Exploring the contributions of vegetation and dune size to early dune building using unmanned aerial vehicle (UAV)-imaging

Short running head: Dune size and vegetation

Abstract

Dune development along highly dynamic land-sea boundaries is the results of interaction between vegetation and dune size with sedimentation and erosion processes. Disentangling the contribution of vegetation characteristics from that of dune size would improve predictions of dune development under a changing climate, but has proven difficult due to scarcity of spatially continuous monitoring data.

This study explored the contributions of vegetation and dune size to dune development for locations differing in shelter from the sea. We monitored a natural dune field of 8 hectares, along the coast of the island Texel, the Netherlands, for one year using an Unmanned Aerial Vehicle (UAV) with camera. After constructing a Digital Surface Model and orthomosaic we derived for each dune 1) vegetation characteristics (species composition, vegetation density, and maximum vegetation height), 2) dune size (dune volume, area, and maximum height), 3) degree of shelter (proximity to other dunes and the sheltering by the foredune). Changes in dune volume over summer and winter were related to vegetation, dune size and degree of shelter.

We found that a positive change in dune volume (dune growth) was linearly related to dune volume over summer but not over winter. Big dunes accumulated more sand than small dunes due to their larger surface area. Exposed dunes increased more in volume than sheltered dunes over summer, while the opposite occurred over winter. Vegetation characteristics did not significantly affect dune growth in summer, but did significantly affect dune growth in winter. Over winter, dunes dominated by *Ammophila arenaria*, a grass species with high vegetation density throughout the year, increased more in volume than dunes dominated by *Elytrigia juncea*, a grass species with lower vegetation density. The effect of species was irrespective of dune size or distance to the sea.

Our results show that dune growth in summer is mainly determined by dune size, whereas in winter dune growth was determined by vegetation. In our study area the growth of exposed dunes was likely restricted by storm erosion, whereas growth of sheltered dunes was restricted by sand supply. Our results can be used to improve models predicting coastal dune development.

Key words: Biogeomorphology, embryo dunes, *Ammophila arenaria*, *Elytrigia juncea*, beach-dune interaction, landform morphology, the Netherlands

1. Introduction

Coastal dunes occur along the sandy shores of most continents (Martínez and Psuty, 2008), and are important to protect these coasts against flooding, provide areas for recreation, store drinking water and shelter unique biodiversity (Everard et al., 2010). Coastal dunes and their services are threatened by climate-induced sea-level rise (Carter, 1991; Feagin et al., 2005; Keijsers et al., 2016). However, dunes also provide self-adapting systems of coastal protection, since the threat by sea-level rise can be mitigated by the development of new dunes. Despite the obvious importance of dunes, we know surprisingly little about the factors that determine early dune development. Understanding these factors is essential for predicting dune development, and for safeguarding their services.

Dune development is the result of an interaction between vegetation and aeolian processes and starts above the high-water line by the establishment of dune-building plant species (Maun, 2009). Once vegetation establishes on the bare beach, it forms a roughness element that facilitates local sand deposition and reduces erosion, forming a small dune within discrete clumps of vegetation (Hesp, 2002). At the lee side of these small clumps of vegetation a shadow dune develops by sand deposition, this shadow dune has a ridge parallel to the wind direction (Hesp, 1981). Vegetation and shadow dune together are known as embryo dunes, or incipient dunes (Hesp, 2002; Hesp and Smyth, 2017). Their further development strongly depends on the balance between summer accumulation of sand and vegetation growth and winter erosion of sand and loss of vegetation (Montreuil et al., 2013). Summer growth and winter erosion depend on weather conditions, such as wind speed, precipitation and storm intensity (Montreuil et al., 2013; van Puijenbroek et al., 2017). As a result, net dune growth can differ from year to year. Over time the smaller vegetated dunes can develop into an established foredune that forms the first line of coastal defense against flooding.

Most research on coastal dune growth and erosion have focussed on processes and factors that influence the supply of sand to the dunes and the effect of storm intensity on dune erosion (Anthony, 2013; Haerens et al., 2012; Houser et al., 2008; Keijsers et al., 2014; Saye et al., 2005; de Vries et al., 2012). However, how coastal dune growth and erosion rates are influenced by the individual dune characteristics, such as dune size, vegetation and degree of sheltering are less well studied. Dune size affects the wind flow pattern, thus affecting sand deposition (Walker and Nickling, 2002) for example increasing height or length of the shadow dune (Hesp, 1981; Hesp and Smyth, 2017). Dune size also influences storm erosion: Claudino-Sales (2008) found that foredunes with a higher volume were less sensitive to erosion. Whether the latter also applies to embryo dunes, is unknown. Differences in vegetation density between plant species are known to modify sand deposition, storm erosion, dune morphology, and growth (Charbonneau et al., 2017; Hacker et al., 2012; Seabloom et al., 2013; Zarnetske et al., 2012). Sheltering by other dunes can decrease the sand supply but can also reduce erosion by waves (Arens, 1996; Montreuil et al., 2013). Although dune size, vegetation and sheltering are known to be important for individual dune development, the relative contributions of these factors are unknown.

