

Dear Dr. Sébastien Fontaine,

Thank you and the reviewers very much for the kind and irradiative comments on our manuscript entitled “*Nitrogen isotopic composition of plants and soil in an arid mountainous terrain: sunny slope versus shady slope*” (The revised title is “Nitrogen isotopic composition of plants and soil in an arid mountainous terrain: south slope versus north slope”, bg-2017-313). These comments are valuable and very helpful for the improvement of our manuscript.

We have revised our manuscript after carefully reading the comments. **The revised parts were marked in red color in the “marked-up manuscript version”**. The detailed replies or explanations on the comments were given on the following pages.

We wish this revised manuscript meet the demands for publication in “*Biogeosciences*”. Thank you again!

Best regards

Yours sincerely,

Guoan Wang

E-mail address: gawang@cau.edu.cn

**Answers to the questions:**

-----

**Reviewer #1:**

**1. Response to comment 1,** The reasoning behind different results and the varying environmental factors determining them on two slopes is not clear. In addition, the correlation of various environmental factors with the  $\delta^{15}\text{N}$  of leaf and soil is very ambiguous and unexplained. I would suggest to authors that the environmental factors and the response variables should be tested with principal component analysis(es) to get a clearer picture.

**Answer:** Special thanks to you for your good comment. According to your advice, we tested all variables using principal component analysis, the results was displayed in the following figure. In principal component analyses, PC1 and PC2 could represent soil conditions and plant traits (especially leaf N content), respectively. The results of principal component analyses (Fig. 4) seem consistent with correlation analyses (please see the following Tables 3 and 4). On the north slope, leaf N content had strong positive while leaf C/N had negative effects on leaf  $\delta^{15}\text{N}$ , MAT and MAP also exerted influences on leaf  $\delta^{15}\text{N}$ , however, soil factors almost did not affect leaf  $\delta^{15}\text{N}$  except silt/clay ratio and soil moisture. Both MAT and MAP had large loadings on soil  $\delta^{15}\text{N}$ , meanwhile, soil  $\delta^{15}\text{N}$  increased with decreasing silt/clay ratio and increasing soil moisture. Compared with the north slope, representation of PC1 and PC2 on the south slope was clearer. Leaf  $\delta^{15}\text{N}$  was primarily correlated with leaf C/N, soil  $\delta^{15}\text{N}$  was significantly controlled by MAP and soil moisture, which might be due to arid environment on the south slope. Principal component analyses and correlation analyses both supported our argument that the relationships between leaf and soil  $\delta^{15}\text{N}$  and environmental factors are localized (lines 216-218, 245-248, 250-252, 276-278, 616-621).

**2. Response to comment 2,** The location of the two observatories on shady slope covers almost the whole range of the sampling gradient. However, on the sunny slope the two observatories merely cover half of the total gradient of the altitude sampled. How would the authors justify the use of climate data obtained from these observatories for the entire gradient of the altitude sampled and studied?

**Answer:** Your comment is right! In this paper, MAT and MAP were interpolated by two observations on each slope. We have to admit that the interpolated climatic data might be not very reliable, but we have no better ways to obtain more reliable climatic data. It is well known that this is also the greatest difficulty that the researchers studying global changes encounter. In fact, the case that two observations distributed at each slope is very rare in the world, and this is also one reason why we conducted the investigation here.

**3. Response to comment 3,** L48: localized is a better word that “local-dependent”.

**Answer:** Thanks, “local-dependent” has been changed to “localized” in revised manuscript (lines 48, 107, 321).

**4. Response to comment 4,** Various instead of varied.

**Answer:** Thanks, “varied” has been changed to “various” in revised manuscript (lines 316).

**5. Response to comment 5,** L316-320: Should the plant not discriminate against the heavier isotope during N uptake, even if it’s very low, thereby resulting in low leaf  $^{15}\text{N}$  signature, when higher N uptake is the routine?

