30

31 **Abstract:** The treatment of organic wastes remains one of the key sustainability challenges  
32 facing the growing global aquaculture industry. Bioremediation systems based on coupled  
33 bioturbation—microbial processing offer a promising route for waste management. We  
34 present, for the first time, a combined biogeochemical-molecular analysis of the short-term

35 performance of one such system that is designed to receive nitrogen-rich particulate  
36 aquaculture wastes. Using sea cucumbers (*Holothuria scabra*) as a model bioturbator we  
37 provide evidence that adjusting the waste C:N from 5:1 to 20:1 promoted a shift in nitrogen  
38 cycling pathways towards the dissimilatory nitrate reduction to ammonium (DNRA),  
39 resulting in net  $\text{NH}_4^+$  efflux from the sediment. The carbon amended treatment exhibited an  
40 overall net  $\text{N}_2$  uptake whereas the control receiving only aquaculture waste exhibited net  $\text{N}_2$   
41 production, suggesting that carbon supplementation enhanced nitrogen fixation. The higher  
42  $\text{NH}_4^+$  efflux and  $\text{N}_2$  uptake was further supported by metagenome predictions that indicate  
43 organic carbon addition stimulated DNRA over denitrification. These findings indicate that  
44 carbon addition may result in greater retention of nitrogen within the system, however  
45 longer-term trials are necessary to determine whether this nitrogen retention is translated into  
46 improved sea cucumber biomass yields.

#### 52 **1. Introduction**

53 Intensive land-based aquaculture produces nitrogen-rich effluent that may  
54 detrimentally impact water quality and other environmental parameters. In conventional  
55 recirculating aquaculture systems (RAS), biological filtration and water exchange are  
56 commonly practiced for nitrogen removal; however, microbial nitrogen removal is limited by  
57 the supply of carbon as an electron donor (Castine, 2013). Carbon supplementation is  
58 employed in a number of treatment technologies to overcome this deficiency (Avnimelech,  
59 1999; Hamlin et al., 2008; Schneider et al., 2006). The addition of exogenous carbon is a pre-  
60 requisite for the successful operation of denitrifying filters that permanently remove  
61 dissolved inorganic nitrogenous wastes by conversion to dinitrogen gas (Roy et al., 2010).  
62 Alternatively, in zero exchange biofloc systems, carbon to nitrogen ratios (C:N) are increased  
63 through the addition of labile carbon sources to promote ammonia assimilation from the  
64 water column by heterotrophic bacteria (Avnimelech, 1999; Crab et al., 2012). The  
65 fundamental difference between these approaches is the ultimate fate of nitrogen within the  
66 system i.e. removal versus retention. Technological advances are focused on the development  
67 of dissimilatory processes to permanently remove nitrogen from the system as  $\text{N}_2$  gas, while

68 ecological-based systems, such as biofloc, aim to re-cycle and re-use nitrogen within the  
69 culture system. This study aims to advance ecologically-based aquaculture bioremediation  
70 systems that may provide an alternative to closing the nitrogen cycle through the promotion  
71 of assimilatory processes (Robinson, *in review*).

72 The stoichiometric approach taken in C:N amendment in biofloc systems recognises  
73 that carbon and nitrogen cycles are coupled; therefore, the relative elemental abundances  
74 control the rate of nutrient cycling and energy flow within the treatment system (Dodds et al.,  
75 2004; Ebeling et al., 2006). The potential for C:N manipulation in sediment-based  
76 aquaculture effluent treatment systems containing deposit feeders (sea cucumbers) was  
77 previously demonstrated by Robinson et al., (*in review*), wherein the addition of soluble  
78 starch to aquaculture waste significantly improved sea cucumber growth rate and biomass  
79 density. Furthermore, redox-stratified sediments that harboured predominately heterotrophic  
80 microbial communities also supported higher sea cucumber yields, indicating that  
81 predominately reducing conditions are more favourable for deposit feeder growth (Robinson  
82 et al., 2015; Robinson et al., 2016). Since reducing conditions favour anaerobic respiratory  
83 and fermentative pathways, organic carbon supplementation may stimulate anaerobic  
84 bacterial metabolism by increasing the availability of electron donors and/or substrates for  
85 fermentation, in addition to increasing heterotrophic  $\text{NH}_4^+$  assimilation (Fenchel et al., 2012;  
86 Oakes et al., 2011).

87 The C:N ratio affects the quantity of nitrogen released during mineralisation, with a  
88 net release of nitrogen occurring below a threshold of 20:1 (Cook et al., 2007; Blackburn,  
89 1986). Robinson et al., (*in review*) hypothesised that C:N manipulation may alter the nitrogen  
90 cycling pathways within the sediment microbial community by mediating a shift from  
91 ammonification (net release) to assimilation (net uptake) of  $\text{NH}_4^+$  by heterotrophic bacteria;  
92 however, the effect of carbon supplementation on nitrogen cycling was not clearly elucidated.  
93 An improved understanding of how C:N manipulation influences benthic nitrogen cycling is  
94 necessary in order to improve nitrogen assimilation and incorporation into secondary  
95 biomass. In the current study, we applied a coupled biogeochemical-molecular approach to  
96 further investigate the effect of carbon supplementation on nitrogen cycling. Incubation  
97 experiments were conducted to quantify benthic fluxes, while sediment microbial  
98 communities were examined using 16S rRNA gene sequencing. The study aimed to test the  
99 hypothesis that increasing the C:N of particulate aquaculture waste from 5:1 to 20:1 would  
100 promote the assimilation of  $\text{NH}_4^+$  by heterotrophic bacteria, drive shifts in microbial  
101 community composition and result in nitrogen retention in the culture system.

## 102 **2. Materials and methods**

### 103 **2.1 Study site and experimental animals**

104 The study was conducted in a purpose-built bio-secure heated conventional  
105 recirculating aquaculture system (RAS) described in Robinson et al. (2015). The experiment  
106 was conducted over a fifteen day period from January 30<sup>th</sup> (day -1) to February 14<sup>th</sup> (day 14)  
107 2014 using juvenile sea cucumbers (*Holothuria scabra*) imported from a commercial  
108 hatchery (Research Institute for Aquaculture III, Vietnam) on September 5<sup>th</sup> 2013, that were  
109 quarantined and acclimated to the experimental system as described in Robinson et al. (*in*  
110 *review*).

### 111 **2.2 Experimental design**

112 Three experimental treatments were randomly allocated to 15 incubation chambers  
113 with five replicates per treatment. The ‘initial’ (In) treatment was included to ensure that  
114 there were no significant differences between treatments prior to the start of the experiment  
115 and as an initial reference point for evaluating the effect of the treatments. The ‘no added  
116 carbon’ treatment (-C) with a C:N of 5:1 received aquaculture waste only (215.06 mg day<sup>-1</sup>  
117 wet weight). The ‘added carbon’ treatment (+C) received aquaculture waste (215.06 mg day<sup>-1</sup>  
118 wet weight) and carbon in the form of soluble starch (44.50 mg day<sup>-1</sup> dry weight) daily to  
119 increase the C:N to 20:1 (mass ratio) from day zero (Table 1). The carbon addition treatments  
120 (+C) were standardised at a concentration of 400 mmol C m<sup>-2</sup> d<sup>-1</sup>.