In this study, we explored the contribution of vegetation and dune size to dune development. Using an unmanned aerial vehicle (UAV) with camera we monitored a natural dune field for one year. From the aerial images we constructed a digital terrain model (DTM) and an orthomosaic. From the

DTM and orthomosaic we extracted detailed data on dune size (dune area, volume and maximum height), vegetation characteristics and the degree of sheltering. We related dune size and vegetation to changes in dune volume over a summer (April - August) and winter period (November - April). We expected dune growth to be a function of dune size and vegetation density, dune growth being the largest for big dunes with high vegetation density. We also expected that the effect of sheltering on dune growth would depend on season: exposed dunes growing faster in summer, but slower in winter.

2. Methods

2.1 Study area

We monitored 8 hectares (200 m x 400 m) of a natural dune field with a large range of dune sizes at 'the Hors', the southern tip of the barrier island at Texel, the Netherlands, coordinates: 52°59'43.70"N, 4°43'47.53"E (Fig. 1). The Hors is a wide dissipative beach with a high degree of hydrodynamic reworking of the sand, which results in a high transport potential and opportunity for dunes to develop. In the last 20 years many vegetated dunes have developed on the beach. At this area permanent dunes are formed by plant species *Ammophila arenaria*, *Elytrigia juncea* or a mixture of both species. These three types of vegetated dunes occurred at similar distances from the sea, making this area ideal for testing the effects of dune size and species composition on dune growth. *A. arenaria* and *E. juncea* differ in their vegetation characteristics: *A. arenaria* grows in dense patches, whereas *E. juncea* has a more sparse growth form. This difference in growth form probably also results into a different dune morphology: *A. arenaria* forms higher 'hummocky' shaped dunes, whereas *E. juncea* builds broader and lower dunes (Bakker, 1976; Hacker et al., 2012). The monitoring area is bisected by a low, continuous foredune ridge that runs parallel to the shore. The dunes that occur at the seaward side of this foredune are more exposed to the sea, while the dunes occurring at the landward side of the foredune are more sheltered from the sea, enabling us to explore whether the effects of dune size and vegetation are modified by the degree of shelter. The foredune in our monitoring area has a maximum height of 7m NAP (NAP refers to Amsterdam Ordnance Date, which refers to mean sea level near Amsterdam).

Summer conditions during our study period were similar to previous years, while winter conditions were calmer than usual (Supplementary S1). The precipitation during the growing season was 276 mm, and the average temperature in June and July was 16 °C. The most common wind direction was South to South-West. The most common wind speed in summer was 4 - 5 m s^{-1}, and the maximum wind speed was 13 m s^{-1}. In winter the wind speed was higher compared to summer, the most common wind speed was 5 – 6 m s^{-1} and the maximum wind speed was 19 m s^{-1}. We registered one storm during the study period. This storm, however, could be classified as relatively weak. The highest water level was 211 cm NAP; compared to 248 cm NAP and 254 cm NAP from previous years. The storm, which was the first of the season, occurred after the beginning of our mapping campaign.

2.2 Data collection

Three UAV flights in November (2015), April (2015) and August (2016) were carried out with a rotary octocopter UAV system (Aerialtronics Altura Pro AT8 v1) and camera equipment of WageningenUR *Unmanned Aerial Remote Sensing Facility*. The octocopter was equipped with a Canon EOS 700D single-lens reflex camera with a 28mm f/2.8 Voigtländer Color Scopar SL-II N objective. The camera sensor was modified to give a false colour output. The red channel of the camera had been converted to be sensitive in the near-infrared, with centre point around 720nm. The blue channel of the camera had been extended to also cover the UV region of the spectrum. The green channel was left with almost original response. The false colour modification enabled the calculation of a modified Normalised Difference Vegetation Index (NDVI), a commonly used measure for vitality and/or cover of the vegetation (Carlson and Ripley, 1997). Aerial images were acquired by auto-piloted flights at an altitude of 80 m at 4 – 5 m s^{-1} velocity. The camera was set to take one image per second. The auto-piloted flights enabled us to have the same flight paths for each of the three mapping campaigns. The flight paths ensured that images had a minimum of 85% forward and 65% side-way overlap. Four flights of 10 minutes were needed to cover the study area, yielding up to 900 RAW false colour images per mapping campaign. Five ground control points were permanently placed in the flight area and measured with a RTK-DGPS Trimble R6 Model 3 (TSC3) to calibrate our images with coordinates. During our mapping campaign, a Spectralon reference panel was measured with our camera immediately before take-off and after landing.

2.3 Radiometric calibration

In order to compare the images over the time, they were calibrated and converted from RAW to 16 bit tiff format. First, we ensured that each individual pixel within an image was comparable, by converting the RAW digital number into radiance units using a pixel-wise dark current and flat field calibration. Second, each radiance image was calibrated to a reflectance factor image in order to correct for changes in incident irradiance on different flight days. This calibration was done by using a Spectralon panel with a known reflectance factor. The radiometric calibration is described in more detail by Suomalainen et al. (2014).

The images were subsequently converted into NDVI images. Usage of the standard NDVI was not possible due to lack of red channel in the false color modified camera. Thus we used a custom NDVI equation (Eq. 1), which was recommended by the company that modified the sensor. On their website (MaxMax.com) this equation was shown to be just as effective for green vegetation as the traditional NDVI formula ($R^2 = 0.77$) where the red band is taken as the absorption channel.

