^{-2}$ in CV+PR+F in relation to CV+PR
318 (Table 6).

319 **3.1.3 West-East patterns of AGB in the Amazon-Cerrado transition**

320 The model used in this study simulates $> 80\%$ of the observed AGB variability in all treatments
321 along the transition area except in T5 (Table 7). It shows that the model is able to capture AGB variability

322 along the transition area, which is relevant when compared to studies that simulate 50% of the observed
323 AGB variability (Senna et al., 2009; Castanho et al., 2013).

324 It is not possible to identify a treatment that best represents AGB in all transects (Table 7). A
325 combined analysis of Table 7 and Figure 5 indicates a general agreement that observed AGB decreases
326 from W to E in T1 to T4, and this is well captured by several configurations of the model, with specific
327 differences among them. Overall, CA and PC configurations, being the least disturbed treatments, yield
328 higher AGB, while the introduction of CV, PG and F reduce the AGB. However, the simulated results
329 may be above or below the observed ones, which suggests that additional local factors are not included
330 in the model.

331 The curves of AGB (Figure 5) show the impact of CV, PG and F along the W-E transition. PG
332 has a high influence on the transition, decreasing the ABG especially in the western part of the transects,
333 where the Amazon vegetation is predominant. This feature is particularly simulated in T3 and T4, where
334 PG decrease the AGB by 2 kg-C m⁻² in the west pixels of these transects (Figure 5). In T1, T2 and T5,
335 AGB decline is also higher with P limitation when compared to the curves limited only by CV. However,
336 in T1 model simulations tend to underestimate the highest and the lowest AGB extremes, and the absolute
337 values were always underestimated, despite the improvement in correlation with the inclusion of the fire
338 component (Table 7).

339 In T2, T3 and T4, however, fire changes the simulated AGB, making it closer to the observed
340 AGB in the eastern pixels of the Cerrado domain (Figure 5). In T5 these relations are similar, with climate
341 presenting less influence on AGB decrease than P, and fire appears mainly as an AGB reduction factor.

342 3.2 Simulated composition of vegetation

343 Most of the pixels in CA show very robust simulations, with more than 90% of the same vegetation
344 cover in the simulated last 10 years (Figure 6a-c and 6g-i). A larger number of pixels with transitional
345 vegetation were simulated in CV (Figure 6d-f and 6j-l). An even higher variability in CV compared
346 to CA simulations was observed when we added the effects of P limitation and fire (Figure 6a and 6j-l).

347 The vegetation composition in all P limitation scenarios for CA simulations resulted in robust
348 simulations for nearly all pixels, except for the north of Cerrado domain (Figures 6a, 6b and 6c). The
349 CA+PC and CA+PR simulations had the same vegetation composition, while CA+PG replaced the
350 deciduous forest by evergreen forest in the central Cerrado region, around 8°S 46°W (Figures 6A, 6B and
351 6C). This behavior might be related to the higher P_{total} values in PG than PR and PC for the Cerrado region
352 (Figure S1). Cerrado was better represented in CV+PC, CV+PR and CV+PG than in the same CA
353 combinations (Figure 6). The occurrence of forested areas in central Cerrado decreased in CV
354 combinations, these being replaced by the savanna or grassland vegetation class.

355 When the effect of fire was added to CA simulations, the model simulated an increase in the
356 uncertainty on the vegetation cover classification in the Cerrado region. The effect of fire reduced the
357 presence of deciduous forest in central Cerrado biome as well as in CA+PC, and the vegetation was
358 replaced by evergreen forest in about 5 pixels with clay soils with large water retention capacity in
359 CA+PC+F (Figures 6G, 6H, 6I). In this situation, where there is little water stress in the CA simulation,
360 both evergreen and drought deciduous PFTs have each one very high LAI, and the PFT that dominates
361 can be defined by minor effects. Fire, although active, is probably too small to be relevant in a non-
362 stressed ecosystem. In CV simulations, however, fire effect results in the replacement of the deciduous

363 and perennial forest by savanna and grasses in all central Cerrado region (Figures 6J, 6K and 6L). These
364 results show the limitations of CA and the importance to consider the interannual climate variability on
365 simulations to improve the vegetation simulated.