**Answer:** Sorry. We did not offer a clear explanation in the original manuscript. We did changes for this in the new version. The explanation is as follows. This is a widely accepted fact that plants are depleted in  $^{15}\text{N}$  relative to its N sources because of  $^{15}\text{N}$  discrimination, but in this paper, we

meant that the plants grown in N-limited environments will enrich more  $^{14}\text{N}$  compared with the plants in N-rich condition. The reason is that soil N transformations, such as  $\text{NH}_3$  volatilization and  $\text{NO}_x$  emission are enhanced when soil N nutrient is rich, consequently, more  $^{14}\text{N}$  losses from soil. This causes  $^{15}\text{N}$  enrichment in soil, subsequently, plant  $\delta^{15}\text{N}$  is more positive. Conversely, plants have more negative  $\delta^{15}\text{N}$  values when soil N is limited because of weak soil N transformations and less  $^{14}\text{N}$  loss (lines 331-339).

**6. Response to comment 6**, L336-340: This explanation presented here just says that cold temperature caused high leaf  $\delta^{15}\text{N}$  on shady slope. But how ?

**Answer:** Sorry. We did not present a detailed mechanism for this (a positive effect of temperature on the north slope) in the manuscript, and the reason is that we are not sure about the mechanism. The probable mechanism is that higher temperature favors more complete plant nitrogen assimilation and transformation, which might decrease isotopic fractionation during N assimilation and transformation, then causes  $^{15}\text{N}$  enrichment in plants. We will add the probable mechanism in the new version (lines 355-369, 511-512, 539-544).

**Reviewer #2:**

**1. Response to comment 1**, The paper would be clearer if the authors referred to north- and south-facing slopes, not sunny and shady. If this is wrong, the authors need to describe how a slope was determined to be either sunny or shady.

**Answer:** According to the reviewer's comment, we have changed shady and sunny slope to north and south slope throughly in revised manuscript.

**2. Response to comment 2**, The authors interpolate mean annual temperature and mean annual precipitation for each site from measurements of MAT and MAP from 4 climate stations, two of which are sunny and two of which are shady. This is not valid. The authors sites are varying by a number of factors that cannot be "interpolated" from just 4 points. Stating that sunny sites are warmer than shady sites will need other data. One recommendation would be to simply remove the MAT and MAP regressions/correlations and examine other factors.

**Answer:** In this paper, MAT and MAP were interpolated by two observations on each slope. We have to admit that the interpolated climatic data might be not very reliable, but we have no better ways to obtain more reliable climatic data. In fact, the case that two observations distributed at

each slope is very rare in the world. Although the obtained climatic data were not very reliable, we think it is necessary to remain the regressions/correlations between  $\delta^{15}\text{N}$  and MAT and MAP in this paper. The reason is that, MAT and MAP effects on leaf and soil  $\delta^{15}\text{N}$  at global scale are different from that at regional scale, this led to our argument (hypothesis) that environmental effects on leaf and soil  $\delta^{15}\text{N}$  could depend on local environment, thus, a comparative study between the south and north slope with significant differently climate conditions was conducted. The regressions/correlations between  $\delta^{15}\text{N}$  and MAT and MAP in this study did confirm our argument. If the MAT and MAP regressions/correlations were removed, our argument (hypothesis) will loss supports. Lacking reliable climatic data is a universal and most trouble for the researchers studying global change and biogeochemistry cycles. Although the regressions/correlations between  $\delta^{15}\text{N}$  and MAT and MAP obtained in this study could be not perfect or reliable due to lacking accurate climatic data, we believe that the present study is also a small progress in science because we first put forward this argument (hypothesis), and confirm it. We hope more researchers to follow it.

Besides climatic data, vegetation types and species provide a strong support for the warmer climate on the south slope than the north slope. The main species occurred on the south slope were *Ephedra sinica*, *Stipa grandis*, *Stipa capillata*, *Achnatherum splendens*, *Nitraria tangutorum*, *Caragana sinica*, and *Suaeda glauca*, all these plants are typical xerophyte species, and they were not found on the north slope. On the north slope, the main species included *Kobresia myosuroides*, *Carex enervis*, *Poa annua* and *Thalictrum aquilegifolium*, they all are not xerophyte species. The information was added in the revised version (lines 139-140, 147-149).