### 121 **2.3 Experimental system and rearing conditions**

122 Sediment incubation chambers were established by transferring unsieved CaCO<sub>3</sub>  
123 builder’s sand sourced from a commercial dune quarry (SSB Mining, Macassar, South  
124 Africa) into Plexiglas® tubes (25 cm long, 8.4 cm internal diameter) sealed with a polyvinyl  
125 chloride (PVC) end cap to a depth of 7.5 cm. The incubation chambers were connected via  
126 4.0 mm air tubing and 4.0 mm variflow valves to a manifold receiving seawater directly from  
127 a RAS biofilter (see Robinson *et al.*, 2015 for further details). The water flow rate was 50 mL  
128 min<sup>-1</sup>, equivalent to 16.34 exchanges h<sup>-1</sup>. The chamber outflows were routed into a main  
129 drainage channel and allowed to flow to waste to prevent soluble carbon sources from  
130 entering the RAS. Unsieved CaCO<sub>3</sub> was pre-conditioned for four weeks in flow-through  
131 tanks prior to its transfer into the chambers. The sediment was allowed to condition and  
132 stabilise into redox-stratified layers for 14 days prior to commencement of the experiment.  
133 No aeration was provided; however, water was continuously mixed at 60 rpm using a

134 magnetic stirring rod positioned 15 cm above the sediment surface. Stirring rates were just  
135 below that which caused sediment re-suspension (Ferguson et al., 2004; Gongol and Savage,  
136 2016).

137 The experimental area was fully shaded from direct sunlight. Light intensity was  
138 measured during daylight incubations using a light meter (LX-107, Lutron Electronic  
139 Enterprise Co. Ltd, Taipei, Taiwan) positioned 10 cm above each chamber. Additionally, a  
140 temperature/light logger (Hobo, UA-002-64, Onset, USA) was placed in an additional  
141 chamber positioned in the centre of the experimental treatments. The mean (hours) natural  
142 photoperiod was 13.34:10.26 (L:D).

#### 143 **2.4 Aquaculture waste and carbon additions**

144 The aquaculture waste, used as feed for the sea cucumbers, comprised uneaten  
145 abalone (*Haliotis midae*) feed and faeces. It was collected daily from the backwash of a sand  
146 filter in a recirculating abalone grow-out system. Samples were sent for organic carbon and  
147 total nitrogen content analysis (Robinson et al., *in review*) and the mean C:N was 5.21:1.  
148 Soluble starch (Merck Millipore, Pretoria, South Africa) was used as an additional carbon  
149 source to increase the C:N to 20:1. Additions of waste with (+C) or without (-C) added  
150 carbon commenced on day zero. The aquaculture waste was mixed into a wet slurry while the  
151 starch was dissolved in seawater and added daily to the respective treatments at 16:00 from  
152 day zero to day 14.

#### 153 **2.5 Experimental timeline**

154 Baseline data were collected at the start of the experiment (i.e. day -1), with fluxes  
155 measured in all 15 chambers under light and dark conditions. All replicates from the In  
156 treatment were sacrificed on day zero and sub-cored for analysis of sediment characteristics.

#### 157 **2.6 Sea cucumber growth**

158 Animals (n = 30) previously acclimated in the RAS were suspended in mesh  
159 containers for 24 h to evacuate their guts prior to weighing and photo-identification  
160 (Robinson et al., 2015). Three juvenile *H. scabra* with a mean ( $\pm$  standard deviation) weight  
161 of  $1.91 \pm 0.36$  g were added to each of 10 chambers (equivalent to a high stocking density of  
162  $1,034.00 \text{ gm}^{-2}$ ) on day zero. They were removed at the end of the experiment (day 14), gut-  
163 evacuated for 24 h and reweighed. Wet weight data were used to calculate growth rate ( $\text{g d}^{-1}$ ;  
164 Robinson et al., 2015).

165 **2.7 Benthic flux incubations**

166 Benthic flux incubations were conducted on day -1 for all treatments (In, -C and +C)  
167 and on alternate days from day one to day 13 for the -C and +C treatments, after sacrifice of  
168 the In treatment. Light incubations were conducted during daylight hours, commencing after  
169 sunrise (08:00 local time) and dark incubations were conducted after sunset (22:00 local  
170 time). When data were collected the flow from each chamber was interrupted, the stirrers  
171 were paused (~ three min.) and the chambers were uncapped by removing the rubber bung. A  
172 portable optical meter (YSI ProODO, YSI Pty Ltd, USA) was inserted through the sampling  
173 port to measure temperature ( $\pm 0.01$  °C) and dissolved oxygen (DO) concentrations ( $\pm 0.01$   
174 mg L<sup>-1</sup>). The pH ( $\pm 0.01$  pH units) was measured electro-chemically (Eutech Instruments pH  
175 6+ portable meter, Singapore).

176 Water alkalinity and nutrient concentration (ammonia, nitrate/nitrite, nitrite and  
177 phosphate) were recorded at the start and end of each light/dark incubation period. To do this,  
178 samples were withdrawn using a 50 mL acid washed plastic syringe connected to the  
179 chamber outflow through 4.0 mm tubing and filtered (Whatman® glass microfiber filters  
180 grade GF/C, Sigma Aldrich, Johannesburg, South Africa) into 15 mL screw-capped  
181 polycarbonate vials. All nutrient samples were immediately frozen at -20 °C and alkalinity  
182 samples were kept cold at 4 °C. The N<sub>2</sub> samples were taken on three sampling occasions  
183 (days one, seven and 13) during dark incubations, as during daylight hours bubbles may form  
184 that interfere with the estimation of N<sub>2</sub>:Ar and thus overestimate N<sub>2</sub> production (Eyre et al.,  
185 2002). To minimise bubble introduction, N<sub>2</sub> samples were collected by allowing the water to  
186 flow by gravity from the chamber outflow directly into 7 mL gas-tight glass vials with glass  
187 stoppers filled to overflowing. The N<sub>2</sub> samples were poisoned with 20 µL of 5 % HgCl<sub>2</sub> and  
188 stored submerged at 20 °C. The N<sub>2</sub> samples were collected in duplicate or triplicate, thus the  
189 final values represent the mean value calculated for each replicate (Eyre and Ferguson, 2005).

190 After withdrawal of all water samples, replacement water was gravity fed into the  
191 chamber directly from the manifold and the chambers were re-capped and the stirrers re-  
192 started. All materials used for sample collection were acid washed, rinsed three times with  
193 distilled water and air dried prior to use. Total oxygen exchange was measured in three  
194 randomly selected chambers during incubations (one from each treatment) to ensure that the  
195 oxygen concentration did not decrease by more than 20 %. Incubation times were kept short,  
196 ranging from 68 to 146 minutes with an average duration of 104 minutes, to prevent oxygen  
197 depletion and ensure that flux rates were linear (Burford and Longmore, 2001; Glud, 2008).

198 **2.8 Nutrient analyses**

199 Dissolved nitrate and nitrite (NO<sub>x</sub>; 0.01 μM) were determined colourimetrically by  
200 flow injection analysis (QuikChem® 8500 Automated Ion Analyzer, Hach Company, U.S.A.)  
201 and a commercially available test kit (QuikChem® method 31-107-04-1-E for the  
202 determination of nitrate and nitrite in seawater). All other nutrient samples were analysed  
203 manually. Ammonium (0.01 μM) and dissolved inorganic phosphate (0.01 μM) were  
204 determined using the methods of Grasshoff (1976) and Grasshoff et al. (1999) respectively,  
205 and nitrite (NO<sub>2</sub><sup>-</sup>; 0.01 μM) was determined according to Bendscheider and Robinson  
206 (1952).

207 **2.9 Gas analyses**

208 Alkalinity (0.01 mg L<sup>-1</sup>) and total dissolved CO<sub>2</sub> (0.01 μM) concentrations were  
209 determined by potentiometric titration according to Edmond (1970) using an automated  
210 titrator system (876 Dosimat plus, Metrohm, USA). Total alkalinity was calculated according  
211 to the method of Snoeyink and Jenkins (1980). CO<sub>2</sub> concentrations were calculated from  
212 alkalinity and pH using the equations given in Almgren et al. (1983). Changes in pH and  
213 alkalinity were used to calculate dissolved inorganic carbon (DIC) fluxes.