366 For all combinations used, transitional forest areas in the northern and southwestern Cerrado
367 biome are not adequately represented. With >90% of concordance, INLAND assigns the existence of
368 tropical evergreen forest rather than deciduous forest in some pixels in the north of the transition, and the
369 existence of tropical evergreen forest rather than savanna in the southwest, indicating difficulty to
370 simulate transitional vegetation in these regions.

371 **4 Discussion**

372 The inclusion of CV, PR and PG and fire in INLAND showed significant influences on the
373 simulated vegetation structure and dynamics in the Amazon-Cerrado border (Figure 4 and Table 6),
374 suggesting that these factors play key role on vegetation structure in the forest-savanna border and can
375 improve the simulated representation of the current contact zone between these biomes. This is broadly
376 consistent with the literature that investigated causes of savanna existence in the real world (Hoffmann et
377 al., 2012; Dantas et al., 2013; Lehmann et al., 2014). In this study, the spatial analysis and the Tukey-
378 Kramer test (TK) show a difference in magnitude among these factors in vegetation, with fire occurrence
379 and P limitation being stronger than inter-annual climate variability along the transects (Figure 4).

380 The spatial analysis showed that CV declines AGB predominantly in eastern Amazonia (Figure
381 4a). Climate of this region is intensely affected by ENSO, which could reduce precipitation by 50%,
382 placing the vegetation under intense water stress (Botta and Foley, 2002; Foley et al. 2002; Marengo et
383 al., 2004; Andreoli et al., 2012; Hilker et al., 2014). This reduction in rainfall in dry years brings in direct

384 changes in carbon flux (NPP) and stocks in leaves and wood, leading to changes in vegetation structure.
385 In addition to inter-annual changes in the rainfall, inter-annual variability in other climate variables in CV
386 also affect AGB, as average, maximum and minimum temperature, as well as wind speed and specific
387 humidity, and influence photosynthesis on the model both directly (through Collatz and Farquhar
388 equations) and indirectly (e.g. through evapotranspiration). Our results showed significant differences for
389 most part of the biomes, except central Amazonia (Figure 4a), where CV and precipitation seasonality
390 have been pointed as secondary effects on vegetation (Restrepo-Coupe et al., 2013), since there is no
391 shortage of water availability during the dry season.

392 Along the Cerrado, lower water availability in some years in CV affects tree biomass, although
393 that vegetation is predominantly grassy-herbaceous. The AGB decline is significant for most part of the
394 simulated Cerrado domain (Figure 4a) and average values could represent half the amount of typical tree
395 biomass in this biome. This reduction in AGB reflects INLAND's ability to simulate similar Cerrado
396 conditions and expose the few trees to high water stress.

397 Throughout the transects, however, no significant difference was found for average AGB between
398 CV+PC and CA+PC by TK at $p < 0.05$ (Table 6). On the other hand, when we analyzed the influence of
399 CV for the same pixels, but using all simulations (Table 3), regardless of P limitation and fire occurrences,
400 the results showed that the decrease in AGB by 0.38 kg-C m^{-2} (5.7%) is statistically significant along the
401 transition.