**3. Response to comment 3,** The authors interpret the difference of leaf and soil delta 15N as "as the isotopic composition of plant-available N". There is no empirical evidence for this. Given the results of Craine et al. 2015 that examines global patterns of soil 15N, there is unlikely to be evidence that the signature of available N is controlled by soil delta 15N. Soil delta 15N at broad scales is likely simply an index of decomposition of the soil organic matter. Unless the authors have a reference to a graph that shows directly this relationship (delta 15N of available N vs. soil delta 15N) this statement is poorly supported.

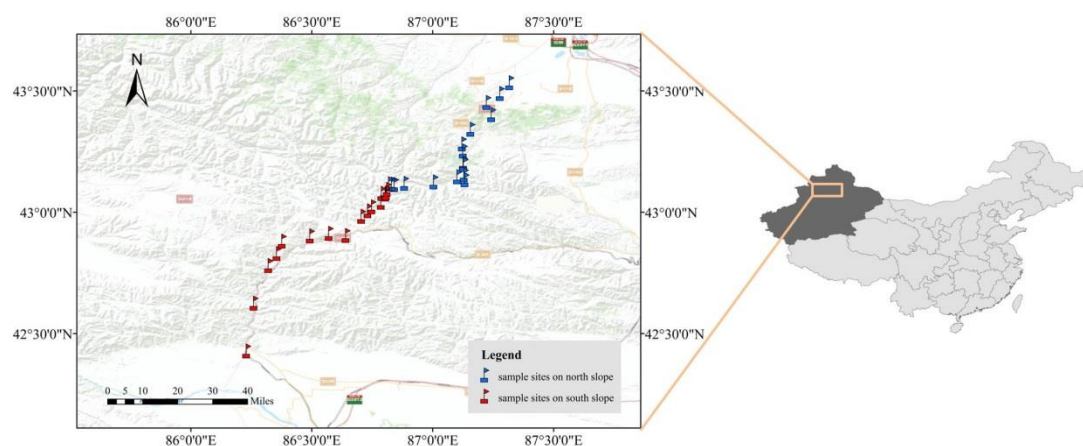

**Answer:** Amundson et al. (2003) suggested that  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  could be interpreted as the isotopic composition of plant-available N provided that isotopic discrimination does not occur during plant

uptake and assimilation. In the present study, we found a highly correlation between leaf  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  both on the two slopes, which is consistent with the result in Craine et al. (2009). As we all recognized, leaf  $\delta^{15}\text{N}$  is a good indicator of plant N sources characteristics. Thus, the relationship between leaf  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  could provide a powerful support for the suggestion in Amundson et al. (2003).

Besides, even though there was no direct evidence to support the relationship between  $\delta^{15}\text{N}$  of bulk soil N and  $\delta^{15}\text{N}$  of available N, the statement that soil  $\delta^{15}\text{N}$  could be used to index the soil N availability had been widely accepted (McLauchlan et al., 2007; Högberg, 1997). The mechanism was that, high soil N availability leads to increased soil N transformation, such as nitrification, denitrification and  $\text{NH}_3$  volatilization, which discriminates against  $^{15}\text{N}$  and causes  $^{15}\text{N}$ -enrichment in soil. Thus, ecosystems with high N availability exhibit high  $\delta^{15}\text{N}$  values in soil (lines 303-314).

**4. Response to comment 4,** Figure 1 needs to redraw at a much larger scale, i.e over less total area. The points all overlap and it is not helpful to see where the sampling is.

