Title: Community specific hydraulic conductance potential of soil water decomposed for two Alpine grasslands by small-scale lysimetry

**Dear Editor Natascha Töpfer!**

**Dear Reviewer!**

Please find enclosed the revised version of 'Community specific hydraulic conductance potential of soil water decomposed for two Alpine grasslands by small-scale lysimetry' (bg-2017-253). We appreciate the time and efforts that you and the reviewers have invested in this manuscript. They have helped us to significantly improve the manuscript. Please find below our specific replies to the reviewers' comments.

---

**Reviewer 1:**

R: It would be definitely worth to explain more clearly what the results really mean for Alpine grassland ecosystems.

**A: We explain more clearly the impacts of climatic changes on agriculturally used Alpine grassland ecosystems in the introduction and specify management implications in the conclusion section.**

R: The manuscript is mostly well-written, however, at the moment there are no distinct sections (introduction, material and methods, results, discussion and conclusion)

**A: The section headings got lost during the submission process and were inserted again in the revised manuscript.**

R: It might be a matter of taste, but some of the sentences are very long (e.g. lines 44- 47, lines 170-173, lines 352-354)}

**A: done**

R: My main criticism is about the relationship presented in Figure 5. I think this apparently strong correlation is mainly related to the fact the two variables are not completely independent from each other (ET and ET/DW). Please check this paper by Kenney (1982). Figure 5 and its explanation should probably be removed from the manuscript. Moreover, the methodology provided by Renton and Poorter (2011), for the log-logscaling method, appears to be different than that presented by the authors in lines 222-225.

**A: this is not a regression type of way to establish a statistical relationship among the different factors defining total ET. Using the log-log scaling we seek to visualize that both parameters do not**

equally contribute to the variability in ET. Biomass Variation has almost no effect, while the abundance of ET variation measured in the experiment is caused by differing rates of ET per unit biomass (water vapour release activity). We added additional description for the procedure to the corresponding section in the Methods chapter.

R: Line 43: which structural changes at the soil-plant-atmosphere interface?

**A: changed to functional**

R: Line 89: The hypothesis is well formulated, but the two types of vegetation should be addressed earlier in the paragraph. For example mention - also already in the abstract that you studied two different Alpine grassland communities with contrasting strategies of water use and adaptation to drought.

**A: We included the a mention on “differently drought-adapted alpine grassland communities” into the abstract**

R: While reading the manuscript I had trouble in understanding when the extended periods of drought were manipulated during the experiment. This is important to state in the text and to show in figures 2, 3, and 4. In the same figures I also suggest to use two different colours for the shaded areas. At the moment it is difficult to see which shaded area belongs to each treatment.

**A: In Fig. 1 we show the occurrence of water provision to the individual plots and that the application of extended drought periods was not equal among all plots of the D(drought)-treatment. Due to a thunderstorm one of the plots had a water inrush just before 10<sup>th</sup> of June. However, we later summarize that “ *it was argued to define variations in water availability not purely on the basis of contrasting regimes of water input (i.e. irrigated vs. non-irrigated) if these are not causing systematic variations in soil moisture (Kramer, 1983) and that “Therefore, regular irrigation and, respectively, its omission can, counter-intuitively, only be an indicator of contrasting water availability. The establishment of drought conditions in the strict sense of a depleted soil water reservoir is realized by the interaction of pre-treatment SWC, standing biomass and atmospheric effects.”***

The assignment of REG and D treatments is a compromise allowing to treat both sets of plots not as the same statistical population, while there were differences within the groups with respect to water provision caused by the accuracy of the irrigation system and in the case of the D-treatment an accidental water influx. However, our main findings are related to differences in water availability based on different SWC% of the soil.

In the case of overlapping standard deviations/ grey shaded areas also different colours would overlap and prevent an assignment to the treatment. Important in these plots are the are the regions when the two treatments are statistically distinct, and standard deviation don't overlap.

R: Please define every acronym the first time it is mentioned. For example in line 16, evapotranspiration (ET).

**A: We defined all acronyms as suggested:**

**A: We have dealt with all following minor comments:**

Line 23: the vegetation's reaction to two -**adopted**

Line 34: add space after transpiration -**adopted**

Line 42: change focused to main -**adopted**

Line 45: change composition to abundance -**adopted**

Line 51: can only be predicted inaccurately-**adopted**

Line 79: climate change -**adopted**

Line 119: transplanted from a meadow in Matsch/Mazia -**adopted**

Table 1: Please check that the soil classification is correct. -**adopted**

In Line 171: add a comma before the word addressing and remove the "and"- sentence restructured

Line 174: in the current experiment -**adopted**

Line 219: add space before bracket-**adopted**

Line 220: please cite the nlme package -**adopted**

Line 227: ET0 should be written as ET0-?

Figure 5: The x-axis of the log(DW) is missing –**same as in the main plots.** ... In any case, see my comments above about this figure.

Line 316: change EVT to ET? -**adopted**

---

**Reviewer2**

R: Authors find that pasture community coming from a wet site (rainfall ca.1100 mm) exhibits a water-spending strategy while the pasture community coming from a mesic site (rainfall ca. 525 mm) exhibit a water-saving strategy, what is non-surprising.

**A: Our manuscript seeks to reveal how these two different strategies are realized in the same environment and along the gradients of combined variation of soil water provision and atmospheric demand. To our knowledge, no comparable dataset was published which contrasts the water spending potential of two vegetation types in this way. Showing that for a given combination of SWC and ET0 values, two vegetation types reveal differences in their eco-hydrological behaviour, which is not primarily product of differences in growth and standing biomass, leads to questions about the underlying mechanisms.**

R: However, some possible artefacts and/or strange results (the surprisingly low biomass production in wet community respect to the mesic community; the 16-fold difference among wet and mesic communities for g DW produced by Kg of water), and some interpretations that are questionable (mesic community use better soil moisture at low range of SWC), besides of many other small details (see annotated pdf) need a revision.

**A: Potential artefacts of the experimental setting on the productivity of our experimental populations are discussed in a revised version of the manuscript and will be addressed in detail in the answers to the specific comments. However, in some cases we can only provide hypotheses as explanation for specific results. The reviewer is arguing that potential artefacts might be the cause for particular results. Artefacts within the experimental proceedings, however, would not have affected particular vegetation x treatment combinations exclusively like reviewer2 argues, but all experimental entities evenly, since they were all treated the same way.**

R: English languages is also sometimes awkward.

**A: We improved language and clarity according to the specific suggestions by the reviewers.**

**A: Answers to specific comments in the pdf RC2-supplements (typos and spelling mistakes found by the editors were corrected and are not listed in the following)**

R: I miss a heading for this section (L25)

**A: The section headings got lost during the submission process and were inserted again in the revised manuscript.**

R: in the temporal occurrence of what (L30)

**A: changed to "temporal occurrence of rainfall events"**

R: Which is the former?

**A: changed to: "as it is"**

R: separation of evaporation from the transpiration seems also fundamental. Frequent rainfall event of low volume increase loss of water by rainfall interception that is directly evaporated from the plant canopy before reaching soil-root system. Rainfall concentrated in less events, if soil can accumulate the water, could be in some way more efficient for the ecosystem (L70-72)

**A: Information regarding the separation of interception from ET was added in the manuscript**

R: I assume you checked common atmospheric parameters inside the sheltered areas (L87-88)

**A: Yes, we did check the atmospheric parameters in the shelters, differences to the outside conditions are mentioned in the M&M section. However, here we intend to say that temperature, air humidity, radiation, and wind speed in the shelters were driven by natural fluctuation (in contrast to precipitation/soil humidity which were controlled). We rephrased the sentence to make this clearer.**

R: A brief description of the soil description, with common soil depth and rooting profile would help. And and brief explanation why you select 30 cm depth. (L110)

**A: Soil parameters were added in table 1, information on rooting distribution which led to the lysimeter depth chosen were added in the text (former studies showed that 90% of the root biomass is located above 20 cm in both vegetation types).**

R: This experimental set up is a peculiar common garden experiment. It is in between a proper common garden (i.e. both vegetation types are planted in similar environmental conditions outside

from their origin) and a transplanting experiment (i.e. each vegetation type is planted in each site). The authors only modified the availability of water, but following this experimental design is difficult to unravel the effect of water from other confounding factors. For instance, even if the availability of water is optimal for the mesic vegetation type, other factors may not (e.g. temperature, soil properties or biota that are modified by a higher availability of water). In my opinion, this set up could bias the results in favor of the vegetation type that has not been out-transplanted. (L117-119)

**A: A potential bias was avoided by an extensive recovery and acclimatization period, see information added at the end of the paragraph.**

R: enough? Did you do any check to ensure the full restoration of plan community/density? (L131)

**A: More than 8 month of recovery time after installation including the winter season and the first growth in spring should be sufficient, the development of the vegetation during the recovery time was visually checked. This information was added in the manuscript**

R: please, rewrite easing the reading (L170-172)

**A: The sentence was simplified in the manuscript.**

R: please, clarify. Do you intend to separate the water directly evaporated from the plant surface (ranfal interception)? (L194-195)

**A: We specified in the introduction that evaporation of intercepted water was not separated from ET as it plays a minor role in the investigated ecosystems.**

R: It is apparent in the figures that biomass followed a non-linear pattern and that was the main reason of using a gamm. I would include this information here to clarify why the author chose this technic and not the linear mixed model used to assess other variables. (L214)

**A: The information requested was added in the manuscript.**

R: a more conservative patter than...what? If you use a higher number of knots then the non-linear patter of the model could be overemphasized. However, chosing 5 knots rather than 4 or 6 seems quite arbitrary decisions. Why not use Generalized cross validation and allow the model to chose the optimal number of knots given the data? (L216)

**A: The information requested was added in the manuscript.**

R: Better placed at the end of the section (L219-L220)

**A: The sentence was moved to the end of the section as suggested.**

R: be specific, which covariates? (L222)

**A: This sentence says that vegetation type was a factor in all models we applied --- additional covariates are described below**

R: This looks like a quite complex model for this type of data. How did the authors validate the model to assess if there are signs of overfitting? (L227-228)

**A: This question is addressed in the revised manuscript.**

R: which covariates? (L231)

**A: The covariates are now described better in the revised version of the manuscript.**

R: whatabout the comparison among underneath and outside conditions?(L236)

**A: Information on the differences of microclimatic conditions inside and outside the shelters were added in the M&M section.**