402 P limitation effect was statistically significant for PR and PG along all the Amazon domain and
403 the main differences between these simulations were the spatial patterns of tree AGB decrease (Figure 4b
404 and Figure 4c). We cannot affirm which of these databases is better because they are the results of

405 different methodologies and observations (Quesada et al., 2009; Yang et al., 2014). However, PG showed
406 a higher AGB decrease in central Amazonia, northeastern Pará and northeastern Mato Grosso state,
407 indicating that in these areas the P limitation is higher. This result does not corroborate the northwest-
408 southeast AGB gradient found in the Amazon basin, which showed a higher productivity in the west
409 where soils are more fertile than those found in the southeast (Aragão et al., 2009; Saatchi et al., 2007;
410 Nunes et al., 2012; Lee et al., 2013). On the other hand, PR AGB agrees with the northwest-southeast
411 gradient, presenting less limitation in the soils of central Amazonia with declines in AGB mainly in the
412 southeastern part of the rainforest (between Pará and northeastern Mato Grosso states) (Figure 4b).

413 In Cerrado, P limitation also influenced vegetation (Figure 4c) and presented statistically
414 significant differences when compared CV+PG – CV+PC. In this biome, as well as in the Amazon, tree
415 abundance richness and diversity have been generally associated with increases of soil fertility (Long et
416 al., 2012; Vourtilis et al., 2013), highlighting the importance of P in the composition and maintenance of
417 vegetation, especially in transition areas.

418 Compared to the Amazon domain, the magnitude of effects of P limitation is lower in the Cerrado.
419 However, few pixels in PR that have P limitation showed a significant decrease in arboreal AGB (Figure
420 4b), while in PG, we found reduction of AGB for most of the Cerrado domain, except only for the southern
421 Tocantins state (Figure 4c). Despite the differences in spatial patterns, there was no statistically significant
422 differences between PR and PG within the transects (Table 4 and Table 6).

423 The spatial difference between PG and PR showed that PG is lower than PR in the western
424 Amazonia, and higher in northern Amazonia. Moreover, PG have low P values in south of the transition
425 compared to PR, while in Cerrado domain P values ranged between 120 to 200 mg kg⁻¹ (Figure S1).

426 Although the PR dataset includes every known P data collected in the region, these differences reinforce
427 the need to improve the data of P_{total} in the soils of the Amazon and Cerrado/Amazon transition domains.
428 Currently, P_{total} data in Cerrado is scarce, and make unfeasible to establish a proxy similar to Castanho et
429 al. (2013), which was specific for the Amazon.

430 In INLAND, the simple P-limitation parameterized through the linear relation V_{max} and P_{total} ,
431 showed significant spatial differences in AGB simulated and an improvement in simulations, highlighting
432 the importance of P-limitation in modeling studies. For the most part, Dynamic Global Vegetation Models
433 (DGVMs) do not consider the complete phosphorus cycle (see exceptions in Goll et al., 2012 and Yang
434 et al., 2014), despite the importance of nutrient cycling for AGB maintenance and tropical vegetation
435 dynamics in dystrophic soils. For example, nutrient cycling in the Amazon/Cerrado transition is closely
436 related to the hyper-dynamic turnover of the AGB (Valadão et al. 2016), in which some key species might
437 also be crucial to the hyper-cycling of nutrients through which vegetation sustain the constant input of
438 nutrients, including large annual amounts of available P (Oliveira et al. 2017). In addition, there is
439 influence between weather and nutrients: a very intense rain can leach nutrients, such as nitrogen, as well
440 as strong winds can carry clay particles where numerous nutrients are adsorbed. However, in this work
441 the nutritional conditions are prescribed and fixed.

442 The fire occurrence is an important factor controlling the AGB dynamics in the Cerrado or in the
443 transition vegetation (Hoffman et al., 2003; Hoffman et al., 2012; Silvério et al., 2013; Couto-Santos et
444 al., 2014; Balch et al., 2015), which this study clearly replicates, showing statistically significant
445 influences when compared to control simulations (Figure 4d and Table 5). In the transition, the fire effect
446 may reduce average AGB by 50% (Table 5), which under climate change or deforestation conditions may

447 lead to an even stronger change in the vegetation structure and dynamics. In INLAND, the fire disturbance
448 reduces the biomass of all pools and PFT's by the same fraction inside each pixel at the end of every year.
449 Thus, upper and lower LAI are decreased, according to the fire probability, triggering competition
450 between both canopies for light, and increasing the photosynthesis rates and stocks of carbon in leaves,
451 stems and roots pools in the lower canopy. The carbon allocation and mortality rates in INLAND are
452 fixed parameters for each PFT and are not modified after fire occurrence. Thus, during recovery from a
453 fire, the vegetation dynamics follows the model standard procedure.