214 Dinitrogen gas (N<sub>2</sub>) was determined from N<sub>2</sub>:Ar using membrane inlet mass  
215 spectrometry (MIMS) with O<sub>2</sub> removal (± 0.01%). Measurement of direct N<sub>2</sub> fluxes using  
216 this technique represents the net benthic flux of N<sub>2</sub> resulting from a combination of processes  
217 that produce N<sub>2</sub>, such as denitrification and anammox, and processes that consume N<sub>2</sub> such as  
218 nitrogen fixation (Ferguson and Eyre, 2007; Eyre et al., 2013a).

219 Nutrient and gas fluxes across the sediment-water interface during light and dark  
220 incubations were calculated using initial and final concentration data according to Equation 1.  
221 Net flux rates, representing the net result of 13.57 h of dark fluxes and 10.43 h of light fluxes  
222 were calculated according to Equation 2 (Veuger et al., 2007). Gross primary production was  
223 calculated according to

224 Equation 3, where light O<sub>2</sub> fluxes represent net primary production and dark fluxes  
225 represent respiration. Remineralisation ratios were calculated according to Equation 4 (Eyre  
226 et al. 2013b).

227 Equation 1 
$$\text{Flux} = \frac{(C_n - C_0) \times V}{A \times t} \times 10,000$$

228 where:

229 Flux = flux (μmol m<sup>-2</sup> h<sup>-1</sup>), C<sub>0</sub> = concentration at time zero (μmol L<sup>-1</sup>), C<sub>n</sub> =

230 concentration at time n ( $\mu\text{mol L}^{-1}$ ), t = incubation time (h), A = area of sediment surface in  
231 chamber ( $\text{cm}^2$ ), and V = volume of water in chamber (L).

232 Equation 2 Net flux rates = 
$$\frac{(\text{hourly dark rates} \times \text{hours of darkness}) + (\text{hourly light rates} \times \text{hours of daylight})}{24\text{h}}$$

233 Equation 3 Gross primary production = light O<sub>2</sub> flux (+ve) – dark O<sub>2</sub> flux (-ve)

234 Equation 4 Remineralisation ratio = 
$$\frac{\text{Dark O}_2 \text{ flux}}{\text{N}_2 + \text{NH}_4^+ + \text{NO}_x}$$

235

## 236 **2.10 Sediment sectioning**

237 On days zero and 14, three sub-cores (internal diameter 30 mm) were extracted from  
238 the In and experimental (-C and +C) chambers respectively. Each sub-core was sectioned into  
239 the following five depth intervals: 0.0 - 0.5, 0.5 - 1.0, 1.0 - 2.0, 2.0 - 4.0 and 4.0 - 6.0 cm for  
240 analysis of sediment characteristics. One set of sub-cores was dried at 50 °C for 24 h for  
241 analysis of total organic carbon and total nitrogen; the second set was frozen in sealed vials in  
242 black bags for spectrophotometric analysis of total carbohydrates. Two sets of samples were  
243 prepared from the third sub-core: sediment samples were frozen in 2 mL Eppendorf tubes for  
244 subsequent deoxyribonucleic acid (DNA) extraction and sequencing. The remaining sediment  
245 was added to 15 mL vials filled with 0.2  $\mu\text{m}$  filtered, one percent buffered paraformaldehyde  
246 and refrigerated for determination of bacterial abundance by flow cytometry.

247 The organic content measured as particulate organic carbon (OC) and total nitrogen  
248 (TN) was determined on an elemental analyser after removal of carbonates by acid  
249 fumigation (Robinson et al., 2015). Total sediment carbohydrates were measured on  
250 defrosted samples using the phenol-sulphuric acid method (Underwood et al., 1995).

## 251 **2.11 Flow cytometry**

252 Aliquots of preserved samples were prepared in duplicate by staining with  
253 4',6-diamidino-2-phenylindole (DAPI) for 15 minutes at 4 °C in darkness (Marie et al.,  
254 1999). Bacterial abundance was analysed with a FACSCalibur flow cytometer (BD  
255 Biosciences, Singapore), fitted with a 488 nm, 15 mW laser, using the FL1 detector ( $\lambda = 530$   
256 nm). TruCount beads (BD Biosciences, Singapore) were used as an internal standard. All  
257 cytometric data were logged and analysed using Cell Quest (Becton-Dickinson) using  
258 *Escherichia coli* cells as a reference. Cell abundance was converted to cells  $\text{g}^{-1}$  of dry  
259 sediment.

260 **2.12 Deoxyribonucleic acid extraction and importation**

261 Genomic DNA was extracted from approximately 250 mg of substrate samples using  
262 a DNA isolation kit (ZR Soil Microbe DNA MiniPrep, Zymo Research, USA) yielding  
263 purified genomic DNA for use in polymerase chain reaction (PCR) amplification. Genomic  
264 DNA was stored in sealed, labelled Eppendorf tubes at -20 °C prior to being couriered from  
265 the Republic of South Africa to the United Kingdom. To comply with the Animal Health Act  
266 1981, the samples were accompanied by a general import license (IMP/GEN/2008/03) for the  
267 importation of animal and poultry products, including DNA, from all non-EU countries.

268 **2.13 Polymerase chain reaction and 16S rRNA sequencing**

269 Library preparation was performed using a modified version of the MiSeq WetLab  
270 protocol (Kozich et al., 2013). One microliter of template DNA was arrayed into 96-well  
271 plate format with 17 µL of Accuprime Pfx Supermix (Thermofisher, UK), leaving two wells  
272 on each plate open for controls. Two microliters of reconstituted indexed primers at 100 µM  
273 were added to the samples to barcode them for identification. To identify any contaminating  
274 operational taxonomic units (OTUs), two control samples were included in the sequencing  
275 run. The negative control consisted of one microliter of PCR grade dH<sub>2</sub>O and the positive  
276 control was one microliter of mock community (HM-278S, BEI Resources, Manassas, USA)  
277 at a 1:3 dilution. The primer pair 515F/806R was used to amplify the V4 region of the 16S  
278 rRNA gene. PCR was performed using the following conditions: initial enzyme activation  
279 and DNA denaturation proceeded at 95 °C for two minutes followed by cycling parameters of  
280 95 °C for 20 s, 55 °C for 15 s, 72 °C for five minutes for 30 cycles. A final extension was  
281 done at 72 °C for ten minutes. Amplification of the PCR products was checked on a subset of  
282 12 samples using gel electrophoresis on a one percent agarose gel prior to library clean up.  
283 Samples from all plates were pooled and libraries were subjected to quality control including  
284 quantification using a KAPA Biosystems Q-PCR kit, obtaining a bioanalyser trace using the  
285 Agilent Technologies HS DNA kit and normalisation using the Invitrogen SequalPrep Plate  
286 Normalisation Kit (Thermofisher, UK). Amplicons were sequenced on an Illumina MiSeq  
287 platform by NU-OMICS (Northumbria University, UK).

288 **2.14 Processing of raw sequence data**

289 The raw fastq files were processed using Mothur (version 1.37.0) based on the  
290 Schloss MiSeq SOP with modifications. Raw forward and reverse sequence reads were  
291 merged to create contigs prior to quality filtering. The sequence reads were trimmed using a

292 sliding window of five base pairs (bp) with an average window quality threshold (Q) of 22 or  
293 greater. Sequences containing an ambiguous (N) base, >8 homopolymers or that had a  
294 sequence length <275 bp were discarded. Quality-filtered sequences were aligned using a  
295 custom alignment created for the variable four (V4) region of the 16S rRNA gene using the  
296 Silva database (version 123; July 2015 release). The reads were screened to include only  
297 overlapping regions (based on alignment positions), pre-clustered (number of differences = 1)  
298 and checked for chimeras using the UCHIME algorithm (Edgar et al., 2011).