1) $$NDVI = \frac{(NIR + G) - (2B)}{(NIR + G) + (2B)}$$

Where NIR, G, and B are the near-infrared, green and blue bands of the false colour image respectively. For photogrammetric reconstruction, the NDVI image layer was stacked with the original green and blue bands to form a three-color image.

2.4 Photogrammetric reconstruction

The large overlap between the consecutive images was necessary for photogrammetric software to successfully process the aerial images into a 3D point cloud. The 3D point cloud was generated using Agisoft Photoscan Professional (v. 1.2.6), using the Structure-from-Motion (SfM) and Multi-View Stereo (MVS) algorithms (Fonstad et al., 2013; Westoby et al., 2012). The correlated 3D points are georeferenced to match the ground control points, and contain pixel intensity values of the input imagery. From this 3D point cloud we interpolated a 5 cm pixel size digital surface model (DSM) and a 1 cm pixel size orthomosaic image. The vertical error distribution of a DSM produced by UAV photogrammetry is expected to be equivalent to airborne LIDAR data and terrestrial laser scanning (Hugenholtz et al., 2013; Mancini et al., 2013). The DSM included also vegetation, which resulted in a vertical error in dune height in areas where vegetation is present. We removed the vegetation from the point cloud by identifying and removing the vegetation points. Vegetation points were removed by distinguishing vegetation from sand using k-means clustering of the 3-D point cloud with NDVI using the Hartigan and Wong (1979) algorithm in R (R Core Team, 2016). The holes in the point cloud that arose by removing the vegetation were filled by using LAStools (the tool Blast2dem) (Isenburg, 2016), which resulted in a Digital Terrain Model (DTM) without vegetation.

2.5 Defining dunes

To be able to relate dune growth to characteristics of an individual dune, we first had to define individual dunes from the DTM. We followed a step-wise procedure for each of our mapping campaigns (November, April, and August) using ArcGIS 10.3 (ESRI, 2016) that resulted into different polygons in which each individual dunes expanded or decreased in volume over the study period. Dune size and growth were later calculated using the same polygons for each measurement campaign through time (see next section). To define the polygons we used the step-wise procedure described below: 1) we constructed a baseline raster by calculating the average elevation in a circle of 5m radius around each pixel in the DTM. A higher or lower radius resulted in either a too low or too high baseline. 2) We then qualified pixels of the DTM as dunes, if they were 5 cm above a baseline raster, or had a slope of 15° or higher. From these selected ‘dune’ pixels we created dune polygons. 3) Dune polygons of consecutive campaigns were overlaid to construct the largest dune-covered area during the study period. 4) Each polygon was visually checked for minimum size and presence of vegetation: dunes consisting of only one clump of vegetation (0.4 m^2 or smaller) and dunes with no vegetation were discarded.

2.6 Variables

For each dune and for each mapping campaign we extracted dune volume (m^3), max height (m) and horizontal area (m^2) from the dune polygons (see previous section) in the DTM. We calculated the absolute change in dune volume by subtracting the current dune volume from the volume of the previous mapping campaign, and we corrected for the number of weeks between the mapping campaigns. To explore relationships irrespective of dunes size, we also calculated the relative change in dune volume per week as (V_t/V_{t-1})/week. Where V_t is the dune volume and V_{t-1} the dune volume of the previous mapping campaign.

We manually identified the species composition on each dune from the orthomosaic. Species identification was verified in the field for a random subset of 100 dunes (23%). To this end we created 2 transects from the southwest border to the northeast border of the area. For these transects we determined the species on each dune in the field in May 2016. We compared the presence of species in the field with the orthomosaic, and adjusted the species composition if necessary. In our dataset, dunes have either *A. arenaria*, *E. juncea* vegetation, or a mixture of both species. A dune was defined as covered by a mixture of both species, when it had distinct vegetation patches of both species present. For each dune and mapping campaign we also extracted the vegetation density and the maximum plant height. To assess vegetation density we first distinguished vegetated pixels from non-vegetated pixels based on the orthomosaic using k-means classification of the NDVI using the MacQueen (1967) algorithm. Hereafter, the vegetation density (NDVI/cm^2 dune) was calculated by summing the NDVI values of all vegetated pixels within the dune polygon and then dividing this summed NDVI by the total number of cm^2 pixels within the dune polygon. The maximum plant height was calculated by subtracting the DTM (with vegetation) from the DSM (without vegetation).

Sheltering can affect the sand supply and storm erosion. We used two methods to define the extent of sheltering. Firstly, we distinguished whether a dune was seaward or landward from the foredune. Secondly we determined how much a dune was clustered with other dunes. We extracted the degree of clustering for each dune by calculating the mean height from the DTM in a 25 m radius around the dune. All data extraction from the DSM, DTM and orthomosaic were done in R (R Core Team, 2016).