R: I think that mm would clearer ad easier to interpret for most readers (L237)

**A: SI unit for ET is defined as kgH<sub>2</sub>O m<sup>-1</sup> d<sup>-1</sup>, we could still change to mm if this is preferred.**

R: How much of this variation is due to differences in soil structure between M and S sites? Or is this effect eliminated because in both cases soil water conditions are dictated by surrounding unaltared soil-plant system? (L250-253)

**A: Information on soil parameters was added to table1. We also discuss possible reasons for the different behavior of SWC in the discussion section.**

R: much higher than ETo (average daily ETo was 3.26). Any comment? (L257)

**A: As the biomass and canopy height of both our vegetation types is much higher than it is assumed for ETo, it is not surprising that actual ET is also higher. This information was also added to the manuscript**

R. I would say that ET is higher in S at least during the first half of the experiment (L259)

**A: The manuscript was adapted accordingly.**

R: Although differences among watering regimes are strong only for a short periods, values seem lower for D most of the time (L261)

**A: The manuscript was adapted accordingly.**

R: differential among what? please, check the phrase. (L276-277)

**A: "differential" was changed to "increment"**

R: I would have expected the contrary. The drought-prone community be less sensitive to water shortage, and the local community to be more productive than the drought-prone community. This deserves an explanation.(L285)

**A: Initial deficient automatic irrigation in the REG-treatment was too low for the local vegetation causing an early peak and early senescence for the S-type, while it was sufficient for the M-type to enable continuous growth. Manual corrections of irrigation were too late for the S-type. This explanation was included in the manuscript.**

R: Where/How can we see this difference in the figure 5? (L302-304)

**A: This sentence was a relict from an older version of the MS, when the log-log-scaling was done with x&y switched and not to the rational in Poorter and Renton. Sentence was removed and the message adopted**

R: in figure 5 you show a range from -0.86 to 7.2. Why? (L311)

**A: field site averages vs average values of individual plots --- the matter was clarified in the MS**

R: Where is this table? (L314)

**A: The table was included in the new version of the manuscript.**

R: differences in figure 4 for S are slight but seem stronger than differences showed here (L330)

**A: Fig 4 also shows that for the REG and the D treatment of the S vegetation the biomass values at the beginning of the experiment were also slightly different - therefore the total biomass gain (end value - start value) in both treatments was about the same for this vegetation type**

R: consequence of any experimental artefact???? (L336-337)

**A: A consequence of insufficient initial irrigation as described before.**

R: 0.16 compared to 2.6. This difference seems abnormally high. (l341-343)

**A: This was influenced by early senescence of the S-vegetation type and is now discussed in the manuscript in more detail.**

R: lower for M mesocosm? Maybe I am missing something, ..... (L343-344)

**A: This phrase was deleted in the revised manuscript.**

R: however, one could say that for M mesocosm ET/DW never reach the values of S mesocosm. that is, S mesocosm seems to be able to transpire more water per DW unit at low SWC. (L360-361)

**A: This part was rephrased accordingly in the revised manuscript.**

R: efficient probably is not the best term, as Figure 6B show that at high ETo, S mesocosm consume more water per DW unit than the M mesocosm. That is, M mesocosm exhibits a higher water use efficiency. (L366)

**A: We agree with the reviewer and rephrased the sentence**

R: The slope is higher for M mesocosm. However at low SWC, ET/DW is always lower for M mesocosm than for S mesocosms. indeed, as you say, for most of the SWC and ETo combinations, M mesocosm showed lower ET/DW values than S mesocosm. From these data, i would not say that M mesocosm has a higher potential to use even scarce water resources ((L368-369)

**A: The manuscript was adapted accordingly stressing the water-saving strategy of the M-type vegetation.**

R: however, soil texture seem finer for M mesocosm (Table 1). One would expect a higher water holding capacity for M than for S. Of course, other factors matter (SOC, structure ...) (l379-380)

**A: More soil properties were integrated in table 1 and the possible influence of soil parameters discussed in more detail.**

R: This information would have been a nice addition to the study (L388)

**A: At least the abundance of functional groups was included in table1**

R: see comments above that question if really M mesocosm work better than S at low SWC (L393)

**A: These comments were answered above.**

---

We sincerely hope that the revised version of this manuscript now fulfils all necessary criteria to be published in *Biogeosciences*.

We thank you very much for your time spent on our manuscript.

Sincerely yours,

Erich Tasser, on behalf of all Authors

31 | **ABSTRACT:**

---

32        For Central Europe in addition to rising temperatures an increasing variability of  
33 precipitation is predicted. This will increase the probability of drought periods in the  
34 Alps, where water supply has been sufficient in most areas so far. For Alpine  
35 grasslands, community specific imprints on drought ~~response~~responses are merely  
36 understood. In a replicated mesocosm experiment we compared evapotranspiration  
37 (ET) and biomass productivity of two differently drought-adapted ~~vegetation~~alpine  
38 grassland communities during two artificial drought periods divided by extreme  
39 precipitation events using high precision small lysimeters. The drought adapted  
40 vegetation type showed a high potential to utilize even scarce water resources  
41 combined with a low potential to translate atmospheric deficits into higher water  
42 conductance with biomass production staying below those measured for the non-  
43 drought-adapted type. The non-drought-adapted type, in contrast, showed high  
44 water conductance potential with strongly increasing ET rates when environmental  
45 conditions became less constraining. With high rates even at dry conditions, this  
46 community appears not to be optimized to save water and might experience drought  
47 effects earlier and probably stronger. In summary, the vegetation's reaction to two  
48 co-varying gradients of potential evapotranspiration and soil water content revealed  
49 a clear difference of vegetation development and between water-saving and water-  
50 spending strategies regarding evapotranspiration.

## 51 INTRODUCTION

---

52 Comprehensive alterations in the climate system of the earth are projected for  
53 the future decades. Due to increased greenhouse gas concentrations in the  
54 atmosphere, the global average temperature is predicted to rise. These changes in  
55 the energy budget of the atmosphere are suggested to propagate alterations in  
56 atmospheric circulation and modify precipitation patterns worldwide (IPCC, 2013;  
57 Knapp et al., 2008; Solomon et al., 2009). Such variations can result in changes of  
58 the spatial distribution of precipitation and thereby affect average values of rainfall  
59 locally. However, concurrent changes in the temporal occurrence of rainfall events  
60 are predicted to increase the variability of rainfall with longer intervals in between  
61 and more extreme events. This will lead to stronger variability in soil water availability  
62 and longer droughts (IPCC, 2013, 2012).

63 The water balance in terrestrial ecosystems is dominantly controlled by plant  
64 processes. It is suggested that up to 80% of the terrestrial water loss to the  
65 atmosphere is mediated through plant transpiration (Jasechko et al., 2013).  
66 Consequently, it is assumed that plants will experience drought stress more  
67 frequently, which may constrain primary productivity as ~~the latter~~ is substantially  
68 controlled by the supply of water (Knapp et al., 2008). These direct effects of limited  
69 water provision to the system will be accompanied by increased water demand in a  
70 warmer world, leading to more negative water balances, which will accentuate  
71 drought effects on vegetation processes (Heimann and Reichstein, 2008). However,  
72 structure and functionality of the ecosystems - defining rates of evapotranspiration -  
73 are also subject to local climatic conditions. Hence, a direct feedback mechanism is  
74 established, which might amplify or dampen the global and local consequences of  
75 climatic change on ecosystems (Heimann and Reichstein, 2008).

76 Defining productivity-precipitation relationships of ecosystems is of ~~focused~~main  
77 interest, because ~~structural~~functional changes in soil-plant-atmosphere interface,  
78 which control water fluxes into the atmosphere, will inherently be affected by the  
79 manifestation of that relationship. However, beyond the direct implications of limited  
80 water availability on biomass production and growth, ~~the composition~~indirect  
81 mechanisms define this relationship. The abundance of individual plant species in  
82 the community and resulting functional structure of that community will adjust,  
83 optimising water use according to different life-history strategies by competitive

84 interactions (Peñuelas et al., 2004). In turn, immediate vegetation responses to  
85 fluctuations in precipitation patterns and the strength of interaction with productivity  
86 functions will strongly depend on the functional composition of the community and  
87 ecosystem considered. Therefore, intrinsic characteristics of vegetation will impose  
88 another layer of complexity for defining the interactive feedbacks in the relationship  
89 between water budget and productivity.

90 | The impact of shifting precipitation regimes can only be predicted—~~only~~  
91 inaccurately if the crucial components of the ecosystem water budget - soils, plants  
92 and the atmosphere - are evaluated separately and isolated. Due to the complex  
93 interactions and processes at different spatio-temporal scales the response of  
94 ecosystems to shifts in the water regime are preferably examined in an integrative  
95 manner on the system level (Silva, 2015). Manipulative experiments are a well suited  
96 option for investigating the effects imposed by changes in precipitation frequency  
97 and intensity below and above the natural range on the ecosystem level (Estiarte et  
98 al., 2016). Since we currently lack knowledge needed to validate the projections for  
99 consequences of future changes in rainfall regimes, insights from such integrative  
100 investigations are highly valuable for providing important benchmarks of model  
101 based assessments (Estiarte et al., 2016).

102 | Numerous studies were performed to reveal the ~~response~~responses of  
103 temperate grasslands to climatic changes and ~~extremes, while only few droughts~~  
104 (Poorter et al. 2012, Reichstein et al. 2013). While investigations on responses of  
105 above- and belowground carbon fluxes targeted Alpine systems (Bahn et al.  
106 2009, Hasibeder et al. 2015, Ingrisch et al. 2017), only few studies addressed  
107 components of the ecosystem water budget (De Boeck et al., 2016). While the Alps  
108 did not often experience droughts during the past (van der Schrier et al., 2007), the  
109 region has undergone exceptionally fast climatic changes during the late 19<sup>th</sup> through  
110 early 21<sup>st</sup> century (Auer et al., 2007; Beniston, 2005; Böhm et al., 2001; Ciccarelli et  
111 al., 2008; Rebetez and Reinhard, 2008). Water availability, especially in the light of  
112 future climatic changes in European Alps in the next 100 years (IPCC, 2007), is  
113 already seen as a limited and valuable resource with the potential of socio-  
114 economical conflicts. Therefore, the importance of agricultural management with a  
115 potentially higher water demand as a consequence of sprinkling becomes evident.  
116 Considering the fundamental role Alpine systems have to water accumulation and  
117 freshwater supply for large parts of Europe (Messerli et al., 2004; Viviroli et al., 2003)

118 it seems surprising that the responses of ecosystems in the Alps to changes in  
119 precipitation have not drawn more scientific attention. However, while projections  
120 suggest only moderate variations of yearly average rainfall in the Alps, significant  
121 alterations within the temporal occurrence of rainfall events with a decrease in  
122 summer precipitation and increases from winter through spring are implied  
123 (Beniston, 2012; Beniston et al., 2007). The decrease of water supply during warmer  
124 summer months will potentially increase the frequency and intensity of drought  
125 events in the near and longer future in Alpine ecosystems (Gobiet et al., 2014).