299 Taxons classified as 'Mitochondria', 'Eukaryota' or 'unknown' were specified during  
300 the `remove.lineage` command. The `count.groups` command was used to determine the  
301 minimum number of reads per sample for normalisation. To standardise sequencing effort, all  
302 samples were subsampled to 550 using the `sub.sample` command, to ensure that all replicate  
303 samples from the experimental treatments (+C and -C) were retained. The subsampled OTU  
304 table (shared file) and assigned consensus taxonomy (`cons.taxonomy.file`) were used in  
305 downstream analyses, including alpha and beta diversity, taxonomic composition and  
306 metagenome predictions of the microbial communities.

### 307 ***2.15 Statistical analyses and bioinformatics***

308 Environmental (light, temperature, salinity) and flux rate data for nutrients ( $\text{NH}_4^+$ ,  
309  $\text{NO}_2^-$ ,  $\text{NO}_x$  and  $\text{PO}_4^{3-}$ ) and gases (DO, DIC and  $\text{N}_2$  – night only) collected on day -1 during  
310 light and dark incubations were averaged to provide a mean value per replicate chamber for  
311 each diurnal period respectively. The data were tested for homogeneity of variance and for  
312 the normal distribution of the residuals using Levene and Shapiro Wilk tests. One-way  
313 analysis of variance (ANOVA) tested for differences in the environmental, nutrient and gas  
314 flux data between the In, +C and -C treatments on day -1.

315 The light, water quality and flux rate data (days 1-13) for nutrients and gases were  
316 averaged to provide a mean value for each replicate incubation chamber. It was not possible  
317 to conduct daytime incubations on day nine due to lowered  $\text{O}_2$  concentrations in the  
318 chambers, therefore light incubation data represents a mean of six values (days one, three,  
319 five, seven, 11 and 13), while the mean dark incubation data were calculated from the full set  
320 of seven incubations. The mean temperature, salinity and mean light, dark and net fluxes of  
321 nutrients and gas fluxes, mean remineralisation ratios and mean gross primary production  
322 measured during the experimental period (days 1-13) were analysed using a Student t-test at  
323 alpha <0.05. Sediment characteristics, including organic carbon, total nitrogen, C:N and  
324 bacterial cell abundance were compared using mixed-model ANOVA with treatment (+C and

325 -C) and sediment depth as fixed factors. When a significant effect was observed, post hoc  
326 comparisons of means were conducted with a Tukey's honest significant difference test.  
327 Differences in *H. scabra* growth rate and biomass density were analysed by Student t-test at  
328 alpha <0.05. Data are presented as mean  $\pm$  standard error unless otherwise stated. All  
329 statistical analyses were performed in Statistica v.13.

330 Alpha (within-sample) diversity metrics for the number of OTUs (observed), richness  
331 (Chao 1), abundance-coverage estimator (ACE) and diversity (Shannon, Simpson and Inverse  
332 Simpson) were calculated and visualised in the phyloseq package in R (McMurdie and  
333 Holmes, 2013). The diversity metrics were generated by the summary.single command by  
334 subsampling to the lowest number of reads per sample (n = 550) and compared across  
335 treatments and sediment depths using mixed model ANOVA.

336 Patterns in bacterial community structure between treatments and sediment depths  
337 were visualised using principal coordinates analysis (PCoA) based on a Bray–Curtis  
338 dissimilarity matrix calculated from the OTU table in R. In addition, a non-parametric  
339 multivariate analysis of variance (PERMANOVA) was performed on the community distance  
340 matrix based on Bray–Curtis dissimilarity index to test the null hypothesis that there was no  
341 difference in the structure of microbial communities between treatments (In vs. -C vs. +C)  
342 and sediment depth using the ‘adonis’ function of the vegan package in R (Oksanen et al.,  
343 2016).

344 Mantel correlation tests were performed on dissimilarity matrices of the community  
345 and environmental data to provide an indication of how well microbial community data  
346 corresponded to the environmental data. The environmental distance matrix was calculated as  
347 Euclidean distances computed from a metadata table containing all of the data describing  
348 light, water quality, sediment characteristics and net flux rates for gases and nutrients. The  
349 significance of correlation coefficients was assessed using a permutation procedure. In  
350 addition, the correlation between environmental data and the sediment microbial  
351 communities was determined using the ‘envfit’ function of the ‘vegan’ package in R  
352 (Oksanen et al., 2016). Since none of the environmental characteristics were significantly  
353 correlated with the microbial community data, the environmental data were not plotted as  
354 vectors on the PCoA ordination.

355 The Tax4Fun package in R was used to predict the metabolic capacities of the  
356 microbial communities from the 16S rRNA sequences. The fctProfiling option was set to  
357 TRUE (default) to predict the metabolic capacities of the metagenomes based on pre-  
358 computed Kyoto Encyclopedia for Genes and Genomes (KEGG) Ortholog reference profiles

359 (Aßhauer et al., 2015). Only KEGG Pathways within ‘nitrogen metabolism’ were retained for  
360 analysis. The KEGG pathway map 00910 for nitrogen metabolism and associated  
361 information was used to extract the KEGG ortholog reference numbers involved in the six  
362 fully characterised reactions listed under ‘nitrogen metabolism’ (supplementary Table 2).  
363 Anaerobic oxidation of ammonia (anammox) was not included, as although this process is  
364 recognised in the KEGG database it has yet to be assigned to a module or reference profile.

365 The relative abundance of functional genes predicted from the 16S rRNA sequences  
366 within each ortholog reference profile were summed to provide a mean value for each  
367 pathway module for each replicate sample from all sediment depths sampled in all treatments  
368 (n = 45). The relative abundance of functional genes in the In and experiment treatments was  
369 illustrated by graphically plotting vertical depth profiles and analysed statistically using a  
370 mixed-model ANOVA.

371

### 372 **3. Results**

#### 373 **3.1 *Sea cucumber growth and survival***

374 Survival of sea cucumbers was 100 % in the +C treatment; however, one replicate  
375 chamber from the -C treatment was terminated on day nine following a period of water  
376 column hypoxia, caused by one animal preventing water exchange by blocking the outflow  
377 valve. This resulted in the mortality of all sea cucumbers in this chamber, reducing the  
378 overall survival to 80 %. There was no significant difference between the mean sea cucumber  
379 wet weight on day zero or day 14 between treatments; however, despite the short duration of  
380 the experiment the sea cucumbers in both treatments lost mass (decreasing from  $1.91 \pm 0.02$  g  
381 to  $1.62 \pm 0.03$  g; an overall mean growth rate of  $-0.02 \pm 0.00$  g day<sup>-1</sup>). The biomass density  
382 decreased from  $1,034.00 \pm 12.73$  g m<sup>-2</sup> to  $874.97 \pm 18.31$  g m<sup>-2</sup>, although the initial stocking  
383 density was comparable to the final densities ( $1,011.46 \pm 75.58$  g m<sup>-2</sup>) achieved in previous  
384 carbon amended cultures standardised at 200 mmol C m<sup>-2</sup> day<sup>-1</sup> (Robinson et al., *in review*).