2.7 Statistical analysis

First we explored if dune area, volume, maximum dune height, clustering (mean height in a 25m radius around the dune), vegetation density and maximum plant height depended on species composition using August 2016 data. As the number of dunes per species composition was unequal, we used an ANOVA type III SS, to compensate for the unequal sample size (Fox and Weisberg, 2011) and then used a Tukey HSD test (Hothorn et al., 2008) to determine significant differences between the dunes with different species compositions.

Secondly, we tested how absolute changes in dune volume over winter (November – April) and summer (April – August) periods related to the dune volume at the beginning of the period at location with different degree in sheltering with a linear regression model.

Thirdly, we analysed how the relative changes in dune volume over winter and summer depended on dune size and vegetation characteristics in separated linear mixed models (Pinheiro et al., 2009). To correct for spatial autocorrelation and species distribution we ran this analyses on a subset of 236 (54%) dunes. To this end we first explored the degree of spatial autocorrelation in our dataset by creating a variogram. To account for the spatial autocorrelation of 25 m in our dataset we imposed a 50 m x 50 m grid over our study area; all dunes that were located within a grid cell (referred to as block) were assumed to show spatial autocorrelation to some extent. This spatial autocorrelation was corrected for in our statistical model by including block as a random intercept. We had 10 blocks seaward from the foredune and 11 blocks landward from the foredune (Fig. 2), in which all species combinations occurred (*A. arenaria* dunes, *E. juncea* dunes and *A. arenaria* + *E. juncea* dunes). By only including dunes that were located within a block in the analysis, our selection was biased towards smaller dunes, since larger dunes often fell within multiple blocks. We do expect that the effect of vegetation is more apparent for these smaller dune compared to larger dunes. To better distinguish between effects of species compositions and vegetation structure we used two different models. The effect of species composition was tested in a model with dune volume, maximum dune height, clustering and species, whereas the effect of vegetation structure was tested in a model with dune volume, maximum dune height, dune clustering, vegetation density and maximum plant height as explanatory variables. Within each model we used the initial conditions for the explanatory variables, with initial conditions being the values at the start of each measurement campaign. We included all two-way interactions. We selected the best model by using Akaike information criterion (AIC). As we were mainly interested in the importance of the explanatory variables relative to each other, we calculated the standardised estimates for all the models by scaling the explanatory data.

The normality and homogeneity of the variance of the data was visually checked. All statistical analyses were conducted in R (R Core Team, 2016). In the results we use statistic notation to show the results of the ANOVA and linear regression models. We mention the F- value (ANOVA) or t-value (linear regression), which indicates the difference of the explanatory variable to the variation in the data. The p-value indicates the probability that the null-hypothesis is correct, we used a p-value of 0.05 as a cut off to reject the null-hypothesis. The number in subscript indicates the degrees of freedom.

3. Results

3.1 Dune characteristics

Within the 8 hectare dune field we distinguished 434 polygons that were covered with dunes for at least one moment during our mapping campaigns. Most of the dunes were *E. juncea* dunes (50.23%), followed by *A. arenaria* dunes (28.11%) and mixed dunes (22.66%) in August 2016. Species composition of the dunes changed along a gradient from sea to land. Close to the sea dunes were vegetated by *E. juncea*, while, further from the sea, dunes were also vegetated by *A. arenaria* alone, or in a mix with *E. juncea* (Fig. 2). Landward of the foredune dunes were also vegetated by *E. juncea*, *A. arenaria* alone, or a mix of both species. The foredune bisecting our study area was mainly vegetated with *A. arenaria*.

In August 2016 dune area, volume and maximum height differed significantly between dunes differing in species composition (volume: $F_{2,428}$=3.05, p=0.048; max. height: $F_{2,428}$=59.6, $p < 0.001$), but did not differ between dunes contrasting in shelter. Dunes with a mix of *E. juncea* and *A. arenaria* had overall the highest volume and maximum height, whereas *E. juncea* dunes had the lowest volume and height. *A. arenaria* dunes had the largest range in dune volume (Fig. 3A, B, C). For *E. juncea* dunes seaward from the foredune the distance between dunes was higher compared to *A. arenaria* dunes and dunes with both species ($F_{2,428}$=52.5, p<0.001), the distance between dunes landward from the foredune was overall smaller than dunes seaward from the foredune (Fig. 3D, $F_{1,428}$=70.2, p<0.001). The dune volume did not significantly differ between dunes seaward and landward from the foredune (volume: $F_{1,428}$=0.76, p=0.39), but the dune height above NAP was significantly higher for dunes landward from the foredune ($F_{1,428}$=15.9, p<0.001).

For the statistical model with relative change in dune volume as response variable, we had to correct for species distribution and spatial autocorrelation. We created a grid, with blocks of 50 m x 50 m, and we selected dunes that fell within a block. In total, we selected 236 dunes, which consisted of 41.95% of *E. juncea* dunes, 36.02% of *A. arenaria* dunes, and 22.03% of dunes with both species. These subset of dunes had an overall lower dunes size compared to all the dunes, but had overall similar dune morphology and vegetation characteristics (Supplementary data S2).