126 For unravelling ecosystem water fluxes at the soil-plant-atmosphere interface,  
127 the lysimeter methodology provides the precise and realistic means ~~by allowing~~. They  
128 also allow to decompose the driving sub-processes: evapotranspiration (ET),  
129 precipitation (P) and drainage below the rooting zone (Peters et al., 2014). Even  
130 quantifying interception would be possible by comparing the increase of lysimeter  
131 weight and soil water content during precipitation. This was however not a focus of  
132 this experiment as interception is estimated to account for less than 10% of rainfall  
133 during the growing season based on Wohlfahrt et al. (2006). By avoiding systematic  
134 errors prone to traditional measurement systems, the determination of the net water  
135 balance is highly accurate and robust (Schrader et al., 2013). If embedded into a  
136 surrounding ecosystem, automated lysimeter units, which do not need access to  
137 perform manual weighing, measure water fluxes with a minimum of disturbance to  
138 the natural boundary layer and microclimatic conditions. Such implementations of  
139 autonomous weighable high precision lysimeters provide unprecedented realism to  
140 the description of ecosystem water balances, especially when filling of the lysimeters  
141 was performed to maintain natural soil layering and the connectivity of pores, while  
142 keeping potential impacts on the vegetation community low. Over the recent years,  
143 several of these units have been established over Europe, e.g. a network of 126  
144 lysimeters at 12 sites has been established to monitor climate ~~change~~change induced  
145 alterations in hydrological cycling within the TERENO project in Germany (Bogena et  
146 al., 2006; Zacharias et al., 2011). However, the large dimensions (1m diameter/  
147 volume) and the corresponding economic efforts for their establishment did mostly  
148 eliminate the possibility for replicated manipulative experiments employing fully  
149 integrated lysimeters.

150 In a common garden experiment we used a network of automated small scale  
151 lysimeters to emerge community specific differences in the temporal dynamics of soil

152 water depletion and evapotranspiration. Two different Alpine grassland communities  
153 were subjected to contrasting levels of water availability. Sheltered from natural  
154 precipitation, soil water content was manipulated by applying two distinct irrigation  
155 regimes: one providing water in regular intervals and another exposing the  
156 corresponding experimental units to extended periods of drought. ~~The natural variability~~  
157 ~~in the~~ Changing atmospheric demand of water vapour driven by the natural variability  
158 of air temperature and humidity coupled to the manipulated water availability in the  
159 soil allowed to investigate and reveal vegetation specific conductance properties and  
160 water utilisation patterns. For this study we hypothesize that the vegetation adapted  
161 to local, humid conditions and characterized by high biomass and a water spending  
162 strategy will keep transpiration rates high while soil water availability is decreasing  
163 until a sudden decline near wilting point. As a consequence it will also continue to  
164 produce biomass until the break point. In contrary, the water saving strategy of the  
165 drought-adapted vegetation will lead to a continuous decrease of transpiration and  
166 biomass production with decreasing soil water availability.

167 **MATERIAL & METHODS**

168 *Characteristics of the experimental field site and lysimeter installation*

169 The study site of the experiment was established during early summer 2014 in  
 170 the LTER-Austria site ‘Stubai’ (valley bottom meadow) Neustift im Stubaital (A). The  
 171 site for the garden-experiment was located on the valley floor at 972 m a.s.l.  
 172 (WGS84: N47.115833, E11.320556) in a meadow used for hay production.

173 Table 1 Summary of site conditions and vegetation properties

174

175 For this experiment six plots of 3.5 × 3.5 m were established. Traversing the  
176 corresponding area, each plot was defined by installing half-cylindrical metal frames.  
177 In the centre of each plot these frames providing the base for the rain sheltering  
178 reached a height of approx. 2.5 m. In each corner at the outer plot margin four  
179 irrigation sprinklers pointing towards the centre of the plot were set up. The irrigation  
180 system described in detail by (Newesely et al., 2015) was used to simulate  
181 precipitation during periods of experimental manipulation of water provision to the  
182 system.

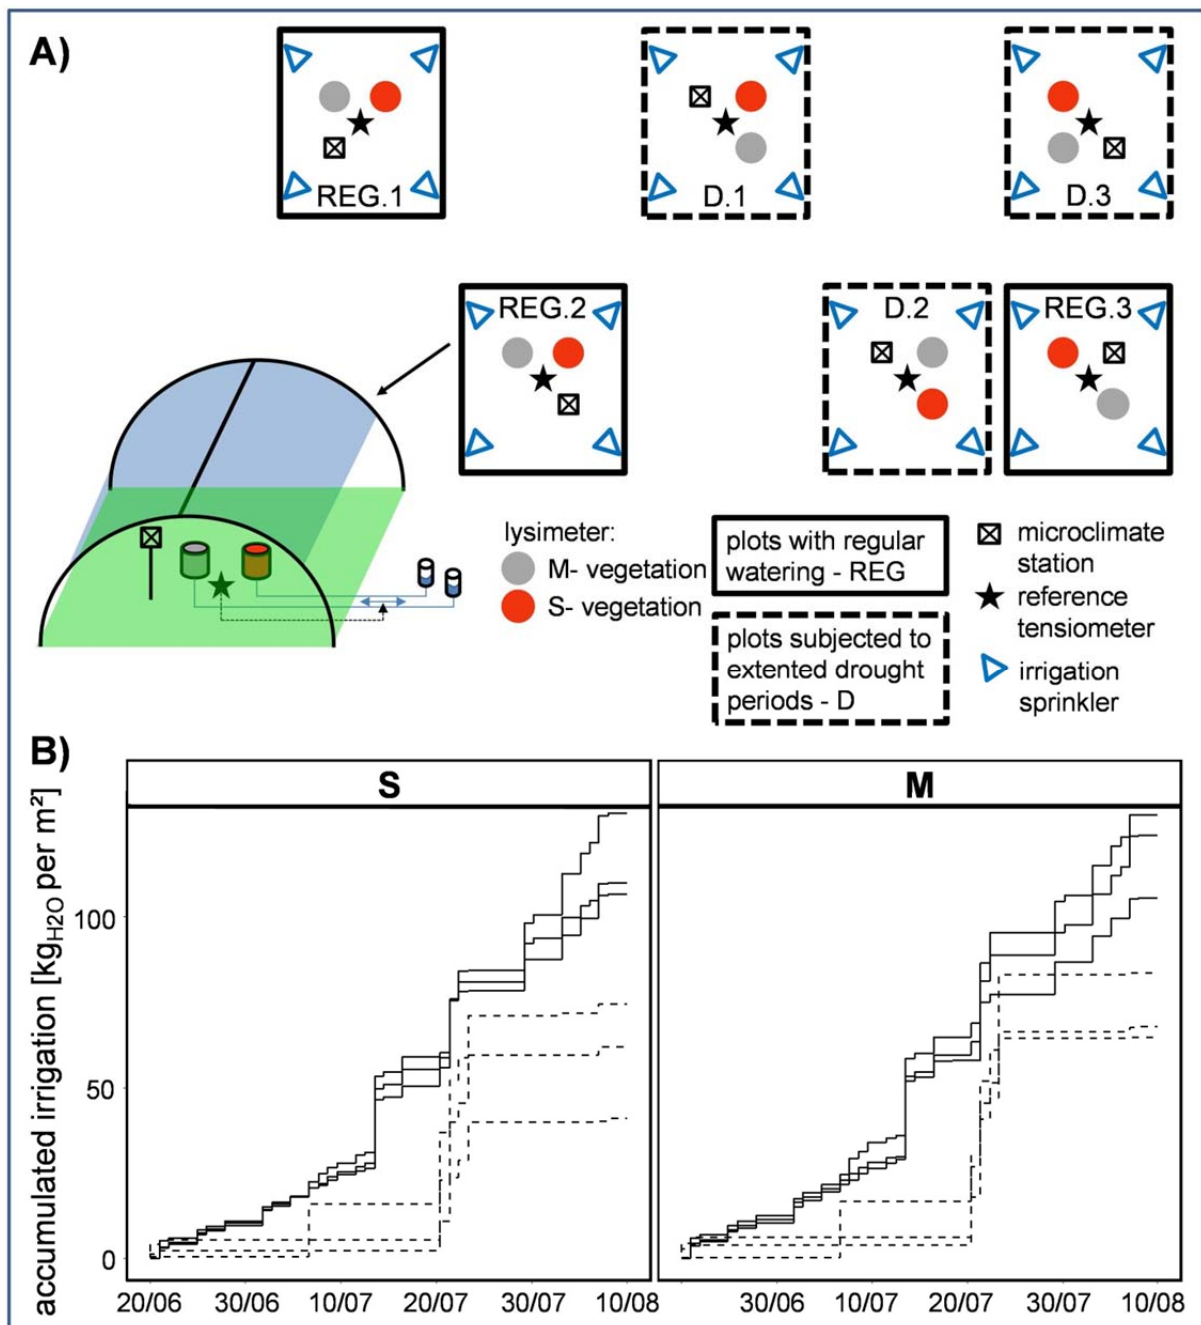

183 In the centre of each plot two small-scale lysimeters with 0.3 m diameter and  
184 0.3 m depth were installed in collaboration with, and supervised by the employees of  
185 the manufacturer (Smart-Field-Lysimeter, UMS/Meter Group Munich, Germany).  
186 Every lysimeter was filled with a soil-vegetation monolith by cutting the hollow  
187 cylindrical lysimeter blank into an undisturbed patch of the corresponding ecosystem.  
188 This compression free procedure allowed to remain the original and unaffected  
189 stratification of the soil and to conserve the natural composition of pore spaces within  
190 the monolith. The filled lysimeter blanks were subsequently excavated and cut  
191 horizontally at a depth of 0.3m. With 90 % of root biomass distributed above 0.2 m in  
192 both investigated vegetation types, a lysimeter depth of 0.3 m was assumed to be  
193 sufficient. The bottom of the lysimeter was closed with a tension controlled hydraulic  
194 boundary connected to a bi-directional pumping system to regulate water flow into  
195 and out of the lysimeter. After inserting soil moisture, temperature (EC-5 Small Soil  
196 Moisture Sensor, Decagon Devices, USA) and matrix potential probes (MPS-2,  
197 Decagon Devices, USA) at 0.05, 0.15 and 0.25m depth into the lysimeter monolith,  
198 each system was placed on a weighing platform (accuracy of 0.005 kg, PL-50,  
199 UMS/Meter Group Munich, Germany). Two of these lysimeter units were installed in

200 | the centre of every experimental plot within a two by two ~~quadraticsquared~~ grid of  
201 | 1.2m edge length with their relative position to each other assigned randomly.