#### 385 **3.2 *Gas and nutrient fluxes***

386 Benthic fluxes of dissolved oxygen and dissolved inorganic carbon (DIC) can provide  
387 an indication of overall benthic metabolism in response to organic enrichment (Eyre et al.,  
388 2011). There were no significant differences in the light, dark or net fluxes of DO, DIC or N<sub>2</sub>  
389 between treatments on day -1 (N<sub>2</sub> dark only; Fig S1). Sediment oxygen consumption was  
390 significantly higher in the +C incubations throughout the experiment in both light and dark

391 incubations (Student's t-test;  $t = -2.87$ ,  $p = 0.006$ ) resulting in a higher net consumption of -  
392  $2,905.84 \pm 99.95 \mu\text{mol O}_2 \text{ m}^{-2} \text{ h}^{-1}$  compared to  $-2,511.31 \pm 116.81 \mu\text{mol O}_2 \text{ m}^{-2} \text{ h}^{-1}$  in the -C  
393 treatment (Fig. 1a). Oxygen and DIC fluxes clearly show that the sediment metabolism was  
394 net heterotrophic. During the day, DIC release from organic matter degradation exceeded  
395 DIC consumption from primary production (Fig. 1b). There was sediment oxygen  
396 consumption during light and dark incubations, indicating that respiration dominated over  
397 photosynthesis; supported by the lower gross primary production in the +C treatment (Fig.  
398 1d). There were no significant differences in the light, dark or net fluxes of DIC with a mean  
399 net efflux of  $12,732.34 \pm 2,031.69 \mu\text{mol C m}^{-2} \text{ h}^{-1}$  across the treatments (Fig. 1b). The  
400 assumed low rates of photosynthesis may have been due to shading and from turnover of the  
401 microphytobenthos standing stock due to grazing by sea cucumbers (Glud et al.,  
402 2008; Mactavish et al., 2012). In addition, DIC fluxes were four-fold higher than oxygen  
403 fluxes, indicating that the majority of the organic carbon was oxidised by anaerobic pathways  
404 (Burford and Longmore, 2001; Eyre et al., 2011).

405 The mean dark  $\text{N}_2$  flux on days seven and 13 was not significantly different between  
406 treatments (Student's t-test;  $t = -1.29$ ,  $p = 0.23$ ; Fig. 1c). Carbon supplementation resulted in  
407 a net  $\text{N}_2$  uptake ( $-142.96 \pm 107.90 \mu\text{mol m}^{-2} \text{ h}^{-1}$ ), indicating that atmospheric nitrogen fixation  
408 dominated over denitrification and anammox during dark incubations. In contrast, the -C  
409 treatment had a small but positive net  $\text{N}_2$  efflux ( $17.33 \pm 36.20 \mu\text{mol m}^{-2} \text{ h}^{-1}$ ), indicating that  
410 nitrogen removal pathways, such as denitrification or anaerobic ammonium oxidation  
411 (anammox), were slightly greater than nitrogen fixation.

412 Ambient environmental conditions recorded in the incubation chambers at the start of  
413 the experiment on day -1, during light and dark periods, are presented in Table S1. There  
414 were no significant differences in the dark or net fluxes of any of the nutrients between  
415 treatments on day -1; except, the  $\text{NH}_4^+$  fluxes during light incubations which were  
416 significantly different (one-way ANOVA;  $F_{(2, 9)} = 12.73$ ,  $p = 0.002$ ; Fig. S2). The In  
417 chambers had a significantly higher  $\text{NH}_4^+$  efflux of  $115.32 \pm 11.43 \mu\text{mol m}^{-2} \text{ h}^{-1}$  compared  
418 with an uptake of  $-9.77 \pm 11.82 \mu\text{mol m}^{-2} \text{ h}^{-1}$  in the -C treatment. The +C treatment had  
419 intermediary values with a mean  $\text{NH}_4^+$  efflux of  $56.03 \pm 25.54 \mu\text{mol m}^{-2} \text{ h}^{-1}$ .  $\text{NH}_4^+$  had the  
420 highest flux rate throughout the experiment (

421 Fig. 2b) with mean efflux significantly higher in the +C chambers during light  
422 incubations compared with the -C treatment ( $182.25 \pm 120.77$  vs.  $83.90 \pm 26.70 \mu\text{mol m}^{-2} \text{ h}^{-1}$ ,  
423 t-test;  $t = 2.93$ ,  $p = 0.005$ ; Fig. 2b). Sediment-water exchange of  $\text{NO}_2^-$ ,  $\text{NO}_x$  and  $\text{PO}_4^{3-}$  were

424 unaffected by carbon addition. Mean fluxes of  $\text{NH}_4^+$ ,  $\text{NO}_2^-$  and  $\text{PO}_4^{3-}$  were positive  
425 irrespective of diel cycle, indicating net release from the sediment (

426 Fig. 2a-c); however,  $\text{NO}_x$  fluxes were variable with opposing trends in light, dark and  
427 net fluxes between treatments (

428 Fig. 2d). As both dissolved oxygen consumption and  $\text{NH}_4^+$  production were higher in  
429 the +C chambers this indicates an overall increase in benthic metabolism during daylight.

### 430 **3.3 Sediment characteristics and remineralisation ratios**

431 The sediment organic carbon (OC) content decreased in the experimental treatments  
432 after 14 days compared to the initial treatment (Fig. 3a). The largest decrease was observed at  
433 the 1.0 – 2.0 cm and 2.0 – 4.0 cm depth intervals spanning the approximate depth of the oxic-  
434 anoxic interface; one of the most active zones of organic matter mineralisation by  
435 heterotrophic microorganisms (Reimers et al., 2013). Vertical profiles of total nitrogen (TN)  
436 and the C:N on days zero and 14 followed a similar trend with the most marked changes  
437 occurring at the 1.0 – 2.0 cm and 2.0 – 4.0 cm depth intervals respectively. Carbon addition  
438 did not affect the OC or TN but sediment depth significantly influenced the OC (mixed  
439 model ANOVA,  $F_{(4, 20)} = 3.54$ ,  $p = 0.024$ ; Fig. 3a) and TN content (mixed model ANOVA,  
440  $F_{(4, 20)} = 3.37$ ,  $p = 0.029$ ; Fig. 3b), being significantly lower at the 1.0 - 2.0 cm depth interval  
441 with mean values of  $0.24 \pm 0.02$  % (OC) and  $0.03 \pm 0.00$  % (TN) respectively. This confirms  
442 that the oxic-anoxic interface supported the highest rates of organic matter mineralisation. In  
443 contrast, the deepest sectioned interval (4.0 – 6.0 cm) had significantly higher OC ( $0.51 \pm$   
444  $0.08$  %) and TN content ( $0.07 \pm 0.01$  %) than the shallower intervals. Carbon addition did not  
445 significantly increase the sediment C:N in the +C treatment ( $7.90 \pm 0.27$ ) compared to the -C  
446 treatment ( $7.12 \pm 0.24$ ; mixed model ANOVA,  $F_{(1, 20)} = 4.52$ ,  $p = 0.054$ ; Fig. 3c). However,  
447 carbon supplementation resulted in mean remineralisation ratios (after exclusion of outliers)  
448 of  $15.68 \pm 7.43$  that were approximately threefold higher than chambers receiving  
449 aquaculture waste only ( $5.64 \pm 4.50$ ), although the difference was not significant (t-test;  $t =$   
450  $1.08$ ,  $p = 0.32$ ). Remineralisation ratios were higher than the sediment C:N in the +C  
451 treatment; a trend that is consistent with nitrogen assimilation by heterotrophic bacteria,  
452 including nitrogen fixation (Eyre et al., 2013b). Conversely, in the -C treatment receiving raw  
453 aquaculture waste at a C:N of 5:1, the remineralisation ratios were lower than the sediment  
454 C:N, indicating net release of nitrogen.