454 The dynamics between the upper and lower canopies and the changes in canopy structure after
455 fire occurrence are exclusively due to the canopy opening and consequently more penetration of
456 photosynthetic radiation into the lower canopy. This competition implies in significant increase on the
457 lower canopy resulting in increment of LAI_{lower} (Table 5).

458 The model does not include fire characteristics such as velocity, intensity and duration of the
459 burning (Hoffman et al., 2003; Rezende et al., 2005; Elias et al., 2013; Reis et al., 2015) or the
460 representation of some tree morphological adaptation that confers to Cerrado species resilience to fire
461 occurrence, such as bark thickness. Thus, trees and grasses throughout the Amazon-Cerrado border are
462 equally exposed to the same fire intensity inside the grid cell, without fire resistance differences.
463 However, despite the limitations in the representation of resilience characteristics and morphological
464 attributes of fire resistance, our results show that simulated biomass is more close to observed biomass in
465 Cerrado areas when the fire module is activated (Figure 5). An improvement in distribution of biomes
466 along the simulated transition area is also observed (Figure 6g-i), highlighting fire as an essential factor
467 to represent the Amazonia-Cerrado border.

468 This study shows an improvement in the correlations between simulated and observed AGB when
469 compared to previous modeling studies, regardless of treatment, with correlation coefficients usually
470 above 0.80 for the transects, except for T5, for which the correlation coefficient value is usually below
471 0.5 (Table 7). Senna et al. (2009) found 0.20 as maximum correlation coefficient between simulated and
472 observed ABG while Castanho et al. (2013) showed 0.80 for Amazonia domain. From Figure 5, it is clear
473 that CV, F and P limitation in the transition zone reduce the AGB, causing the simulated data to approach
474 the observed data. However, the inclusion of these effects is still insufficient to represent the correct
475 distribution of the vegetation types throughout the Amazon-Cerrado border (Figure 6L). In our
476 interpretation, this means that other important factors are still missing from the simulation, especially in
477 T5, where soils are rocky and shallow. A better spatial representation of soil physical properties, including
478 shallow rocky soils, as well as spatially varying physiological parameterizations of the vegetation such as
479 carbon allocation, deciduousness of vegetation, residence time, are probably needed to improve the
480 simulations, in particular in the northern and southern extremes of the border (T1 and T5).

481 In addition, literature shows that in the transition area, soils are very different than Amazon soils,
482 and that essential proprieties for modeling are peculiar (Silva et al., 2006; Vourlitis et al., 2013; Dias et
483 al. 2015). For example, Dias et al. (2015) recently showed that the pedological functions normally used
484 by DGVMs may underestimate the saturated hydraulic conductivity (K_s) by >99%, transforming a well-
485 drained soil with $K_s = 1.5 \cdot 10^{-4} \text{ m.s}^{-1}$ (540 mm.h⁻¹) in reality into an impervious brick with
486 $K_s = 3.3 \cdot 10^{-7} \text{ m.s}^{-1}$ (1.2 mm.h⁻¹) in the model.

487 For all transects, the AGB curves have similar patterns (Figure 5); the smaller difference is
488 observed between CA+PC and CV+PG curves, while the larger difference is when fire is present. The

489 effect of P limitation appears as an effect of intermediate magnitude, reducing the AGB by more than the
490 effect of inter-annual climate variability. In the east, it is observed that there is little or no difference
491 among AGB simulated by CA+PC, CV+PC and CV+PG, revealing that inter-annual climate variability
492 and P have smaller influence in the AGB. However, in the east of T2, T3 and T4, fire is the factor that
493 adjusts the simulated to the observed data (Figure 5), differently than the grid points in the West, where
494 CV+PG is a better proxy between observed and simulated data.