202 | The two monoliths in every plot were excavated from different types of  
203 | vegetation, one containing a mesocosm of the meadow surrounding the  
204 | experimental field site (S, Table 1), and another one which was excavated and  
205 | transplanted from a meadow in Matsch/Mazia with contrasting environmental and  
206 | biotic properties to those of the study site (M, Table 1). The Stubai grassland is  
207 | classified as Poo trivialis - Alopecuretum pratensis with a community of low  
208 | complexity: abundant Poaceae accompanied by some herb species (Wohlfahrt et al.,  
209 | 2008). The meadow is actively managed, cut two to three times each year and  
210 | fertilized with cow manure in spring and autumn (approximately 0.35 kg dry matter  
211 | per m<sup>2</sup>, Table 1). The local climate is dominated by high total precipitation values,  
212 | especially in the summer. The vegetation of second origin (Matsch/Mazia) is  
213 | characterised by the traditional, more extensive use of the corresponding system.  
214 | The Matsch Valley has a dry inneralpine climate with a mean precipitation of 527 mm  
215 | per year and a mean temperature of 6.6 °C (Hydrographical Department of the  
216 | Autonomous Province of Bozen-South Tyrol). The vegetation is a dry hay meadow  
217 | (Ranunculo bulbosi - Arrhenatherum, Ellmauer) on loam to sandy loam. The site is  
218 | fertilized with cow dung and cut two times each year. The excavation location of the  
219 | replicate lysimeters was optimized according to the presence of representative and  
220 | joint species in the respective vegetation patches. After installing the local and  
221 | transplanted lysimeter mesocosms during early summer 2014 into the experimental  
222 | plots, the vegetation surrounding the lysimeters ~~could~~was allowed to recover from  
223 | disturbances of necessary soil works required to wire the fully automated measuring  
224 | system until spring 2015.This extensive recovery period of more than 8 months  
225 | including the winter season and the initial growth phase until the first harvest in the  
226 | actual measuring year should provide a sufficient acclimatisation and regeneration of  
227 | both vegetation and soil in the lysimeters and prevent a bias between vegetation  
228 | types.

229 | At the field site, all experimental plots and the vegetation in the lysimeters was  
230 | managed (cut, fertilized) concurrently to land-use scheme of the surrounding  
231 | meadow. The experimental period started in the last third of June 2015 during the re-  
232 | growth interval after the first cut at the beginning of June. With beginning of the

233 experiment on June 10<sup>th</sup> 2015 rain shelters were closed using a UV permeable  
234 transparent polythene film (Lumisol Clear AF, 88% - 92% light transmittance). ~~In order~~  
235 ~~to avoid shielding of the wind and to allow the establishment of natural boundary conditions,~~Air  
236 temperature (on average 0.26 K higher in the shelter) and humidity (+0.11 %) were  
237 hardly affected by the shelters while radiation was reduced by 25% and wind speed  
238 by 50% even though shelters were left open on the sides facing the main wind  
239 direction and closed down to just 0.5 m above the soil level on the lateral sides. ~~Over~~  
240 ~~a period~~ to minimize shielding of 52 days ~~the plots of the experiment were subjected to control~~  
241 ~~watering within the two different irrigation schemes (Fig. 1).~~wind. Concurrently with closing of  
242 the rain shelters (10/06) precipitation was provided from the irrigation sprinklers  
243 mimicking average rain fall amounts and intensities for the 30 year period between  
244 1970 through 2000 ~~in the treatment with regular watering. However, due to a mistake by the~~  
245 ~~technician responsible for setting up the automated irrigation protocol.~~Over a period of 52 days  
246 (20/06-10/08) the plots of the experiment were subjected to control watering within  
247 the two different irrigation schemes (Fig. 1), one providing water on a regular basis  
248 (REG) and one with extended drought periods (D). However, due to technical  
249 problems the watering scheme stayed below the intended amounts for approximately  
250 the first half of the experimental period making manual compensation occasionally  
251 necessary. (starting on 15/07). Automated irrigation was programed to occur around  
252 mid-night in order to avoid immediate transpiration from the surface and allow the  
253 provided water to penetrate into the soil compartment. Manual adjustments and  
254 checks on the precipitation simulator were usually performed during day-time. The  
255 lysimeter mesocosms in the treatments with regular watering (REG) received  
256 approx. 117 kg<sub>H2O</sub> per m<sup>2</sup>, those in the treatments with extended drought periods an  
257 average of 65 kg<sub>H2O</sub> per m<sup>2</sup> throughout the duration of the experiment and according  
258 to the scheme presented in Fig. 1.

259

260 Fig 1: A) Schematic overview of the experimental design and plot setup; B)  
 261 Manipulation of water availability for individual lysimeters of the two vegetation types  
 262 (Stubai (S) & Matsch/Mazia (M)) by contrasting irrigation schemes - one providing  
 263 water on a regular basis (REG, solid lines), one with extended drought periods (D,  
 264 dashed lines)

265

266 *Automated measurements*

267 In the centre of each of the six plots a microclimate station measuring air  
268 temperature and relative humidity (height: 1m; U23-002 HOBO<sup>®</sup> External  
269 Temperature/Relative Humidity Data Logger, Onset Computer Corporation, USA),  
270 solar radiation (height: 1m; S-LIB-M003, Solar Radiation Sensor, Onset Computer  
271 Corporation, USA), wind speed (height: 1 m; DAVIS<sup>®</sup> Standard Anemometer 7911,  
272 Davis Instruments, USA) and soil water content 0.05 and 0.2m below the ground (S-  
273 SMA-M005, Soil Moisture Smart Sensor – 0.2 m ECH2O<sup>®</sup> probes, Decagon, USA)  
274 was installed. The corresponding measurements were logged for every ten minutes  
275 interval (HOBO Microstation<sup>®</sup> Data Logger; Onset Computer Corporation, USA).

276 For each of the lysimeter, weight data were recorded every minute, data  
277 received from matric potential, soil temperature and water content sensors (each in  
278 0.05, 0.15 and 0.25 m depth) in ten minutes intervals. The hydraulic boundary at the  
279 bottom of each lysimeter was connected to a reservoir of drainage water with the  
280 corresponding container also being placed on a balance. A bi-directional pumping  
281 system allowed the adjustment of the water content at the lower boundary of the  
282 lysimeter by transferring water either from the drainage container into the lysimeter  
283 or the contrary direction. This implementation allowed to adjust the water levels at  
284 bottom of the lysimeter according to a reference matric potential measured at the  
285 same depth in the natural unaffected soil column of the respective experimental  
286 plots.

287

#### 288 *Manual measurements of biomass development*

289 ~~Since variation in total~~Variability of water flux from vegetation canopies to the  
290 atmosphere ~~is~~has two components: a-product of the variation in standing biomass and  
291 b) the water vapour release activity per unit biomass. Therefore, decomposing and  
292 addressing these two factors independently is advisable, especially ~~in-replicated~~  
293 ~~experiments or when~~ functionally different communities with ~~different biomass progression~~  
294 ~~rates~~differing biomasses are being compared ~~over longer periods~~. However, non-  
295 destructive biomass estimation of complex stands in the field can be challenging with  
296 respect to desired accuracy. In order to generate robust estimates different  
297 methodologies were combined in the current experiment. Measurements of  
298 maximum and average canopy height (Machado et al., 2002) were supplemented  
299 with a pin point procedure (Jonasson, 1988) and measurements of projected area  
300 (Lati et al., 2013) for the biomass estimation ~~of biomass present~~ in the lysimeters. For

301 measuring pin contacts a thin metal rod was lowered through a plate placed above  
302 down to the lysimeter. Pin measurements were replicated in seven (out of 21)  
303 randomly assigned positions for each lysimeter and point in time. Pin contacts were  
304 referenced within three height classes (0-20, 20-40, 40+ cm above the ground) and  
305 by functional group identity of the plants. For the determination of projected area of  
306 the lysimeter canopies the methodology proposed by Tackenberg (2007) was  
307 adapted. Digital images of the lysimeter stands in front of a white half-cylindrical  
308 background were scaled according to a size standard in each picture, converted to a  
309 black-white colour scheme, before black pixels were enumerated. On average,  
310 biomass of the lysimeters was estimated for every third day through the period of the  
311 experiment. The different methods for non-destructive biomass estimation were  
312 calibrated against weighted biomass at the harvests prior and subsequent to the  
313 experiment- (10/06 and 10/08). Based on these calibrations the biomass  
314 development in the lysimeters was predicted throughout the experimental period.

315

#### 316 *Data processing and statistics*

317 To calculate the water mass fluxes at the soil-vegetation-atmosphere interface  
318 of the upper lysimeter boundary, weight differentials of the drainage reservoir and  
319 the lysimeters were summarized and subsequently cleared for spikes and signals of  
320 implausible strength (Schrader et al., 2013). The latter was necessary because the  
321 sensitive weighing elements are susceptible to environmental noise or accidental  
322 interference by other experimental proceedings (e.g. biomass estimation), while  
323 providing a high accuracy and temporal resolution. The combined weight signal was  
324 separated into irrigation induced weight gain of the lysimeter units and weight loss  
325 caused by evapotranspiration from the upper lysimeter boundary ~~based on the recorded~~  
326 ~~activity times of the precipitation simulator.~~ Subsequently, daily totals were calculated for  
327 both mass differentials.