Figure 3 approximately here

Vegetation characteristics depended on the plant species dominating the dunes and on the degree of shelter. *E. juncea* dunes had significantly the lowest vegetation density, *A. arenaria* dunes the highest and dunes which consisted of both species had an intermediate vegetation density (Fig. 3E, $F_{2,428}$=49.30, p<0.001). Similar to vegetation density, *E. juncea* dunes also had the lowest maximum plant height, whereas *A. arenaria* and dunes consisting of both species had the highest maximum plant height (Fig. 3F, $F_{2,428}$=42.70, p<0.001). Dunes landward from the foredune had significantly higher vegetation densities compared to seaward dunes ($F_{1,428}$=45.7, p<0.001). There was no significant difference in maximum plant height between dunes seaward and landward from the foredune ($F_{1,428}$=0.41, p=0.52).

3.2 Change in dune number and volume

The number of dunes within the measurement area changed over time, with dune numbers declining over winter and increasing during summer. The degree of dynamics depended on season, species and degree of sheltering.

3.2.1 Summer

Of the 434 dunes present in August 2016, 22.36% appeared over summer (April – August). Most of these new dunes (65.93%) were *E. juncea* dunes, 31.87% were *A. arenaria* dunes and only 2.20% were mixed dunes. Most (73.63%) new dunes developed seaward from the foredune and were quite small in size with a volume of 2.72 ± 0.29 m^3 (mean ± SE). We assumed that most of these dunes established over the growing season, as the orthomosaic showed a large amount of wrack line material (plant material, woody debris, rope etc.) in their polygon in November and April. However we cannot exclude that part of the large increase in the smaller *E. juncea* over summer is a result of their poor recognition in November and April.

Over summer, most dunes increased in dune volume, including the foredune which increased over summer with 0.28% per week, reaching a volume of 64,444 m^3 in August. Only 4.15% of the dunes showed a small decrease in the volume with a mean of -0.041±0.014 m^3/week. Changes in dune volume were positively related to dune volume (Fig. 4A, t-value$_{430}$= 57.20, $p<0.001$) and were higher for dunes seaward of the foredune compared to dunes landward of the foredune, resulting in a significant effect of shelter (t-value$_{430}$=-41.70, $p<0.001$).

Figure 4 approximately here

Over summer, the relative change in dune volume was mainly influenced by sheltering, were the relative change in dune volume was higher seaward of the foredune compared to landward of the foredune (Fig. 5A). We found no significant difference in relative change in dune volume between dunes with different species composition (Fig. 5A, Table 1). In our statistical model plant height had a statistically significant effect on the relative dune growth. However, when tested in a single linear mixed model with block as random intercept, plant height had a R^2 of 0.0038, thus hardly explaining any variation in relative dune growth (Table 2). Several dune size variables were significant, but the individual variation explained by dune volume, and dune height was very low, their R^2 ranging between 0.05 – 0.0033. The significant interactions between variables were mostly caused by the slight correlations between the explanatory variables. The clustering of dunes did not significantly affect the relative dune growth. We tested whether the effect of clustering was masked by the use of blocks as random intercept, since the amount of clustering was different between the blocks. We re-analysed the data without the blocks as random factor and found again no effect of clustering on the relative growth rate of dunes.

Manuscript under review for journal Biogeosciences
Discussion started: 17 May 2017

Table 1 & 2 approximately here

3.2.2 Winter

Over winter (November – April) 7.85% of the 344 dunes disappeared, of which 40.74% were *E. juncea* dunes, 55.56% were *A. arenaria* dunes and 3.70% dunes with both species. These dunes disappeared both seaward (40.74%) and landward (59.26%) from the foredune and were overall quite small with an average volume of 2.23 ± 0.19 m^3.

Over winter dunes still increased in volume, the large foredune even increased with 0.22% per week. However on average the changes in dune volume was less positive than over summer, 21.20% of the dunes decreased -0.061±0.015 (SE) m^3/week in volume, particularly seaward of the foredune. 25.00% of these decreased dunes were covered with *A. arenaria* , 50.00% with *E. juncea* and 25.00% with both species. The absolute change in dune volume between November and April was positively related to dune volume in November (Fig. 4B, t-value$_{430}$=2.1, p=0.033), but was only significant for dunes landward of the foredune. Dunes seaward of the foredune showed no relationship between absolute change in dune volume and the dune volume in November (t-value$_{430}$=16.37, p<0.001).

The relative change in dune volume was influenced by species composition and degree of shelter (Table 1). Dunes with *E. juncea* increased relatively less in volume than *A. arenaria* dunes (Fig. 5B); this effect was only significant for dunes seaward of the foredune. We found no significant relationship between relative change in dune volume and vegetation density or maximum plant height (Table 2). There was a significant interaction between vegetation density and sheltering by the foredune, which could be related to the higher vegetation density at the dunes landward of the foredune. Dune volume, the position relative to the foredune, had a significant negative effects on the relative change in dune volume, whereas clustering had a positive significant effect, but the relationship was very weak (R^2 between 0.002 – 0.05).

3.3 Net dune growth

Net absolute dune growth per week over the whole observation period November – August was higher at the seaward side of the foredune than at the sheltered landward side (slope seaward dunes: 0.37%, slope landward dunes: 0.25%, dune volume*position from foredune: t-value$_{430}$ = -11.7, $p<0.001$). Seaward dunes also had a slightly higher relative change in dune volume over November to August compared to the landward dunes (seaward dunes: 0.27 ± 0.00009 (m^3/m^3)/week (means±SE), landward dunes: 0.026±0.0001 (m^3/m^3)/week, F-value$_{1,230}$ = 18.51, $p<0.001$).