495 Such conditions are interesting because they reflect the different mechanisms that regulate the
496 structure of these ecosystems and probably the phytophysiognomies distribution. For example, P
497 limitation seems to be the factor that improves simulated AGB in regions where the predominant
498 vegetation type is the tropical rainforest. Fire, on the other hand, improves the AGB in grid points where
499 the Cerrado occurs. Moreover, important factors such as productivity partitioning into leaves, roots and
500 wood carbon pools are assumed to be fixed in space and time within a given PFT, neglecting the natural
501 capacity of transitional forests to adapt itself and to adjust their metabolism to local environmental
502 conditions (Senna et al., 2009). In years of severe drought, or under frequent fire occurrence, transitional
503 forests could prioritize the stock of carbon in fine roots instead of the basal or leaf increment to maximize
504 access to available water, make hydraulic redistribution of soil moisture to maintain the greenness and
505 photosynthesis rates, or increase the capacity to resprout after fire occurrence (Hoffman et al., 2003;
506 Brando et al., 2008). Brando et al. (2008) found changes in carbon allocation after an artificial drought in
507 eastern Amazonia, with wood production reduced by 13-60%, and associated increase in root production.
508 Although in INLAND low soil moisture can reduce the photosynthetic rates, carbon allocation rates are
509 fixed (Figure 5a).

510 T2, T3 and T4, located in the central part of the Amazon-Cerrado transition, showed the highest
511 average correlations between observed and simulated data (Table 7). For these transects, INLAND seems
512 to be able to capture the high variability of AGB gradient.

513 At T5, located at the south of the transition, the average correlations were low for all treatments,
514 indicating that INLAND has difficulty to represent the AGB gradient there (Table 7). However, it captures
515 the lower AGB as compared to the northern ones. In this region, the vegetation is characterized by a wide
516 diversity of physiognomies, which varies with other preponderant factors, such as lithology, soil depth,
517 topography and fertility. The observed data also showed high AGB variability, indicating that there are
518 changes in the vegetation structure, featuring medium-sized and small vegetation types on different soil
519 types. In INLAND, however, features such as lithology and water-table depth are not considered due to
520 the complexity of its representation on the large scale, limiting the representation of a heterogeneous
521 environment throughout the transition.

522 Patterns of vegetation distribution along the Amazon-Cerrado border exist are influenced not only
523 by inter-annual climate variability, P limitation, and fire, but also by the ecophysiological parameters.
524 Additional field experiments are needed to understand the relationship between currently fixed parameters
525 (such as carbon allocation, residence time, and deciduousness, among others) to the environmental
526 conditions and soil proprieties.

527 Another point to discuss is that the model simulates, in a few pixels in southeastern Cerrado, very
528 robust simulations of the presence of savanna and grassland even in the absence of fire (Figure 6A-F and
529 6a-f). This is, in our view, a result of the intense water and heat stress in this region. In the Brazilian
530 Cerrado, the high temperatures ($> 35\text{ }^{\circ}\text{C}$) combined to the dry season duration (as long as 6 months with

531 little or no rain) exposes the vegetation to a severely stressed situation, so that a low biomass, low LAI
532 vegetation may exist without the need of a frequent disturbance.