328 A soil-specific calibration of the soil moisture and the MPS-2 sensors ~~sensor~~ is a  
329 necessary prerequisite ~~for a sensor~~ to achieve its highest degree of absolute accuracy  
330 in soil water content (SWC) measurements. A substrate moisture retention curve (pF  
331 vs. volumetric water content) and the hydraulic conductivity as a function of pF  
332 (log10 of the matric potential) were determined for both types of soil-vegetation

333 monoliths (M, S). The soil hydraulic parameters were determined in the laboratory,  
334 using the method of (Schindler, 1980) with the HYPROP system (UMS/Meter Group  
335 Munich, Germany). Using the soil specific moisture retention curve, absolute SWC  
336 was corrected based on soil matrix potential data. To summarize the time course of  
337 water availability in the soil of each lysimeter unit, the average values of SWC of  
338 both layers between 0.05 - 0.15m and 0.15 - 0.25m were integrated and  
339 summarized on a daily basis.

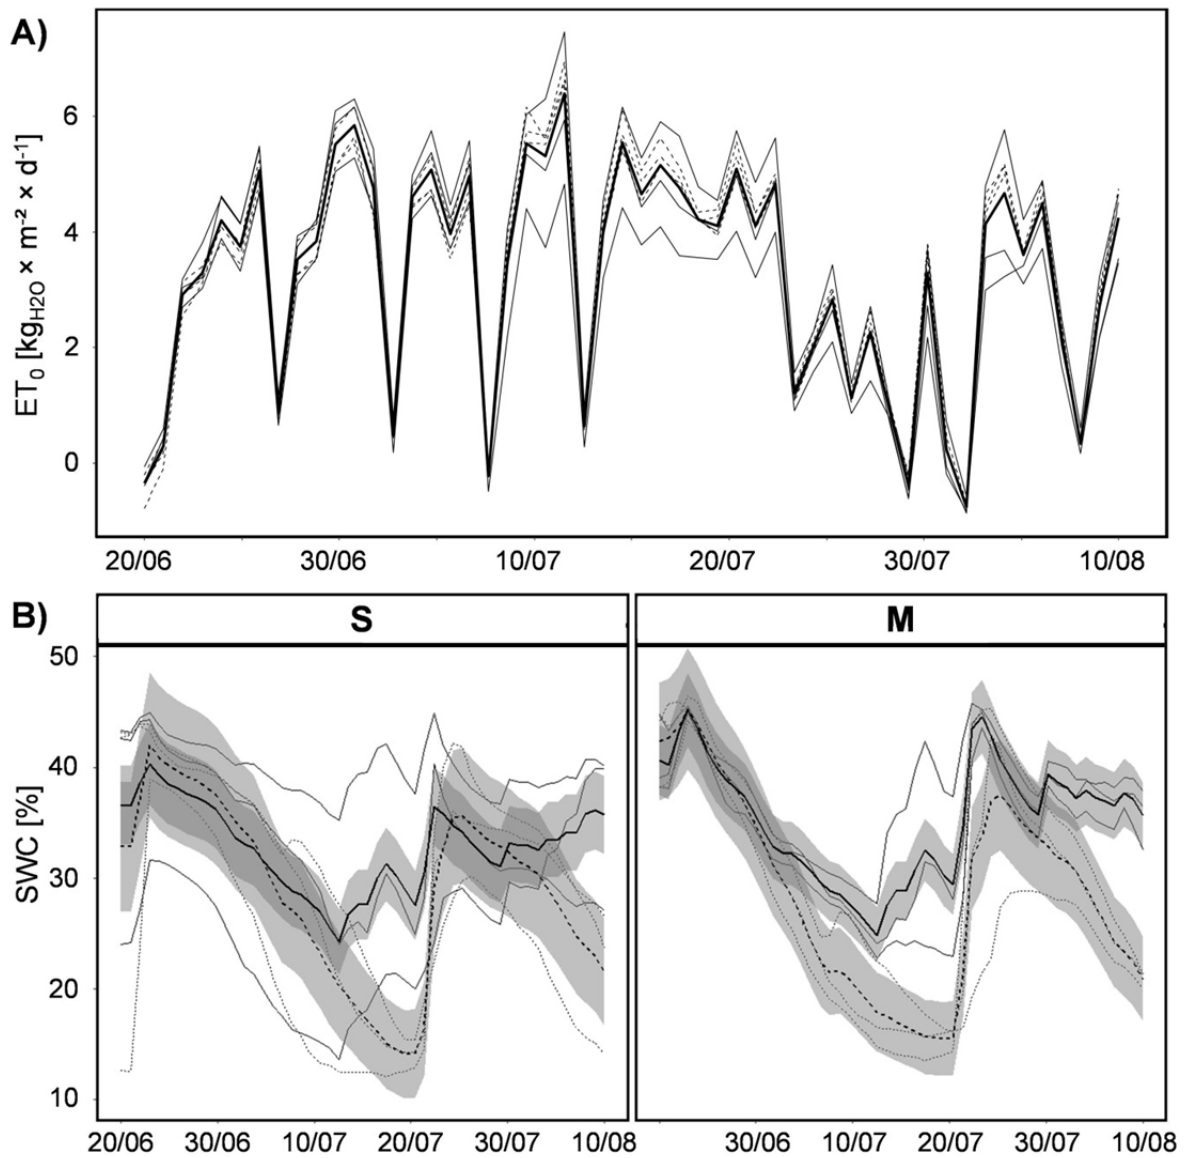

340 The evaporative demand of the atmosphere is expressed by the reference crop  
341 evapotranspiration ( $ET_0$ ). It represents the evapotranspiration from a standardized  
342 vegetated surface and was calculated in this study after the FAO Penman-Monteith  
343 standard method (Allen et al., 1998).  $ET_0$  integrates the most important atmospheric  
344 components (solar radiation, temperature, VPD and wind velocity) defining the  
345 atmospheric water demand. Daily averages were used as a summed up explanatory  
346 parameter to capture the atmospheric draw of water vapour from the lysimeter  
347 vegetation for further analysis.

348 Non-destructive estimates for the standing biomass in the lysimeters were  
349 calibrated at the harvests before and after the experimental period. Nine different  
350 regression models were generated for the different estimation techniques individually  
351 and in combinations ~~(appendix 1)~~. Based on the prediction of these models biomass  
352 was estimated for every measurement (total of 16) during the experiment.  
353 GeneratingThe biomass development in the different lysimeters followed a non-linear  
354 trajectory. To generate a consensus time-course ~~for~~describing the ~~biomass~~  
355 developmentgrowth progression in every lysimeter, a general additive mixed model  
356 smoother was fitted for each unit (gamm-function in the mgcv-package, R  
357 Development Core Team, 2015) with the different prediction methodologies defining  
358 random (observer) - effects. ~~In order to generate a more conservative pattern, the~~The  
359 flexibility of the time course defined with these smoothers was constrained by  
360 allowing a maximum of five knots for these smoothers. Granting an approximate  
361 average of three measurement points per knot (16 to 5) successive sampling points  
362 were capable to change the trend of biomass progression while implausible  
363 fluctuation were prevented. Based on these models, standing biomass was predicted  
364 on a dry weight basis for every lysimeter entity and each day of the experiment.

365 ~~All statistical analysis presented here were performed using the R statistical programming~~  
366 ~~language (R Development Core Team, 2015).~~ For the evaluation of evapotranspiration

367 | responses mixed effects models were fitted using the *nlme*-package. ~~These~~ [\(Pinheiro](#)  
368 | [et al., 2017\)](#). ~~All these~~ models included the identity of the different vegetation types  
369 | (categorical) in full factorial combination with additional covariates defining the fixed  
370 | part of the model. ~~as detailed below~~. To reveal the drivers of variation in daily ET  
371 | rates and separate the effects of ~~variability~~ [variation](#) in biomass (DW –dry weight) and  
372 | evapotranspiration rates per unit biomass (ET/DW) among the different monoliths, a  
373 | log-log-scaling method was applied on the formula  $ET = ET/DW \times DW$  based on the  
374 | methodology provided by (Renton and Poorter, 2011). [This procedure allows](#)  
375 | [decomposing the importance of different factors of sources in the variation of a](#)  
376 | [synergistically \(multiplicative\) defined trait and is not meant to establish a statistical](#)  
377 | [relationship between independent parameters](#). For summarizing the time courses of  
378 | SWC and  $ET_0$  the day of the experiment and the two irrigation schemes were  
379 | considered as additional categorical variates. For modelling the response surface of  
380 | ET along the two dimensions of  $ET_0$  and SWC, the latter [two](#) and all possible  
381 | interactions with vegetation type were defined as continuous covariates for the fixed  
382 | part of the model. However, all models included a random intercept for the  
383 | experimental plot in which the data were collected. Nested within the random effect  
384 | for the plot, the lysimeter identity was included as another random effect to fully  
385 | represent the dependence structure in the hierarchical design of the experiment.  
386 | ~~Were~~ [Where](#) they were found to significantly improve the model fit, lysimeter specific  
387 | response to continuous covariates in the fixed part were included as random slopes.  
388 | [\(see Table 2\)](#). Further, to account for autocorrelative errors according to the time-  
389 | series origin of the data, a continuous autocorrelation structure (corCAR1 in *nlme*-  
390 | package) was defined by the day of the experiment. [All statistical analysis presented](#)  
391 | [here were performed using the R statistical programming language](#) [\(R Development](#)  
392 | [Core Team, 2015\)](#).

394

395 Fig 2: Atmospheric demand ( $ET_0$ ) and soil water content (SWC) as drivers of ET, A)  
 396 dynamics of daily average  $ET_0$  over the course of the experiment (bold line: all plot  
 397 average, thin lines: individual plots); B) dynamics of daily average SWC for two  
 398 vegetation types (S & M, see Table 1) in contrasting irrigation schemes (REG - solid  
 399 lines, D - dashed lines; bold lines: treatment average; shaded area: standard  
 400 deviation, thin lines: individual plots); S: Stubai, M: Matsch/Mazia.

401

402 | ~~The drivers of ET:~~ The average air temperature during the course of the experiment was  
 403 17.5 °C ( $\pm 3.1^\circ\text{C}$  – standard deviation). Among the different plots no systematic  
 404 variation of temperature, relative humidity and solar radiation was measured by the  
 405 microclimate stations underneath the shelters. Summarizing the different  
 406 atmospheric components defining rates of ET,  $ET_0$  was calculated. During the  
 407 duration of experiment the average daily  $ET_0$  was  $3.26 \text{ kg}_{\text{H}_2\text{O}} \text{ m}^{-2} \text{ d}^{-1}$  ( $\pm 1.95 \text{ SD}$ ) with  
 408 a minimum at 0.75 and a maximum of  $6.4 \text{ kg}_{\text{H}_2\text{O}} \text{ m}^{-2} \text{ d}^{-1}$ . However, since  $ET_0$  is  
 409 subject to short-term natural variation of the underlying environmental parameters,  
 410 fluctuations between consecutive days were found to be very pronounced and no  
 411 temporal trend was revealed over the period of the experiment (Fig. 2).