### 455 **3.4 Microbial community analysis and nitrogen metabolism functional gene prediction**

456 A total of 781,701 16S rRNA reads were generated. Four samples from one replicate  
457 of the In treatment were removed during sub-sampling due to a low abundance of reads, and  
458 therefore excluded from further analysis. A total of 780,612 sequences in the 41 samples  
459 remained subsequent to quality control, primer trimming, size exclusion, and removal of  
460 unassigned taxons, mitochondria and Eukaryota.

461 Neither carbon addition, sediment depth nor the interaction between the factors  
462 (treatment  $\times$  sediment depth) significantly affected the number of sequences, OTUs  
463 (observed species), community richness (Chao and ACE), or diversity measured as Simpson  
464 and Inverse Simpson indices (mixed model ANOVA;  $p < 0.05$ ; Fig. 4). Sediment depth  
465 significantly influenced Shannon diversity, with the highest diversity of 2.85 recorded in the  
466 sediment surface layer (0 - 0.5 cm) and the lowest (1.54) in the 4 - 6 cm layer (mixed model  
467 ANOVA;  $F_{(4, 26)} = 3.14$ ,  $p = 0.031$ ).

468 Flow cytometry data compared relatively well with the 16S rRNA amplicon  
469 sequencing data. Bacterial abundance (cells  $g^{-1}$ ; Fig. 3e), the number of sequences and OTUs  
470 were higher in the In chambers than the experimental chambers sampled on day 14,  
471 presumably in response to grazing by the sea cucumbers. The number of OTUs decreased  
472 from  $286.81 \pm 128.13$  in the In chambers to  $176 \pm 65.15$  and  $181.20 \pm 45.90$  in the +C and -C  
473 treatments respectively. Overall, the community diversity was low: Shannon diversity =  $2.31$   
474  $\pm 0.13$ , Inverse Simpson =  $5.79 \pm 0.51$ . There was a marked increase in community richness  
475 at the 1 - 2 cm depth interval, coinciding with the oxic-anoxic interface. In the In chambers  
476 the number of OTUs was  $778.00 \pm 731.00$ , compared with  $343.33 \pm 199.25$  and  $322.67 \pm$   
477  $307.25$  in the +C and -C treatments respectively. The Chao 1 richness indicator also followed  
478 this trend (Fig. 4).

479 The majority of sequences (99.8 %) were assigned to the Bacteria, with only 0.12 %  
480 assigned to Archaea. Taxa from three archaeal phyla were present, including Euryarchaeota,  
481 Thaumarchaeota and Woesearchaeota. *Natronorubrum* (Euryarchaeota), a halophilic aerobic  
482 chemoorganotroph (Xu et al., 1999), was the most abundant genus representing 14 of the 27  
483 archaeal reads.

484 The bacterial community contained a total of 18 phyla, four candidate phyla and the  
485 candidate division WPS-2. Proteobacteria and Firmicutes were the two dominant phyla  
486 accounting for 47.64 and 34.71 % of the total sequences respectively, with Cyanobacteria  
487 accounting for 7.42 %. Planctomycetes (2.45 %), Actinobacteria (2.34 %), unclassified  
488 Bacteria (2.12 %) and Bacteroidetes (1.33 %) were minor components. The remainder of the

489 phyla, candidate phyla and the candidate division WPS-2 each represented less than 1 % of  
490 the community. Candidate phyla included Hydrogenedentes (formerly NKB19),  
491 Latesbacteria (formerly WS3), Parcubacteria (formerly OD1) and Poribacteria.

492 Taxa within the Oxalobacteraceae and the genus *Herbaspirillum* were significantly  
493 more abundant in the -C treatment (Welch's two-sided t-test;  $p < 0.05$ ; Fig. 5). In  
494 comparison, the genera *Blastopilella* and *Litorilinea* were significantly enriched in the +C  
495 treatment. There were no significant differences in the mean proportion of taxa between  
496 experimental treatments at phylum, class or order levels, underscoring the high degree of  
497 similarity among the microbial communities between treatments (Fig. 6). Further, there was  
498 no correlation between the microbial community and environmental data (Mantel test;  $r =$   
499  $0.04$ ,  $p = 0.27$ ). The first axis in the PCoA ordination explained 53.4 % of the variation and  
500 appeared to be associated with sediment depth, while the second axis (4.7 % of the variation)  
501 appeared to be associated with experimental treatment. Treatment did not significantly  
502 influence microbial community structure (PERMANOVA;  $p < 0.05$ ; Table 2), which may be a  
503 function of the relatively short duration of the experiment. By contrast, there was a  
504 significant effect of sediment depth on the microbial community (PERMANOVA;  $p = 0.011$ ;  
505 Table 2).

506 There were no significant differences in the predicted relative abundance of genes  
507 involved in the six nitrogen transformation pathways (mixed model ANOVA;  $p > 0.05$ ; Fig.  
508 7). The relative abundance of predicted nitrification genes peaked at the 0.5 – 1.0 cm depth  
509 interval in the -C treatment, coinciding with the oxic zone. In the +C treatment, the relative  
510 abundance of predicted denitrification and DNRA genes were higher in the sediment layers  
511 sectioned at 1.0 – 2.0, 2.0 – 4.0 and 4.0 – 6.0 cm. Overall, DNRA was the dominant pathway  
512 ( $20.52 \pm 0.01$  %) predicted to occur in all treatments and sediment depths, with the exception  
513 of the surface layer (0.0 - 0.5 cm) in the +C treatment, where there was a higher predicted  
514 relative abundance of denitrification genes (Fig. 7). Denitrification was the second most  
515 abundant predicted pathway ( $18.02 \pm 0.01$  %), followed by complete nitrification ( $8.80 \pm$   
516  $0.43$  %), indicating that the potential for coupled nitrification-denitrification was present in  
517 all treatments. Genes predicted to be involved in nitrogen fixation represented  $2.85 \pm 0.32$  %.

#### 518 **4. Discussion**

519 Effluent (especially particulates) discharged from intensive land-based aquaculture  
520 can impact the marine benthos through the organic enrichment of the underlying sediment. In  
521 this study, the comparison of vertical sediment profiles before and after the experiment

522 indicated that the addition of particulate aquaculture waste to treatments with sea cucumbers  
523 stocked at densities of  $>1 \text{ kg m}^{-2}$  did not increase the organic carbon content, total nitrogen or  
524 C:N. Overall, the values were generally lower after 14 days of daily waste addition than at  
525 the start. This is consistent with previous studies that concluded that sea cucumbers are  
526 efficient bioturbators that stimulate benthic microbial metabolism and organic matter  
527 remineralisation and may partly ameliorate the effects of organic matter enrichment from  
528 aquaculture effluent (MacTavish et al., 2012).

529 It was hypothesised that increasing the C:N would mediate a shift from  
530 ammonification (net release) to  $\text{NH}_4^+$  assimilation (net uptake), leading to an overall decrease  
531 in  $\text{NH}_4^+$  efflux, however, net  $\text{NH}_4^+$  production was higher in +C treatment. In addition to sea  
532 cucumber excretion,  $\text{NH}_4^+$  can originate from four nitrogen transformation pathways;  
533 ammonification (degradation of organic nitrogenous waste), nitrogen fixation, assimilatory  
534 reduction of nitrate to ammonia (ARNA), and dissimilatory nitrate reduction to ammonia  
535 (DNRA). ARNA and nitrogen fixation are both assimilatory pathways that occur within  
536 organisms, and therefore do not contribute to an increase in  $\text{NH}_4^+$  concentration at the  
537 sediment-water interface (Gardner et al., 2006). Ammonification and DNRA are therefore the  
538 only pathways with the potential to contribute to increased  $\text{NH}_4^+$  production in the +C  
539 treatment. The increased  $\text{NH}_4^+$  concentration may have originated from an increase in  
540 ammonification consistent with the increase in metabolism observed in the +C treatment.