**Answer:** Thank you for your advice, we have redrawn Figure 1 in revised manuscript (lines 568-575).

**Fig 1. Sketch of study area. Locations of the sampling sites are indicated with points. A total of 17 sites (blue dots) were selected on the north slope, and 16 sites (red dots) on the south slope.**

23 **Abstract**

24 Nitrogen cycling is tightly associated with environment. South slope of a given  
25 mountain could significantly differ from north slope in environment. Thus, N cycling  
26 should also be different between the two slopes. Since leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  and  
27  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  ( $\Delta\delta^{15}\text{N}_{\text{leaf-soil}} = \text{leaf } \delta^{15}\text{N} - \text{soil } \delta^{15}\text{N}$ ) could reflect the N cycling  
28 characteristics, we put forward a hypothesis that leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$   
29 should differ across the two slopes. However, such a comparative study between two  
30 slopes has never been conducted yet. In addition, environmental effects on leaf and  
31 soil  $\delta^{15}\text{N}$  derived from studies at global scale were often found to be different from  
32 that at regional scale. This led to our argument that environmental effects on leaf and  
33 soil  $\delta^{15}\text{N}$  could depend on local environment. To confirm our hypothesis and  
34 argument, we measured leaf and soil  $\delta^{15}\text{N}$  on the south and north slopes of Mount  
35 Tianshan. Remarkable environment differences between the two slopes provided an  
36 ideal opportunity for our test. The study showed that leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  and  
37  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  on the south slope were greater than that on the north slope although the  
38 difference in soil  $\delta^{15}\text{N}$  was not significant. The result confirmed our hypothesis and  
39 suggested that the south slope has higher soil N transformation rates and soil N  
40 availability than the north slope. Besides, this study observed that the significant  
41 influential factors of leaf  $\delta^{15}\text{N}$  were temperature, precipitation, leaf N, leaf C/N, soil  
42 moisture and silt/clay ratio on the north slope, whereas on the south slope only leaf  
43 C/N was related to leaf  $\delta^{15}\text{N}$ . The significant influential factors of soil  $\delta^{15}\text{N}$  were  
44 temperature, precipitation, soil moisture and silt/clay ratio on the north slope,

45 whereas on the south slope, MAP and soil moisture exerted significant effects.  
46 Precipitation exerted contrary effects on soil  $\delta^{15}\text{N}$  between the two slopes. Thus, this  
47 study supported our argument that the relationships between leaf and soil  $\delta^{15}\text{N}$  and  
48 environmental factors are **localized**.

49

## 50 **1 Introduction**

51 In natural terrestrial ecosystem, nitrogen (N) is not only the most required element,  
52 but also is usually a key limiting resource for plants (Vitousek et al., 1997), thus,  
53 studying N cycling is of vital importance. The variations of nitrogen isotope ratio  
54 ( $\delta^{15}\text{N}$ ) in plants and soil are tightly associated with many biogeochemical processes  
55 including N mineralization, ammonia volatilization, nitrification, denitrification  
56 (Högberg, 1997; Houlton et al., 2006). Mineralization produces available N,  
57 including ammonium and nitrate, which are the substrates for ammonia volatilization,  
58 nitrification and denitrification. During these processes, gaseous N loss is more  
59 likely to be depleted in  $^{15}\text{N}$ , which will cause the remaining N pool and subsequently  
60 plants to enrich  $^{15}\text{N}$  (Högberg, 1997). Additionally, the difference between leaf  $\delta^{15}\text{N}$   
61 and soil  $\delta^{15}\text{N}$  ( $\Delta\delta^{15}\text{N}_{\text{leaf-soil}} = \text{leaf } \delta^{15}\text{N} - \text{soil } \delta^{15}\text{N}$ ), which is also named enrichment  
62 factor (Emmett et al., 1998), was also suggested to be an indicator of ecosystem N  
63 cycling (Charles and Garten, 1993; Kahmen et al., 2008; Fang et al., 2011), and it  
64 was also reported to be correlated with soil N transformation rates (N mineralization  
65 or nitrification rates) (Garten and Van Miegroet, 1994). Thus, nitrogen isotopes have  
66 been widely applied in studies of terrestrial ecosystem N cycling (Handley et al.,

67 1999; Evans, 2001; Robinson, 2001; Hobbie and Colpaert, 2003; Houlton et al.,  
68 2007).