412  
 413 Fig 3: Dynamics of daily average ET over the course of the experiment for two  
 414 different vegetation types (S & M, Table 1) subjected to contrasting irrigation regimes  
 415 (REG - solid lines, D - dashed lines; shaded area – standard deviation); S: Stubai, M:  
 416 Matsch/Mazia.

417  
 418 During the time of the experiment the two contrasting irrigation schemes led to  
 419 distinct SWC dynamics within the respective mesocosms (Fig. 2). Since SWC in all  
 420 lysimeters was high at the beginning of the experiment the value initially decreased  
 421 in all plots irrespective of treatment indicating that the water irrigated on plots with  
 422 regular irrigation did not fully compensate the loss of water by ET of the  
 423 corresponding communities. The first clear effects of ~~differential~~different irrigation

424 became ~~only~~ apparent in the lysimeters with the M-type of vegetation only after  
425 applying approximately two weeks of drought. ~~Variation in SWC of~~ In the lysimeters  
426 ~~belonging to~~ with the S-type of vegetation the variability of SWC was ~~rather strong and it~~  
427 ~~took those units longer to manifest~~ far stronger, a distinct ~~effects of the different difference~~  
428 between watering schemes could be observed there only after the start of additional  
429 manual watering. After approximately one month, SWC in both vegetation types  
430 revealed clear effects of the contrasting irrigation strategies. At that time, SWC of  
431 both treatments was restored to similar values observed during the initial stages of  
432 the experimental period in order to avoid distress in the drier mesocosms. Rates of  
433 daily ET from the lysimeters were varying very strongly through the period of the  
434 experiment and did not reveal a general temporal trend (Fig. 3). ~~The~~ As the canopy  
435 height and biomass of both vegetation types was clearly higher than the reference  
436 vegetation assumed for ET<sub>0</sub>, the average evapotranspirative water loss for the  
437 lysimeter unit during the duration of the experiment ~~was~~ also surpassed ET<sub>0</sub> with 4.9  
438 kg<sub>H2O</sub> m<sup>-2</sup> d<sup>-1</sup>. Subject to the atmospheric water vapour pressure deficit the recorded  
439 fluxes were characterised by a similar unsteadiness as the variability of the  
440 underlying environmental parameters would suggest. ~~No consistent differences in daily~~  
441 ~~water flux from~~ During the lysimeter mesocosms ~~to the atmosphere could be detected according to~~  
442 ~~the identity~~ first third of the community. ~~Also the~~ experiment ET of the S-type lysimeters  
443 was on average higher than the M-type, afterwards no clear difference between  
444 vegetation types could be detected.. A clear difference of ET between contrasting  
445 irrigation regimes ~~did not impose a overall difference in the rates of ET within the experimental~~  
446 ~~period. However,~~ was only found during periods of strong divergence of SWC among  
447 the two ~~irrigation treatments,~~ daily ET was lower for entities subjected (approx. 15/07 to  
448 25/07) during the rest of the experimental period ET on the drought regime was only  
449 slightly lower than in the regular one.

450

451 | Fig 4: Trajectories Predictions of biomass development for the two vegetation types  
 452 | (S: Stubai, M: Matsch/Mazia, Table 1) subjected to contrasting irrigation regimes  
 453 | (REG - solid lines, D - dashed lines; shaded area – standard deviation) throughout  
 454 | the duration of the experiment based on non-destructive measurements

455

456 | The prediction of biomass development combined from the different non-  
 457 | invasive estimation methods suggested distinct growth trajectories for the two  
 458 | vegetation types in interaction with the two irrigation regimes. The mesocosms with  
 459 | communities belonging to the local S-type revealed larger biomass  
 460 | differentials increment during early stages of the experiment irrespective of the applied  
 461 | irrigation regime. However, with increasing duration of the experiment, growth  
 462 | dynamics started diverging in treatments with contrasting water provision, with  
 463 | biomass differences peaking at the mid-time of the experimental period. After that  
 464 | peak, the prediction of dry weight suggested a decline in standing biomass for both  
 465 | water regimes in the S-communities. Towards the end of the experiment, biomasses  
 466 | of communities in the different water treatments converged to similar values. This  
 467 | pattern of vegetation development indicates that the early irrigation rates of the REG  
 468 | treatment were indeed too low and the manual compensation came too late for a  
 469 | regular development of the vegetation. Thus, also the S-type lysimeters subjected to  
 470 | the REG-treatment suffered a drought related early peak of biomass and subsequent  
 471 | senescence with just a short delay to the D-treatment. A different pattern of biomass

472 development was detected for the transplanted mesocosms (M). From the beginning  
 473 of the experiment growth processes of the different irrigation treatments yielded  
 474 distinct trajectories. In the treatment experiencing regular water provision the  
 475 biomass gain per unit time was stronger than in the mesocosms being subjected to  
 476 irregular watering. That pattern was consistent throughout the experiment, with a  
 477 strictly monotonic increase of standing biomass in the M communities of well-  
 478 watered plots. In contrast, the vegetation of the M-type in the plots with restricted  
 479 watering growth started stagnating during the second half of the experimental period.  
 480 Unlike the S-type, at the end of the investigation period, biomasses in the M-type  
 481 communities were clearly distinct according to the different watering regimes, with  
 482 the standing mass in the regularly watered plots approximating double the amount  
 483 compared to the treatment with restricted water provision.

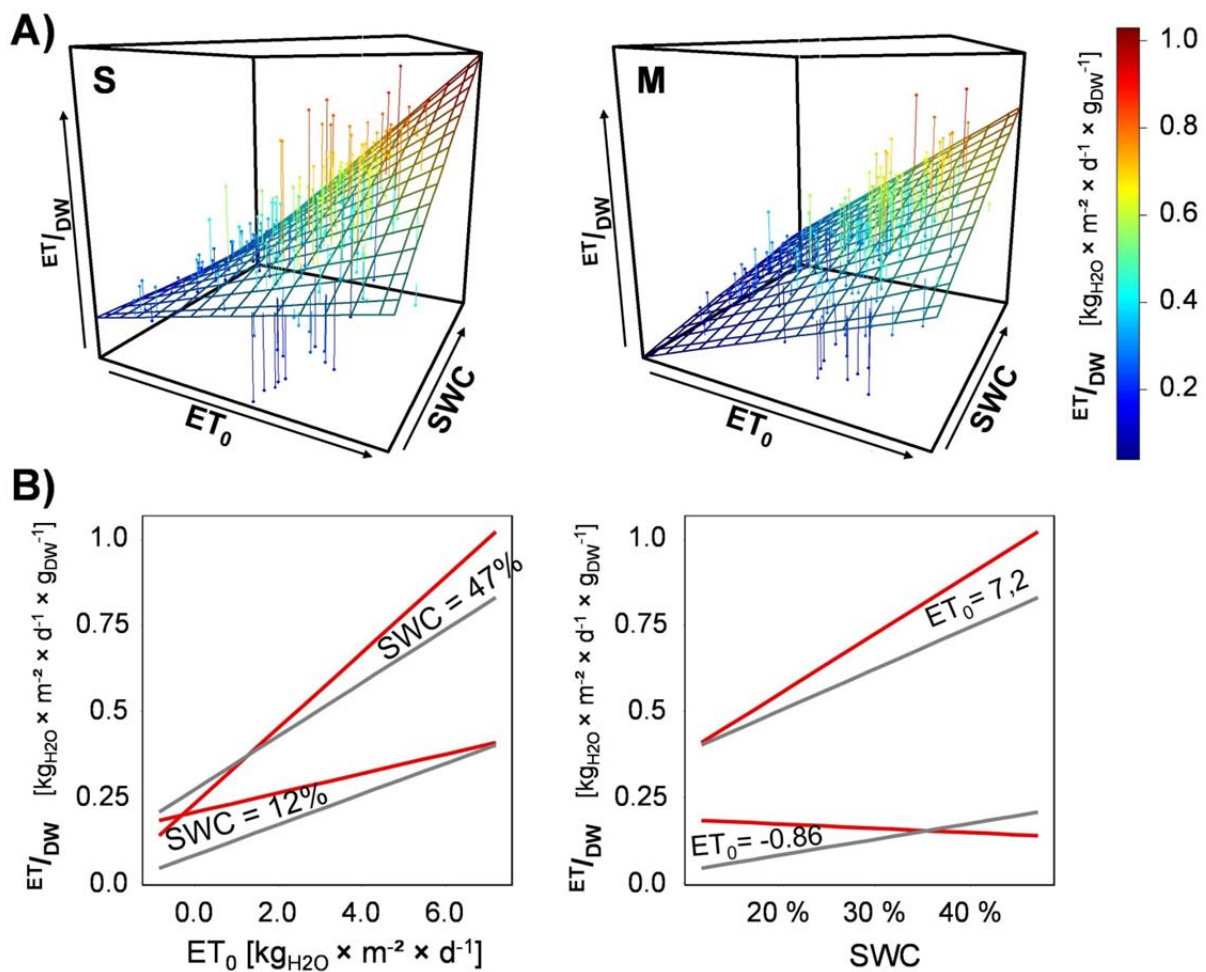

484

485 Fig 5: Log-log scaling for the two factors defining variability of ET: ET rates per unit  
 486 dry weight (ET/DW) and standing biomass (=dry weight, DW) for the two different  
 487 vegetation types (S & M, Table 1) subjected to contrasting irrigation regimes (REG -  
 488 solid lines, D - dashed lines; shaded area – standard deviation), red line indicates a  
 489 reference function with the slope of 1. X-axes of the sub-plots have the same limits  
 490 and units as the corresponding main plots.