533

534 **5 Conclusions**

535 This is the first study that uses modeling to assess the influence of inter-annual climate variability,
536 fire occurrence and phosphorus limitation to represent the Amazon-Cerrado border. This study shows
537 that, although the model forced by a climatological database is able to simulate basic characteristics of
538 the Amazon-Cerrado transition, the addition of factors such as inter-annual climate variability,
539 phosphorus limitation and fire gradually improves simulated vegetation types. These effects are not
540 homogeneous along the latitudinal/longitudinal gradient, which makes the adequate simulation of
541 biomass challenging in some places along the transition. Based on the F-statistic in Tables 3, 4 and 5, this
542 work shows that fire is in the main determinant factor of the changes in vegetation structure (LAI, AGB)
543 along the transition. The nutrient limitation is second in magnitude, stronger than the effect of inter-annual
544 climate variability.

545 Overall, although INLAND typically simulates more than 80% of the variability of biomass in the
546 transition zone, in many places the biomass is clearly not well simulated. Situations for clearly wet or
547 markedly dry climate conditions were well simulated, but the simulations are generally poor for
548 transitional areas where the environment selected physiognomies that have an intermediate behavior, as
549 is the case of the transitional forests in northern Tocantins and Mato Grosso.

550 There is evidence that the inclusion of spatially explicit parameters such as woody biomass
551 residence time, maximum carboxylation capacity (V_{\max}), and NPP allocation to wood may improve

552 Amazon rainforest AGB simulation by DGVMs (Castanho et al., 2013). However, in the transition, the
553 lack of field parameters measured limits the inclusion of the variability of these biophysical parameters
554 in DGVMs. Additional field work and compilation of existing ones are necessary to obtain physiological
555 and structural parameters through the Amazon-Cerrado border to establish numerical relationships
556 between soil, climate and vegetation. With the help of these data, dynamic vegetation models will be able
557 to improve simulation of current patterns and future changes in vegetation considering climate change
558 scenarios. In addition, it is also needed to include not only the spatial variability, but also temporal
559 variability in physiological parameters of vegetation, allowing a more realistic simulation of the
560 soil-climate-vegetation relationship. Finally, our results reinforce the importance and need of the DGVMs
561 to incorporate the nutrient limitation and fire occurrence to simulate the Amazon-Cerrado border position.

844

845

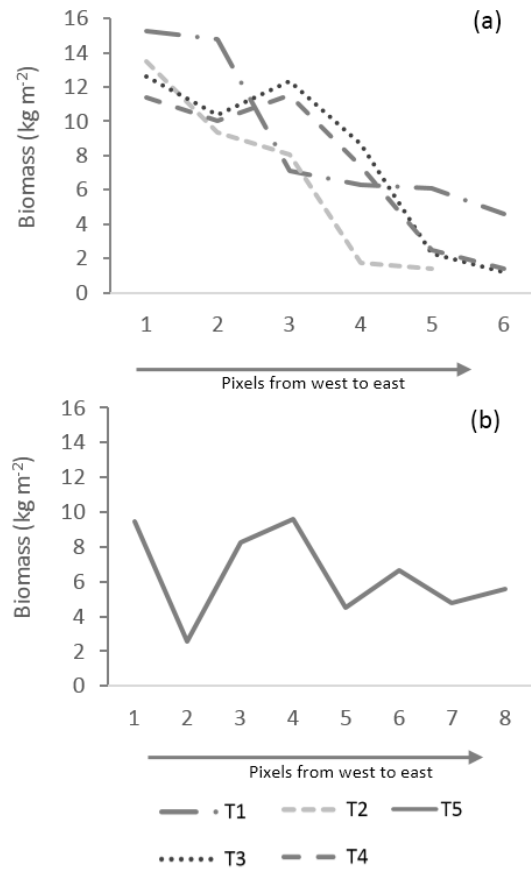

846 **Figure 1.** Delimitation of the study area Amazonia (in light gray) and Cerrado (in dark gray) (IBGE,
 847 2004), and the location of five transects used in this work (from T1 to T5). The dashed line represents the
 848 border between biomes.

849

850 **Figure 2.** (a) Map of regional total P in the soil (PR), (b) Map of global total P in the soil (Yang et al.,
 851 2013) (PG).