4. Discussion

The aim of this study was to explore the contributions of vegetation and dune size to dune development and how these effects are modified by the degree of shelter. We expected dune growth to be a function of dune size and vegetation density, dune growth being the largest for big dunes with high vegetation density. We also expected that the effect of sheltering on dune growth would depend on season: exposed dunes growing faster in summer, but slower in winter. Our results show that the contribution of vegetation and dune size depended on season and degree of shelter. In summer dune volume change was explained by dune size and to a lesser extent by dune height, while species composition, vegetation height or density had no effect. In winter dune volume change was explained by vegetation and dune size, depending on the degree of shelter. Exposed dunes with sparsely growing *E. juncea* grew less in volume than exposed dunes with densely growing *A. arenaria*. In contrast, growth of sheltered dunes was a function of dune volume. These findings are the first to show the relative contribution of vegetation and dune size for dune development over a winter and summer season, and these results can be used for modelling coastal dune development.

4.1 Dune size

4.1.1 Summer growth

We found a positive linear relationship between dune volume and the absolute change in dune volume over summer. It is known that dunes affect sedimentation by changing the wind flow patterns (Dong et al., 2004; Li et al., 2008). Previous studies have found that with increased dune volume the area where the wind speed is reduced increases, which result in higher sedimentation rates (Hesp, 1981; Hesp and Smyth, 2017). The linear relationship between dune volume and dune growth found in our study indicates that different dune sizes have similar effect on the wind flow pattern per unit of area. This result has also been found in a modelling study by Walmsey and Howard (1985), who found that different sized desert barchan dunes experienced similar disruptions of wind flow patterns, suggesting similar relative rates of deposition and erosion.

Our study focussed on a relatively small size range. It is likely that the linear relationship between dune volume change and dune size will saturate when dunes continue to grow and processes other than wind speed reduction become important. The latter is supported by the volume change of the low foredune bisecting our study area. Over summer the large foredune increased 0.28% per week in volume, which is much lower than the overall increase of 0.81% per week of the dune seaward of foredune. Therefore, we expect that there is a critical dune size at which the relationship between dune volume and absolute dune growth is no longer linear. However, what exactly the critical dune size is, is difficult to predict, it probably depends on multiple factors such as available sediment supply and vegetation growth. The wind flow patterns are not only influenced by dune volume, but also by maximum dune height (Walker and Nickling, 2002). In our study we found a significant, albeit weak effect of the maximum dune height on the relative growth, suggesting differences in height did not have a large effect on the wind flow pattern and the subsequent deposition of sand.

The positive linear relationship between dune volume and dune growth was modified by sheltering; dunes landward of the foredune increased 0.60% per week less in volume than dunes seaward of the foredune. This reduction in dune growth rate is likely the result of decreased sand supply landward of the foredune; presumably a large amount of the sand was captured by the foredune as was also observed for other foredunes (Arens, 1996). In our study the decrease in sand transport was less sharp as observed by Arens (1996), however the difference in foredune sink strength between the foredune in our study and those measured in Arens (1996) could be related to its smaller size, its relatively low height and/or its sparse vegetation cover of 29% (Keijsers et al., 2015). Clustering of dunes did not have any significant effect on the relative growth rate, which suggests that these smaller dunes do not significantly reduce the sand supply to the landward situated dunes.

4.1.2 Winter

In winter dune size was only a good predictor for growth of the dunes occurring landward of the foredune. For these sheltered dunes, growth again followed a linear relationship with dune volume. The absence of a relationship between dune size and dune growth for the exposed dunes occurring seaward form the foredune, suggests that dune erosion is less dependent on dune size than dune growth. Dune erosion has mainly been attributed to wave run-up during storms (Haerens et al., 2012; Vellinga, 1982). Therefore, it seems reasonable to assume that the degree of erosion depends on whether the dune can be reached by high energy waves. Large dunes that are reached by high water levels can erode substantially, whereas small dunes can have no erosion if they are protected by other dunes from the high water.

Interestingly, the sheltered dunes had a slightly higher dune growth in winter compared to summer. This increase in dune growth can perhaps be explained by more frequent and/or intensive aeolian transport events during winter resulting into higher sand supply to the sheltered dunes.

4.2 Vegetation characteristics

Vegetation characteristics were a poor predictor of dune volume change over the summer period, but were a significant predictor for dune volume change over winter. Over summer dune growth did not differ between dunes covered by different dune building plant species when corrected for dune size. Similarly we did not find a clear effect of vegetation density and plant height on dune growth. This results contrast with other studies that report a significant difference in the ability of species to trap sand mediated by differences in shoot density and cover (Keijsers et al., 2015; Zarnetske et al., 2012). Perhaps the discrepancy with our study can be explained by the differences in spatial scale used between studies. We studied dune volume change at the scale of a dune, whereas the other studies focussed on the scale of the vegetation patch, where species specifics effects are probably more pronounced than at the scale of the whole dune. Also Al-Awadhi and Al-Dousari (2013) found that the effects of vegetation on dune growth are scale dependent for coastal dunes. They found that the linear relationship between shrub vegetation characteristics and dune morphology levels off for bigger dunes. In our statistical models we selected the smaller dunes, which was a consequence of only selecting dunes that were located within one block. However even for these smaller dunes vegetation had no significant effect on relative dune growth.