491

492 Variability of ET is subject to variation in evapotranspiration rates per unit  
 493 biomass (ET/DW) and the variation in the standing biomass. Hence, when  
 494 comparing rates of ET differentiating both underlying components will provide deeper  
 495 insights on how the vegetation interface of different communities mediates the water  
 496 flux from the soil. A strong positive correlation of total daily ET and ET/DW was  
 497 found (Fig 5). The log-log-scaling of ET/DW with ET revealed a slope of 0.998  
 498 arguing that variation in ET rates measured during the course of this experiment is  
 499 almost exclusively defined by the variation in ET rates per unit biomass (100% = 1).  
 500 This relationship was independent of vegetation type and irrigation scheme. ~~The effect~~  
 501 ~~of biomass variation on the variance of total rates of ET however did have a very small and~~  
 502 ~~insignificant effect. For the local communities (S) the more biomass to be found in the lysimeter~~  
 503 ~~mesocosms the bigger was the total daily water flux to the atmosphere, while the transplanted~~  
 504 ~~communities revealed a different pattern. For M-type communities the amount of biomass in the~~  
 505 ~~lysimeters had no strong effect on the rates of total ET.~~ However, variations of biomass did not  
 506 have an effect on the variability of total ET rates (Fig. 5).

508 Fig 6 A) 3D plots: response surface of ET per unit DW (ET/DW) along the two-  
509 dimensional variation of  $ET_0$  and SWC for the two different vegetation types (S:  
510 Stubai, M: Matsch/Mazia, Table 1); B) projections of ET/DW response along  $ET_0$  and  
511 SWC at maximum/minimum value of the particular other (red: S-communities, grey:  
512 M-communities)

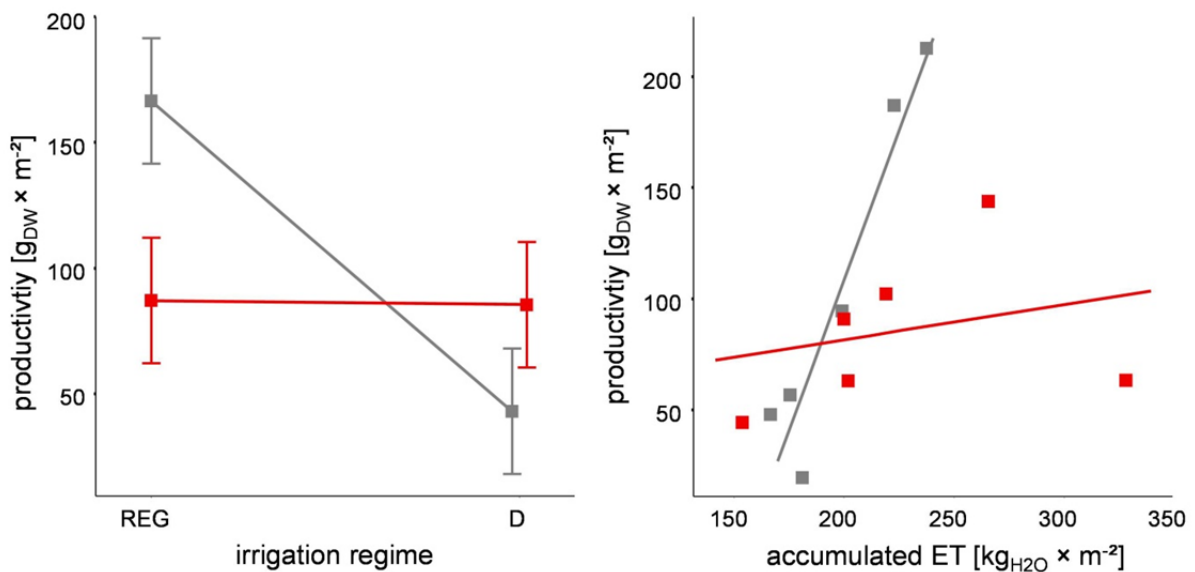

513 After revealing ET/DW as the most important driver in defining variation in the  
514 rates of total ET from the lysimeter mesocosms, the effect of combined variation in  
515  $ET_0$  and SWC on rates of ET per unit biomass was modelled in dependence of the  
516 vegetation type ( $ET/DW = f(ET_0 \times SWC \times \text{vegetation type})$ ). ~~The~~ On the entire field site,  
517 on average the daily sums of  $ET_0$  ranged from -0.75 to a maximum of  $6.4 \text{ kg}_{\text{H}_2\text{O}} \text{ m}^{-2}$   
518 d<sup>-1</sup>, while the within the individual plots daily average values ranged from -0,86 to 7,2  
519 of  $6.4 \text{ kg}_{\text{H}_2\text{O}} \text{ m}^{-2}$ . The averaged SWC realized during the duration of the experiment  
520 covered a range from approximately 12-47% (Fig. 5). Both,  $ET_0$  and SWC had a  
521 highly significant and positive effect on achieved rates of ET/DW (Fig. 6, Table 2).  
522 However, as implied by a significant synergistic interaction of  $ET_0$  and SWC, rates of  
523 ET/DW increased stronger if SWC and  $ET_0$  increased concurrently than the  
524 individual gradients of either would imply (Fig 6.). With increasing  $ET_0$  the response  
525 of ~~EV~~ ET/DW was stronger the higher SWC was. However, there was a significant  
526 difference how both vegetation types responded within the landscape of  
527 environmental drivers defining ET/DW (Table 2). The local (S) vegetation had higher  
528 rates of ET/DW - when both  $ET_0$  and SWC were low - than the transplanted  
529 vegetation type (M), suggesting a higher base rate of ET/DW. On the low end of  
530 investigated SWC the M-vegetation had a stronger response to  $ET_0$  than the local S-  
531 vegetation. Despite that stronger response of the transplanted vegetation (M) along  
532 the  $ET_0$  gradient at low SWC, the maximum rates of ET/DW converted to similar  
533 values due to the higher base flux at low  $ET_0$ / low SWC in the S-vegetation. In turn,  
534 under conditions of high soil water availability the  $ET_0$ -response of the S-type was  
535 much more pronounced than in the M-type. A similar pattern was found comparing  
536 the SWC-response of both vegetation types for the range of different  $ET_0$  values  
537 realized during the experiment. At low  $ET_0$  the M-type vegetation responded stronger  
538 to variations in SWC, while there was almost no response in the S-type. However, at  
539 high  $ET_0$  the response of the S-type to increasing SWC was again much more  
540 pronounced than in lysimeters with the M-type. Because of the higher rates of

541 ET/DW at low ET<sub>0</sub>/SWC and the overall increased response potential of the S-type  
 542 vegetation, the ET/DW values achieved in the M-communities stayed below those  
 543 found in the local vegetation for almost the entire range of combinations between  
 544 ET<sub>0</sub> and SWC investigated in this experiment.

545 Table 2 Parameter and parameter interactions affecting the ET<sub>0</sub>-SWC landscape of  
 546 ET

Parameter	F-value	p-value
ET <sub>0</sub>	341.31	<0.001
SWC	28.09	<0.001
vegetation type	2.81	0.154
ET <sub>0</sub> × SWC	37.20	<0.001
ET <sub>0</sub> × vegetation type	1.24	0.265
SWC × Vegetation type	2.74	0.098
ET <sub>0</sub> × SWC × Vegetation type	7.08	0.008

547

548

549 Fig 7: Productivity of two vegetation types (± standard error, Stubai - red &  
 550 Matsch/Mazia - grey; Table 1) subjected to contrasting irrigation schemes (Fig 1),  
 551 right panel: dry matter productivity of two vegetation types (see above) as function of  
 552 accumulated evapotranspiration over the experimental duration

553 Comparing the productivity of the two vegetation types among the two irrigation  
 554 treatments revealed a contrasting response for the DW productivity (Fig. 7, left

555 panel). For the local S-Type the biomass gain over the experimental period did not  
556 show a strong dependence on the applied watering regime. ~~The~~Due to the insufficient  
557 irrigation mentioned before the productivity of the S-type stayed well below from  
558 what would be expected for the vegetation outside the experimental site in both  
559 treatments. For the M-communities, however, productivity was on average more than  
560 two fold higher in the plots experiencing regular water provision compared to those  
561 exposed to extended periods of drought.

562 Integrated over the entire experimental period, the biomass productivity per unit  
563 water usage was significantly higher for the transplanted mesocosms M (Fig 7, right  
564 panel). The data suggested a productivity increase of 2.6g<sub>DW</sub> per kg of water for the  
565 M vegetation. In contrast, for the S-type mesocosms the average increase of  
566 productivity per 1kg of evapotranspiration was approximately only 0.46g. 1.6g<sub>DW</sub> per kg  
567 but was strongly influenced by highly variable productivity of the two lysimeters with  
568 the highest accumulated ET (Neglecting this one observation, productivity in the S-  
569 vegetation was around 0.91g<sub>DW</sub> per kg of water). This pattern suggests that biomass  
570 generation in the M-type vegetation is ~~significantly more~~strongly dependent on ET and  
571 therefore water availability, ~~while the differences in the slope imply lower~~. For the S-type  
572 vegetation the early decrease of biomass in both treatments and the high variability  
573 of productivity at high ET made it difficult to assess an integrated trend in water use  
574 efficiency of water use with respect to dry weight accumulation in the S mesocosms.

575 | for the entire experimental period.

576

## 577 | **DISCUSSION**

---

578 | It is intuitive to understand, that  $ET_0$  and SWC impose independent and  
579 | interacting effects on water fluxes from the soil to the atmosphere with one of either  
580 | constraining the total rates of ecosystem ET (Kim and Verma, 1991; Perez et al.,  
581 | 2006). Beyond the effects of these abiotic drivers, the measurements of the present  
582 | experiment reveal a community specific signal in the definition of ecosystem water  
583 | exchange. The community specific configuration of the soil-plant-atmosphere  
584 | interface is instinctively acknowledged if distinct vegetation types are compared.  
585 | Water fluxes from the system will to some degree always scale with productivity and  
586 | total biomass of the vegetation (Zeppel et al., ~~2014~~2014 and references therein).  
587 | This ~~context~~relationship will drive variation in ET of contrasting biomes together with  
588 | environmental parameters affecting the availability ~~of water~~ and the atmospheric  
589 | ~~deficit~~demand of water.