541 An increasing number of studies have demonstrated the importance, and indeed  
542 dominance of DNRA in nearshore shallow water coastal environments, particularly in  
543 tropical ecosystems (Decleyre et al., 2015; Fernandes et al., 2012; Gardner et al., 2006; Song  
544 et al., 2014; Erler et al., 2013). For example, Fernandes et al. (2012) showed that DNRA can  
545 account for 99 % of nitrate removal in nitrogen-limited mangrove ecosystems. In marine  
546 sediments, DNRA and denitrification compete for nitrate; however, denitrification results in  
547 the permanent removal of nitrogen from the system whereas DNRA retains bioavailable  
548 nitrogen in sediments by reducing nitrate to  $\text{NH}_4^+$  (Gardner et al., 2006). Since these nitrogen  
549 transformation processes are reductive pathways, mediated by heterotrophic bacteria in the  
550 anaerobic zone of redox-stratified sediments, carbon addition can stimulate both  
551 denitrification and DNRA (Hardison et al., 2015). In some aquaculture systems the  
552 availability of organic carbon is known to limit  $\text{N}_2$  production via denitrification (Castine et  
553 al., 2012); therefore, carbon supplementation is employed to successfully operate denitrifying  
554 filters (Castine, 2013; Roy et al., 2010). However, Castine (2013) found no significant  
555 differences in  $\text{N}_2$  production when aquaculture slurries were amended with particulate

556 organic matter or methanol as carbon sources. Other studies have found that high organic  
557 loading rates and/or the addition of exogenous carbon sources stimulated DNRA and  
558 concluded that high organic carbon loading is a pre-requisite for DNRA to be favoured over  
559 denitrification (Hardison et al., 2015; Capone, 2000). In the present study, the higher  $\text{NH}_4^+$   
560 efflux in the +C treatment, supported by the metagenome predictions and the uptake of  $\text{N}_2$   
561 gas, would suggest that organic carbon addition stimulates DNRA over denitrification.

562         Increasing the organic carbon availability can potentially stimulate all four nitrogen  
563 reduction pathways (supplementary Fig. 2). These pathways, with the exception of  
564 denitrification, result in ammonia production and therefore contribute to nitrogen retention  
565 within the system (Hardison et al., 2015). The factors regulating the balance between the  
566 different nitrogen processes are not well understood. For example, the quality and quantity of  
567 organic carbon may influence the balance between denitrification and nitrogen fixation  
568 (Fulweiler et al., 2013). Historically, denitrification has been considered to be the main  
569 pathway of nitrogen loss, based on mass balance calculations (Seitzinger, 1988). However, in  
570 sediment-based systems enriched with particulate organic waste (such as settlement ponds in  
571 aquaculture systems), the processes of permanent nitrogen removal account for a very small  
572 fraction of the total nitrogen that is permanently removed from the system. For example,  
573 Castine et al. (2012) found that denitrification and anammox only removed 2.5 % of total  
574 nitrogen inputs to settlement ponds in intensive shrimp and barramundi farms.

575         Sediment nitrogen fixation can equal or exceed  $\text{N}_2$  loss in estuarine systems (Newell  
576 et al., 2016a). The genetic potential for nitrogen fixation is widespread within the Bacteria  
577 and Archaea (Newell et al., 2016b; Zehr and Paerl, 2008a). Heterotrophic nitrogen fixation  
578 has not been widely demonstrated in sediments beyond the observation of  $\text{N}_2$  uptake (Gardner  
579 et al., 2006); however, recent studies provide direct evidence by measuring *in situ*  $\text{N}_2$   
580 production combined with molecular and genomic tools to quantify the presence of the  
581 nitrogenase reductase (*nifH*) gene (Newell et al., 2016b; Baker et al., 2015). Indirect evidence  
582 for nitrogen fixation is provided in the present study by the presence of *nifH* (K02588) in all  
583 samples and the taxonomic composition of the microbial communities.

584         Nitrogen fixation can be mediated by photoautotrophic and heterotrophic diazotrophs.  
585 Heterotrophic diazotrophs, including Gammaproteobacteria and Group A cyanobacteria, are  
586 the dominant nitrogen-fixing organisms in oceanic and estuarine systems (Halm et al., 2012;  
587 Bentzon-Tilia et al., 2015). In this study, Cyanobacteria was the third most abundant phylum.  
588 In the rhizosphere of seagrass beds most nitrogen fixation is mediated by sulphate-reducing  
589 bacteria (Welsh et al., 1996). The Deltaproteobacteria, which contains most of the sulphate-

590 reducing bacteria, represented a very small proportion (<0.5 %) of the community; however,  
591 Firmicutes were the second most abundant phylum, demonstrating that taxa capable of  
592 nitrogen fixation were present (Zehr and Paerl, 2008b).

593         The addition of exogenous carbon sources including glucose, sucrose and lactose, has  
594 been found to stimulate heterotrophic nitrogen fixation in cyanobacteria and sulphate  
595 reducing bacteria (Welsh et al., 1997; Newell et al., 2016a). The +C treatment exhibited an  
596 overall net N<sub>2</sub> uptake whereas the control receiving waste only exhibited net N<sub>2</sub> production,  
597 indicating that carbon supplementation enhanced nitrogen fixation. Similar to DNRA and  
598 denitrification, the rates of heterotrophic nitrogen fixation in coastal marine sediments are  
599 frequently limited by organic carbon availability (Welsh et al., 1997; Newell et al., 2016a).

600         Benthic incubation chambers integrate the exchange of gases and nutrients across the  
601 sediment-water interface; thus, while many reactions may be occurring within the sediments,  
602 the net outcome of sediment reactions are translated into benthic fluxes. It was anticipated  
603 that combining this traditional approach with next generation sequencing would elucidate the  
604 response of sediment microbial communities to carbon addition by highlighting shifts in  
605 taxonomy and functional potential. Benthic flux incubations detected a significant  
606 enhancement of NH<sub>4</sub><sup>+</sup> production during light incubations in response to carbon  
607 supplementation; however, no statistically significant differences in the microbial community  
608 or predicted nitrogen transformation pathways were observed. Robinson et al. (2016) showed  
609 that increasing the availability of rate-limiting electron acceptors (oxygen) had a marked  
610 effect on the sediment microbial taxonomic composition, structure, metabolic capacity and  
611 functional potential. In contrast, increasing the availability of potential electron donors  
612 through carbon supplementation did not significantly affect the microbial community  
613 structure. Significant variations at different sediment depths was likely due to the partitioning  
614 of processes within the oxic and anoxic layers. None of the environmental parameters,  
615 sediment characteristics, and gas or nutrient fluxes were significantly correlated with  
616 microbial community structure and no significant differences were observed in the relative  
617 abundance of predicted genes involved in the major nitrogen transformation pathways.

618         The benthic nitrogen cycle is one of the most complex biogeochemical cycles,  
619 characterised by a diverse set of dissimilatory microbial processes (Thamdrup and Dalsgaard,  
620 2008). The lack of significant changes in microbial community structure and functioning may  
621 indicate that processes that contribute NH<sub>4</sub><sup>+</sup> to the sediment were operating concurrently with  
622 transformations that removed NH<sub>4</sub><sup>+</sup> from the system, such as anammox and coupled  
623 nitrification-denitrification. Furthermore, organic carbon can fulfil many functions under

624 reducing conditions: as an electron donor in redox reactions; a substrate for fermentation; or  
625 as an organic substrate assimilated by heterotrophic bacteria coupled with  $\text{NH}_4^+$  uptake. The  
626 dual biogeochemical-molecular approach holds promise to further our understanding of  
627 nitrogen cycling, the challenge remains to resolve net biogeochemical fluxes with molecular  
628 tools that define microbial communities.