69 For a given mountain, its south slope may be significantly different from its north  
70 slope in climate and environment. It is well known that ecosystem N cycling is  
71 associated with climatic and environmental conditions (Amundson et al., 2003;  
72 Craine et al., 2009; Yang et al., 2013; Zhou et al., 2016), thus, ecosystem N cycling  
73 should vary across south and north slopes. Since leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$   
74 could reflect and indicate ecosystem N cycling, differences in leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$   
75 and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  were expected to appear between south and north slopes.  
76 Comparisons on leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  across two slopes of a  
77 mountain would provide a good insight into the response of terrestrial ecosystem N  
78 cycling to climate and environment. However, to our knowledge, such a comparative  
79 study has never been conducted yet.

80 Most of the published works consistently suggested that leaf  $\delta^{15}\text{N}$  increased with  
81 increasing mean annual temperature (MAT) and decreasing mean annual  
82 precipitation (MAP) at large regional or global scales (Austin and Sala, 1999;  
83 Amundson et al., 2003; Craine et al., 2009). However, in contrast to the commonly  
84 reported patterns, leaf  $\delta^{15}\text{N}$  was found to be negatively related to MAT in some  
85 Asian regions, e.g., in Inner Mongolian (Cheng et al., 2009) and eastern China  
86 (Sheng et al., 2014). Relative to plant  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  has been little addressed. Some  
87 studies demonstrated that soil  $\delta^{15}\text{N}$  decreased with increasing MAP and decreasing  
88 MAT at the global scale (Amundson et al., 2003; Craine et al., 2015b). However,

89 studies based on local or region scale showed inconsistent results with the global  
90 patterns. Cheng et al. (2009) reported that soil  $\delta^{15}\text{N}$  increased with decreasing MAT  
91 in Inner Mongolian. Sheng et al. (2014) showed that the soil  $\delta^{15}\text{N}$  in tropical forest  
92 ecosystems were  $^{15}\text{N}$ -depleted than in temperate forest ecosystems of eastern China.  
93 Yang et al. (2013) found that soil  $\delta^{15}\text{N}$  did not vary with either MAT or MAP on the  
94 Tibetan Plateau. Wang et al. (2014) revealed a second-order polynomial relationship  
95 between soil  $\delta^{15}\text{N}$  and aridity index across arid and semi-arid regions. The above  
96 inconsistent observations led to our argument that the relationships between  
97 environmental factors and leaf  $\delta^{15}\text{N}$  or soil  $\delta^{15}\text{N}$  would depend on local environment.  
98 Comparisons on the effects of climatic and environmental factors on leaf  $\delta^{15}\text{N}$  and  
99 soil  $\delta^{15}\text{N}$  between south and north slopes of a given mountain could test the  
100 argument.

101 This study was conducted on the south slope and the north slope of Mount  
102 Tianshan. It is an ideal place for testing our hypotheses because its south slope  
103 differs greatly from its north slope in climatic and environmental conditions (Deng et  
104 al., 2015; Zhang et al., 2016). The first objective of the present study was to confirm  
105 our hypothesis that the south slope differs from the north slope in leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$   
106 and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$ . The second objective was to test our argument that environmental  
107 effects on leaf  $\delta^{15}\text{N}$  and soil  $\delta^{15}\text{N}$  are **localized**.

108

## 109 **2 Materials and methods**

### 110 **2.1 Study area**

111 Mount Tianshan is one of the largest seven mountains over the world. It has a total  
112 length of 2500 km straddling four countries including China, Kazakhstan,  
113 Kyrgyzstan and Uzbekistan. In China, Mount Tianshan stretches 1700 km along the  
114 east-west direction in the Xinjiang Uygur Autonomous Region and covers about  
115 570,000 square kilometers and accounts for one third of the whole area. Mount  
116 Tianshan divides Xinjiang into two parts, the south of Tianshan is the Tarim Basin  
117 and the north is the Dzungaria Basin.