590 | However, results of this experiment reveal that vegetation specific differences  
591 | have a component, which defines ecosystem water flux beyond the impact of  
592 | variations in total biomass. Such differences will be important to understand and to  
593 | consider if communities of the same type need to be evaluated with respect to their  
594 | particular impact on the hydrological regulation of the ecosystem. The response of  
595 | water fluxes along co-operating gradients of SWC and  $ET_0$  indicated divergence in  
596 | the conductance potential of the two alpine grassland communities, which were  
597 | independent from the biomass present. At low SWC ~~the response~~lower values of  
598 | ET/DW for the M-type ~~to~~ vegetation indicate a better ability to control water loss in  
599 | dry conditions event though the difference to the S-type diminishes with increasing  
600 |  ~~$ET_0$  was much stronger than for the S-type arguing for a higher efficiency to mobilise limited water~~  
601 | ~~resources from the soil column~~. Conversely, under conditions of high soil water availability  
602 | water fluxes from the S-type responded much stronger to increases of  $ET_0$   
603 | suggesting a higher overall conductance potential. Similar implications were  
604 | revealed along the gradient of soil water availability. SWC variations had almost no  
605 | effect on the S-type communities when the atmospheric draw was small, while the  
606 | M-type mesocosm still mediated fluxes to the atmosphere. Under high  $ET_0$  however,

607 the divergence in the response of ET between S & M-communities to varying SWC  
608 suggests that, from starting at similar rates, ET of the S-type ~~became much more efficient~~  
609 ~~to conduct water to the atmosphere~~ increased far stronger the less soil water became  
610 limiting. These differences between the two vegetation types indicate different  
611 strategies in the water utilisation. For the M-type this strategy may be summarized by  
612 ~~a high potential to utilize even scarce water resources, a~~ overall ~~lower potential to translate~~  
613 ~~atmospheric deficits into higher water conductance with~~ ET rates ~~of ET staying below those~~  
614 ~~measured~~ than for the S-type for most environmental scenarios included within the  
615 experimental period and a stronger control of transpiration especially at low SWC.  
616 This implies an overall conservative and water saving strategy. For the S-  
617 communities, in contrast, which show high water conductance potential with strongly  
618 increasing ET rates when environmental conditions become less constraining, an  
619 acquisitive strategy is suggested. With high rates even at base level ~~these~~  
620 ~~communities~~ this community appear not to be optimized to save water and might  
621 experience drought effects earlier and probably stronger, when water availability  
622 becomes limiting. There might be some dampening effect ~~as soil hydrological properties~~  
623 ~~indicate a higher amount of plant available water for the S-type. The permanent wilting point (pF 4.2)~~  
624 ~~in the main rooting zone (averaged values for 0.05m, 0.15m, 0.25m soil depth) was at a SWC of 13%~~  
625 ~~(± 8.3 SD) and 17% (± 3.1 SD) for the S-vegetation type and the M-vegetation type, respectively.~~  
626 ~~Whereas field capacity (pF 2.1) was found to be at a SWC of 46% (± 4.4 SD) and 43% (± 6.8%) for~~  
627 ~~the S-vegetation type and the M-vegetation type, respectively. In summary, the plant available water~~  
628 ~~was found to be 33 vol% for the S-type and 26 vol% for the M-type. However, the variation at 0.05m~~  
629 ~~soil depth was very low and even a slightly higher amount of plant available water was found for the~~  
630 ~~M-type (S-type: 28 vol%; M-type: 29 vol%) at this soil depth.~~ of soil hydrological properties  
631 event though the slightly higher amount of plant available water for the S-type might  
632 be offset by a finer texture and higher organic matter content regarding soil water  
633 storage capacity. The different pattern of SWC with an earlier distinction between  
634 REG- and D-Treatment after the first 2-3 weeks of the experiment are more likely  
635 caused by the lower ET of the M-type vegetation during this period. Although soil  
636 hydrological properties play a role in the community specific conductance potential of  
637 soil water to the atmosphere, differences found for the investigated two different  
638 vegetation types turned out to be not decisive in this context.

639 Sharing a common environment, the differences in biomass-independent  
640 conductance potential between the two Alpine grassland communities are likely to  
641 have a foundation in a contrasting physiological, functional and structural

642 organisation of the vegetation. Functional divergence in water utilisation,  
643 evapotranspiration and other aspects of hydrological regulation of ecosystems (e.g.  
644 infiltration, surface run-off) between communities can be manifested by the  
645 frequency distribution in the values of particular traits (Díaz et al., 2013). Canopy  
646 complexity - density and size, growth form composition, composition and diversity of  
647 vascular structures, stomatal density and conductance mediate community specific  
648 differences in the evapotranspiration aboveground (de Bello et al., 2010)  
649 Belowground, the structure and depth of the individual rooting systems is an  
650 important determinant for the water utilisation potential of communities (Knapp et al.,  
651 2008). Along the variation and composition of these traits water usage and  
652 consequently also drought resistance of contrasting communities is defined. The  
653 differences in the two vegetation types suggest high exploitation potential for scarce  
654 soil water, probably facilitated by a higher priority on water exploitation in the soil in  
655 the M-mesocosms and, conversely, a stronger importance on aboveground  
656 structures mediating light capture and gas-exchange, leading to an increased  
657 response potential of ET for atmospheric triggers in the local S-communities.

658 The clear vegetation response to variable water availability observed in the  
659 present experiment is not common in studies targeting Alpine grasslands (de Bello et  
660 al., 2010). Based on multi-annual measurements of evapotranspiration at 16 sites in  
661 the Austrian Alps, it was suggested, that even during years with low annual  
662 precipitation Alpine grasslands do not experience water stress (Wieser et al., 2008).  
663 Gilgen and Buchmann (2009) could not conclude on a general drought response of  
664 grasslands in Switzerland, while acknowledging a site-specific impact with  
665 communities receiving less annual precipitation being more susceptible to drought  
666 stress than those at higher rainfall levels. Also arguing for a co-defined and  
667 interactive manifestation in the effects of varying water availability, a strong drought  
668 response of Alpine grassland functioning was revealed under scenarios of co-  
669 occurring heat waves (De Boeck et al., 2016). A modelling study for grassland  
670 ecosystems in the Austrian- and French Alps suggested a higher vulnerability to  
671 drought for communities with a water spending strategy targeting on water provision  
672 of the ecosystems in general (Leitinger et al., 2015). However, it seems  
673 inappropriate to synthesize a general summary on the response of Alpine grasslands  
674 to variations in water availability given the small body of research performed.  
675 Considering the different spatio-temporal scales, the range of parameters measured,

676 and the management and biodiversity spectrum of different grassland types in the  
677 Alps, drawing broad and universal generalisation yet becomes unrewarding. For  
678 experiments with contrasting treatments the practicalities of manipulating water  
679 availability potentially also need to be considered for the interpretation of the results.

680 Drought scenarios are usually generated by rain-out shelters using a UV-  
681 permeable, transparent film for roofing. If compared to unroofed controls,  
682 temperature differences and attenuation of photosynthetically active radiation  
683 reducing total productivity will have to be expected as pure artefacts of the sheltering  
684 (Vogel et al., 2013). However, even if both treatments are sheltered, differential  
685 irrigation may not immediately lead to the realisation of varying water availabilities.  
686 The beginning of the present experiment was marked by the establishment of the  
687 rain-out shelters and the omission of irrigation in the treatments with irregular  
688 watering (D). From this point, it took approximately two weeks for the SWC of both  
689 irrigation schemes to diverge significantly in M-type mesocosms, for the S-type even  
690 longer. Therefore, regular irrigation and, respectively, its omission can, counter-  
691 intuitively, only be an indicator of contrasting water availability. The establishment of  
692 drought conditions in the strict sense of a depleted soil water reservoir is realized by  
693 the interaction of pre-treatment SWC, standing biomass and atmospheric effects.  
694 Variations in vegetation water status have to be defined in context of water  
695 availability (supply) and physiology, phenology and the leaf-to-air evaporative  
696 gradient (Gilbert and Medina, 2016). The beginning of the experiment was  
697 characterized by combination of days with consistently high averages of  $ET_0$  and  
698 high SWC in all mesocosms. This combination led to high ET and a decrease of  
699 SWC for all experimental units. Due to the parallel decline of SWC irrespective the  
700 watering regime applied, the water availability differentiation among the treatments  
701 was delayed. For such reasons, it was argued to define variations in water  
702 availability not purely on the basis of contrasting regimes of water input (i.e. irrigated  
703 vs. non-irrigated) if these are not causing systematic variations in soil moisture  
704 (Kramer, 1983). Defining water supply based on the continuous range of SWC rather  
705 than discrete irrigation treatments considers soil type specific characteristics of  
706 matric potential and hydraulic conductivity. Also practical problems with realizing  
707 discrete treatments of water availability in the field (i.e. precipitation entry to  
708 sheltered plots due to heavy winds, spatio-temporal variation in the effectiveness of  
709 automated irrigation) will be mitigated by referencing ecosystem responses to

710 gradients of water supply. Defining vegetation responses along continuous ranges of  
711 environmental factors will further yield stronger information about the response  
712 surface of the system and improves model building and testing (Beier et al., 2012).

713

## 714 **CONCLUSION**

---

715 Irrespective the variability of different water availabilities within the two irrigation  
716 regimes, mesocosms subjected to regular watering (REG) had on average a higher  
717 productivity than those with irregular and in total less irrigation. However, significant  
718 differences between the different communities were found in the response to  
719 variations in the water supply (Fig 7). Relating total productivity to the amount of  
720 evapotranspirative water release over the experimental period revealed a higher  
721 biomass gain per unit water in the M-type communities. The higher water use  
722 efficiency in the biomass production of these mesocosms together with their overall  
723 stronger water saving strategy reinforces their optimisation to scarce water supply.  
724 For the local S-communities, in contrast, the low biomass differential per unit water  
725 consumption indicates a high potential to conduct water from the soil to the  
726 atmosphere and that productivity of this vegetation is probably not often constrained  
727 by water availability in its natural context. (Brilli et al., (2011) expect from a water  
728 spending strategy to have a cooling feedback in terms of climate warming. Hence,  
729 the optimization of future grassland management could play a crucial role by  
730 adapting species composition. Furthermore, understanding the specific hydraulic  
731 conductance potential of soil water for varying grassland ecosystems is a  
732 prerequisite to achieve maximum agricultural yield in a future environment. However,  
733 a negative feedback for water provision services (i.e. down-stream water users) has  
734 to be expected. Further decisive changes remain debatable: How will 'water  
735 spending' plant communities adapt if droughts occur more frequently and possibly  
736 with higher intensities (Bahn et al., 2014; Reichstein et al., 2013). To what extent  
737 play – at least initially - physiological and morphological changes a role or is there an  
738 immediate shift to a better adapted community?

739