629 Our findings indicate that carbon addition may partly bioremediate nitrogen-rich  
630 effluent by retaining nitrogen within the system, however longer-term trials are necessary to  
631 determine whether this translates into improved sea cucumber biomass yields. In the current  
632 study, the sea cucumbers decreased in mass with growth rates of  $0.02 \text{ g}\cdot\text{day}^{-1}$ , however there  
633 was no significant difference in mean wet weight of the sea cucumbers at the start or end of  
634 the experiment. Two key factors are likely to have accounted for the differences in growth  
635 performance of *Holothuria scabra* in the present study and the previous study of Robinson et  
636 al. (*in review*). Firstly, chambers were shaded from direct sunlight in this experiment to  
637 mitigate against water temperature spikes that would likely have caused hypoxia in the small  
638 sealed chambers. However, because high light levels may be important for *Holothuria scabra*  
639 growth (Battaglione et al. 1999), this may have resulted in the lower growth  
640 performance. Secondly, the duration over which the sediment microbial community was  
641 allowed to develop differed between the studies. In Robinson et al. (*in review*) the trials  
642 lasted 112 days compared with the current 28 day study (14 day preconditioning and 14 day  
643 experimental).

644

## 645 **5. Conclusion**

646 Pathways that support retention of nitrogen in sediments can dominate over pathways  
647 for permanent removal (Newell et al., 2016a), particularly in tropical ecosystems such as  
648 seagrass and mangrove systems (the natural habitat of *H. scabra*). This imbalance between  
649 denitrification and nitrogen fixation is partially responsible for nitrogen limitation in these  
650 systems (Fulweiler et al., 2013; Newell et al., 2016b). Thus, DNRA and heterotrophic  
651 nitrogen fixation are important processes for retaining nitrogen and sustaining ecosystem  
652 productivity (Fernandes et al., 2012; Enrich-Prast et al., 2016; Decleyre et al., 2015). In  
653 shallow euphotic sediments, these processes are likely important for overcoming nitrogen  
654 limitation and competition with benthic microalgae and cyanobacteria, by recycling and  
655 retaining  $\text{NH}_4^+$  in the sediment. The increase in  $\text{NH}_4^+$  efflux combined with net uptake of  $\text{N}_2$   
656 into the sediment in response to carbon addition indicates that under nutrient loading rates

657 consistent with hypereutrophic estuaries ( $400 \text{ mmol C m}^{-2} \text{ day}^{-1}$  and  $240 \text{ N m}^{-2} \text{ day}^{-1}$ ; Eyre  
658 and Ferguson, 2009), pathways that retained nitrogen dominated over pathways of permanent  
659 removal, underscoring the immense capacity of sediments for assimilating nitrogen from  
660 land-based intensive aquaculture systems.

661 The coupled biogeochemical-molecular approach was useful in providing an  
662 overview of the functional potential for different nitrogen cycling pathways; however, given  
663 the complexity of nitrogen cycling in marine sediments, future studies should include more  
664 disparate C/N treatments of longer duration and measure all individual processes including  
665 denitrification, anammox, DNRA and nitrogen fixation. Furthermore, the use of more  
666 targeted molecular approaches, such as metagenomic shotgun sequencing or quantitative  
667 polymerase chain reaction (qPCR) in conjunction with stable isotope labelling studies (e.g.  
668 Eyre et al. 2016) are recommended to fully elucidate the pathways of nitrogen cycling in  
669 response to C:N manipulation.

882

883 **Figure legends**

884 **Fig. 1.** Mean ( $\pm$  standard error) net fluxes (in  $\mu\text{mol m}^{-2} \text{h}^{-1}$ ;  $n = 5$ ) of: a) dissolved oxygen  
885 (DO); b) dissolved inorganic carbon (DIC); c) dinitrogen gas ( $\text{N}_2$ ); and, d) gross primary  
886 production (GPP) in incubation chambers containing sea cucumbers and aquaculture waste  
887 with (+C) or without (-C) carbon addition, incubated under light and dark conditions between  
888 day 1 and day 13.

889 **Fig. 2.** Mean ( $\pm$  standard error) benthic light, dark and net fluxes (in  $\mu\text{mol m}^{-2} \text{h}^{-1}$ ;  $n = 5$ ) of:  
890 a) phosphate ( $\text{PO}_4^{3-}$ ); b) ammonium ( $\text{NH}_4^+$ ); c) nitrite ( $\text{NO}_2^-$ ); and d) nitrate and nitrite ( $\text{NO}_x$ )  
891 in incubation chambers containing sea cucumbers and aquaculture waste with (+C ) or  
892 without (-C) carbon addition, incubated under light and dark conditions between day 1 and  
893 day 13.

894 **Fig. 3.** Vertical depth profiles of sediment characteristics: a) organic carbon; b) total nitrogen;  
895 c) carbon to nitrogen ratio (C:N); d) total carbohydrate; and, e) bacterial abundance. Cores  
896 were sectioned on day zero prior to the addition of aquaculture waste (initial; In) and after  
897 waste addition, both with and without carbon supplementation (carbon and no carbon  
898 respectively) on day 14.

899 **Fig. 4.** Alpha diversity metrics calculated on subsampled data. Observed = the number of  
900 operational taxonomic units (OTUs); ACE = abundance-coverage estimator; InvSimpson =  
901 Inverse Simpson diversity metric.

902 **Fig. 5.** The mean proportion (%) and the difference in the mean proportion of taxa at: a)  
903 family and b) genus level between +C and -C treatments with 95 % confidence intervals.  
904 Significant differences in mean proportions were determined using two-sided Welch's t-tests  
905 ( $\alpha = 0.05$ ).

906 **Fig. 6.** Principal Component Analysis ordination of the microbial community structure  
907 between the initial (In), +C and -C treatments at the five sediment depth intervals performed  
908 on a Bray-Curtis community dissimilarity matrix.

909 **Fig. 7.** Vertical depth profiles of the predicted relative abundance of genes involved in the six  
910 nitrogen transformation pathways: a) nitrogen fixation; b) dissimilatory nitrate reduction to  
911 ammonium (DNRA); c) assimilatory nitrate reduction; d) denitrification; e) complete

912 nitrification; and, f) nitrification, under the pathway module of nitrogen metabolism in the  
913 Kyoto Encyclopaedia for Genes and Genomes (KEGG) database.

914

915

916

917

918 **Table 1.** Description of the experimental treatments. The presence (✓) or absence (x) from  
 919 day zero of aquaculture waste, added carbon source or sea cucumbers is indicated.

Treatment	Treatment code	No of replicates	Aquaculture waste	Sea cucumber	Carbon source	C:N
Initial	In	5	x	x	x	n/a
No added carbon	-C	5	✓	✓	x	5:1
Added carbon	+C	5	✓	✓	✓	20:1

920

**Table 2.** Results of a non-parametric multivariate analysis of variance (PERMANOVA) testing the differences in microbial community structure at the five sediment depths prior to the addition of aquaculture waste (In) and after waste addition, both with and without carbon supplementation.

	<b>df</b>	<b>SS</b>	<b>Mean squares</b>	<b>F model</b>	<b>R<sup>2</sup></b>	<b>p</b>
Treatment (T)	2	0.797	0.399	1.195	0.058	0.115
Sediment depth (D)	4	1.705	0.426	1.278	0.123	0.011
T × D	8	2.656	0.332	0.996	0.192	0.494
Residuals	26	8.672	0.334		0.627	
Total	40	13.830			1.000