852

853

854 **Figure 3.** Average variations of AGB in pixels from West to East in the Amazonia-Cerrado transition

855 for transects T1, T2, T3 and T4 (a), and T5 (b).

856

857 **Figure 4.** Effects of inter-annual climate variability (a), Regional P limitation (b), Global P limitation (c),
 858 and fire (d) on AGB. The hatched areas indicate that the variables are significantly different compared to
 859 the control simulation at the level of 95% according to the t-test. The thick black line is the geographical
 860 limits of the biomes.

861

862 **Figure 5.** Average longitudinal AGB gradient in Amazonia-Cerrado transition simulated for T1 to T5
 863 considering different combinations: observed data; seasonal climate control simulation (CA+PC); inter-
 864 annual climate variability (CV+PC); inter-annual climate variability + global P limitation (CV+PG); and
 865 inter-annual climate variability + P + fire occurrence (CV+PG+F).

Figure 6. Results for the dominant vegetation cover simulated by INLAND for the different treatments (A-L) and a metric of variability of results (a-l). Simulations are considered very robust if the dominant vegetation agrees on 9-10 of the last 10 years of simulation, robust if it agrees on 7-8 years, and transitional if on 6 or fewer years.

874 **Table 1.** Simulations with different scenarios evaluated by INLAND model in Amazonia-Cerrado
875 transition. CA, climatological average, 1961-1990; CV, monthly climate data, 1948-2008; the nutrient
876 limitation on V_{\max} - PC, no P limitation ($V_{\max} = 65 \mu\text{mol-CO}_2 \text{ m}^{-2} \text{ s}^{-1}$); PR, regional P limitation; PG,
877 global P limitation).

Climate	CO ₂	Fire (F)	V_{\max}		
			PC	PR	PG
CA	Variable	Off	CA+PC	CA+PR	CA+PG
CA	Variable	On	CA+PC+F	CA+PR+F	CA+PG+F
CV	Variable	Off	CV+PC	CV+PR	CV+PG
CV	Variable	On	CV+PC+F	CV+PR+F	CV+PG+F

878

879

880 **Table 2.** Individual and combined effects for each simulation in Amazonia-Cerrado transition. CA,
 881 climatological seasonal average, 1961-1990; CV, monthly climate data, 1948-2008; the nutrient limitation
 882 on V_{\max} - PC, no P limitation ($V_{\max} = 65 \mu\text{molCO}_2 \text{ m}^{-2} \text{ s}^{-1}$); PR, regional P limitation; PG, global P
 883 limitation)

Climate (C)	Phosphorus (P)	Fire (F)
(CV+PC)-(CA+PC)	(CA+PR)-(CA+PC)	(CA+PC+F)-(CA+PC)
(CV+PR)-(CA+PR)	(CV+PR)-(CV+PC)	(CV+PC+F)-(CV+PC)
(CV+PG)-(CA+PG)	(CA+PG)-(CA+PC)	(CA+PR+F)-(CA+PR)
	(CV+PG)-(CV+PC)	(CV+PR+F)-(CV+PR)
		(CA+PG+F)-(CA+PG)
		(CV+PG+F)-(CV+PG)

884

885

886 **Table 3.** Summary of average NPP, LAI and AGB for the Amazonia-Cerrado transition at the transects
887 domains, considering all simulations with CA and CV regardless of fire presence or P limitation. The
888 results of a one-way ANOVA are also shown, including the *F* statistic, and *p* value. Values within each
889 column followed by a different letter are significantly different ($p < 0.05$) according to the Tukey–Kramer
890 test ($n=1860$: 31 pixels x 10 years x $n_{\text{simulation}/2}$).

Group 1	NPP		LAI_{total}		LAI_{lower}		LAI_{upper}		AGB	
	kg-C m ⁻² yr ⁻¹		m ² m ⁻²		m ² m ⁻²		m ² m ⁻²		kg-C m ⁻²