Over winter *E. juncea* dunes had a significantly lower relative growth rate than *A. arenaria* dunes, presumably because of their higher sensitivity to erosion. This species-effect might be related to the sparser growth form of *E. juncea* in comparison to *A. arenaria* as dense vegetation has been found to reduce the amount of dune erosion, by more effective wave attenuation (Charbonneau et al., 2017; Koch et al., 2009; Silva et al., 2016). However, the effect of vegetation density was not significant in our model suggesting that the species effect might be due to other species differences, such as differences in rooting pattern. Another explanation is that the vegetation density measurement did not reflect the real vegetation density, *E. juncea* was difficult to detect due to the low NDVI values. The species effect was only significant for dunes situated at the exposed, seaward side of the foredune where erosion by water likely occurred during the single storm covered by our study period. Despite being statistically significant, the differences in relative growth rate between exposed *A. arenaria* and *E. juncea* dunes was not very large. Nevertheless the species effect might become more pronounced with higher erosion pressure during more stormy winters (Charbonneau et al., 2017).

Interestingly, our species did show differences in dunes size. On average, *A. arenaria* dunes were higher than *E. juncea* dunes, that were broader (Bakker, 1976; Zarnetske et al., 2012). This difference in dune morphology suggests a higher sand catching efficiency of *A. arenaria* that might be masked by using dune volume, mean height or dune area as explanatory variables. We explored whether there is an effect of species composition on the change in maximum dune height over summer, but found no consistent effect. Perhaps the difference in dune morphology could be a result of differences in erosion between the dune types over winter.

4.3 Implication for dune development

4.3.1 Net dune growth

Exposed dunes had an overall higher net growth compared to sheltered dunes, indicating that summer growth offset winter erosion in our study period which was characterised by an average summer and calm winter. This balance might have been different if winter conditions had been more severe.

During winter, storms determine the erosion of dunes seaward of the foredune. Multiple low intensity storms can lead to more erosion than one high intensity storm (Dissanayake et al., 2015; Ferreira, 2006; van Puijenbroek et al., 2017). Whether exposed dunes have a higher net dune growth compared to dunes landward from the foredune depends mainly on the storm intensity and frequency. A single high intensity storm can erode all the sand that exposed dunes have accumulated over a whole summer, and in such case sheltered dunes could have a higher growth rate than the exposed dunes. The exact relative growth rate over summer depends on the number of aeolian transport events. Linking the number of aeolian transport event to the relative growth rate over summer would be a worthwhile avenue for future research.

Sand supply and storm intensity are also affected by local conditions as beach morphology. A minimum beach width is needed to reach maximum aeolian transport, the fetch length (Delgado-Fernandez, 2010; Dong et al., 2004; Shao and Raupach, 1992). Our study site had a wide beach (0.9 km wide), and we assume that the maximum aeolian transport was reached. The net growth of our foredune was approximately 30 m^3 per m foredune parallel to the sea for a period of 10 months. This growth rate does also occur at other places along the Dutch coast, but is not very common (Keijsers et al., 2014). Storm intensity is also influenced by beach morphology. The presence of intertidal bars and a wide beach can reduce the storm intensity by wave attenuation (Anthony, 2013; Ruggiero et al., 2004). Therefore we can assume that the net dune growth we found in our study will depend on the beach morphology. On smaller beaches we expect the net dune growth to be lower compared to wider beaches, due to the lower sand supply by reduced fetch length and higher storm erosion of dune (van Puijenbroek et al., 2017)

4.4.2 Vegetation

For coastal dune development vegetation is essential, however the species-composition of the vegetation seems less important than we assumed: species did not seem to affect dune growth over the summer, but did affect dune growth over winter.

We did find differences in dune morphology between the species, which indicates an effect of species composition on dune morphology. However, this difference in dune morphology is probably also caused by vegetation succession. In Western Europe, the primary succession of coastal dunes is generally assumed to start with *E. juncea*. Only after a fresh water lens has developed in the *E.* juncea dune, *A. arenaria* will establish (Westhoff et al., 1970). Over time *A. arenaria* will outcompete *E. juncea*. This assumed succession pathway matches part of the spatial patterns that we found in our study site and explains why dunes with only *E. juncea* are relatively small. Over time these small dunes merge together after which *A. arenaria* is assumed to establish. However, we found that *A. arenaria* has a large range in dune volume suggesting that, contrary to current assumptions, *A. arenaria* can also establish on the bare beach without *E. juncea*, as long as the soil salinity is not too high.

At our study site only two dune building species occur, however there are many different dune-building species. It could very well be that other dune building species do have a significant effect on the dune growth over summer. For further research it would be interesting to study if these results are similar in another dune system with different plant species.

4.4.4 Application

To our knowledge, we are the first to report on the relationship between dune volume and dune growth in the field. The linear relationship that we found in our studies can be incorporated in mathematical models that predict dune development. Furthermore, our research shows that for predicting dune growth species identity does not matter during the summer, however it does matter during the winter. This indicates that for dune building models, species identity is especially important when winter survival of dunes is modelled. Furthermore, for the construction of an artificial dune it appears to be crucial to plant the more storm resistant species.

Despite the presence of smaller dunes seaward of the foredune, the foredune showed a large increase in volume compared to similar foredunes along the Dutch coast. This indicates that sand supply to the foredune was not seriously hampered by the presence of the small vegetated dunes, while the smaller dunes seaward of the foredune likely added to the protection of the foredune against storm erosion. For coastal management it could be beneficial for foredune growth to have embryo dunes seaward of the foredune given a high sand supply.

5. Conclusions

The purpose of this study was to explore the contribution of vegetation and dune size on dune development at locations differing in shelter from the sea. Our results show that 1) the contribution of vegetation and dune size depend on season and degree of shelter. 2) Vegetation does not affect dune growth over summer, but does affect dune growth during winter, particularly at exposed sites. 3) During early dune development, dune growth is linearly related to dune volume, whereas dune volume does not seem to matter for dune erosion. 4) Sheltering by a foredune reduces both sand supply and dune erosion; the net effect of shelter on dune growth therefore likely depends on beach morphology and weather conditions. These results can be incorporated in models predicting dune development and can be used by managers to determine coastal safety.

Acknowledgements We thank Ministry of Defence and Staatsbosbeheer to allow UAV flights in their nature area. We thank the technology foundation STW (grant number STW 12689 S4) for funding the NatureCoast project, which made this research possible.

Competing interests The authors declare that they have no conflict of interest.

Data availability Data will be made available through the 4TU.Center for Research Data (http://researchdata.4tu.nl/home/)

Author contributions MvP, CN and JS performed UAV flights and image calibration. MvP, CN and JL analysed the data. MvP, CN, JS, AdG, MR, FB and JL provided guidance on the scope and design of the project, and contributed to the writing of the manuscript.

Supplement S2 Dune morphology of selected dunes

Table 1. Statistical models for the relative change in dune volume between April – August (summer) and November – April (winter). In this model we tested the effect of species, dune size, and degree of sheltering. The data was analysed with a general linear mixed model with blocks as random intercept. The standardized estimates and level of significance are shown for the models. Model selection was performed with AIC (Akaike information criterion) as selection criteria. Marginal R^2 is the variation explained by the fixed factors, whereas the conditional R^2 is the variation explained by the fixed and random factors.

Table 2. Statistical models for the relative change in dune volume between April – August (summer) and November – April (winter). In this model we tested the effect of vegetation characteristics, dune size and degree of sheltering. The data was analysed with a general linear mixed model with blocks as random intercept. The standardized estimates and significance values are shown for the models. Model selection was performed with AIC as selection criteria. Marginal R^2 is the variation explained by the fixed factors, whereas the conditional R^2 is the variation explained by the fixed and random factors.

Figure captions

Fig. 1 Overview of the Hors on Texel, the Netherlands. The white lines show the flight path for the four different flights. The points show the position of the ground control markers. The white polygon is the monitoring area, which is 200 m x 400 m.

Fig. 2 Overview of the monitoring area. A) The elevation is shown with the Digital Terrain Model (m NAP), the green pixel indicates grass cover and the polygons indicate the dunes. B) The colour indicates the species present on the dune and the squares the blocks. The foredune in the middle of the monitoring area is excluded from the statistical analysis. Some dunes that were cut-off by the edge of the DTM, we discarded these dunes.

Fig. 3 Different dune characteristics for dunes in August with *A. arenaria*, *E. juncea* and a mix of both species separated for dunes seaward and landward of the foredune: A) Dune area, B) Maximum dune height, C) Dune volume, D) Clustering: mean height around a 25m radius around the dune, E) Vegetation density, F) Plant height. The letters denote the significant difference between the bars. Seaward of the foredune there were 41 *A. arenaria* dunes, 198 *E. juncea* dunes, and 53 dunes with both species, landward of the foredune there were 81 *A. arenaria* dunes, 23 *E. juncea* dunes, and 41 dunes with both species. NAP refers to Amsterdam Ordnance Date, which refers to mean sea level near Amsterdam

Fig. 4 The relationship between dune volume (m^3) and the absolute change in dune volume (m^3/ week) for: A) summer (April – August); B) winter (November – April). The data is shown for dunes seaward and landward of the foredune. The black line shows the regression prediction, the grey dashed line the 95% confidence interval. The formulas are the result of a linear regression model.

Fig. 5 Relative change in dune volume (m^3/m^3)/week for dunes with *A. arenaria*, *E. juncea* and a mix of both species and separated for dunes seaward and landward of the foredune for: A) summer, April – August; B) winter, November – April. The letters denote the significant difference between the bars. Seaward of the foredune there were 28 *A. arenaria* dunes, 77 *E. juncea* dunes, and 28 dunes with both species, landward from the foredune there were 57 *A. arenaria* dunes, 22 *E. juncea* dunes, and 25 dunes with both species.