118 This study was conducted along an elevation transect on the north and south  
119 slopes on eastern Mount Tianshan ( $42.43^{\circ} - 43.53^{\circ}\text{N}$ ,  $86.23^{\circ} - 87.32^{\circ}\text{E}$ ) (Fig.1).  
120 Mount Tianshan is characterized by an arid mountainous climate; vertical variations  
121 in temperature and precipitation are very pronounced, temperature decreases and  
122 precipitation increases with altitude on both slopes. The north slope differs  
123 significantly from the south slope both in climate and vegetation. On the north slope,  
124 the annual mean temperature (MAT) ranges from  $-6.40^{\circ}\text{C}$  to  $3.90^{\circ}\text{C}$  with the  
125 average temperature of  $-1.85^{\circ}\text{C}$ , and the annual mean precipitation (MAP) ranges  
126 from 314 mm to 472 mm with the average precipitation of 402 mm. While on the  
127 south slope, the MAT varies from  $-5.65^{\circ}\text{C}$  to  $9.23^{\circ}\text{C}$  with the average  
128 temperature of  $1.03^{\circ}\text{C}$ , and the MAP varies from 124 mm to 308 mm with the  
129 average precipitation of 246 mm. There were four meteorological observatories  
130 along our elevation transects, two on either slope of Mount Tianshan (Table 1).

131 Fig. 1

132 Table 1

133

134 Intact and continuous vertical vegetation and soil spectrums can be observed along  
135 the two slopes. On the north slope from bottom to top, vegetation spectrum consists  
136 of upland desert (800–1100 m), upland steppe (1100–2500 m), frigid coniferous  
137 forest (1800–2700 m), subalpine meadow (2500–3300 m), alpine meadow (3000–  
138 3700 m), alpine sparse vegetation and a desert zone (3700–3900 m), and an alpine  
139 ice-and-snow zone (> 3900 m). The main species on the north slope included  
140 *Kobresia myosuroides*, *Carex enervis*, *Poa annua* and *Thalictrum aquilegifolium*. A  
141 corresponding soil spectrum on the north slope includes brown calcic soil (800–1100  
142 m), chestnut soil (1100–2500 m), mountain grey cinnamon forest soil (1800–2700  
143 m), subalpine meadow soil (2500–3300 m), alpine meadow soil (3000–3700 m) and  
144 chilly desert soil (> 3700 m). While on the south slope, it includes upland desert  
145 (1300–1800 m), arid upland steppe (1800–2600 m), subalpine steppe (2600–2800 m),  
146 alpine meadow and cushion plants (2800–3800 m), an alpine desert zone (3800–  
147 4000 m), and an alpine ice-and-snow zone (> 4000 m). The main species occurred  
148 on the south slope were *Ephedra sinica*, *Stipa grandis*, *Stipa capillata*, *Achnatherum*  
149 *splendens*, *Nitraria tangutorum*, *Caragana sinica*, and *Suaeda glauca*. The  
150 corresponding soil spectrum of the south slope consists of sierozem (1300–1800 m),  
151 chestnut soil (1800–2800 m), alpine meadow soil (2800–3800 m), and chilly desert  
152 soil (> 3800 m).

153

## 154 2.2 Plants and soil sampling

155 An altitudinal transect of 1,564 to 3,800 m above sea level (a.s.l.) was set on the  
156 north slope, and 1,300 to 3,780 m a.s.l. on the south slope. Few human habitats  
157 distribute along the two transects. Plant and soil samples were collected in July of  
158 2014. To minimize the influences of human activities, light regime, or location  
159 within the canopy, the sampling was restricted to open sites that are far from the  
160 major roads and human habitats.

161 Plants and soil were collected along the two transects at altitudinal intervals of  
162 about 100 m. Almost all plant species that we found at each sampling site were  
163 collected, and at each site, 5–7 individual plants of each species were collected and  
164 the same number of leaves was sampled from each individual plant. For shrubs and  
165 herbs, the uppermost leaves of each individual plant were collected; for tree species,  
166 8 leaves were collected from each individual, 2 leaves were collected at each of the 4  
167 cardinal directions from the positions of full irradiance, about 8–10 m above the  
168 ground. The leaves from the same species of each site were combined into one  
169 sample. Excluding N-fixing plants and mosses, a total of 90 plant samples were  
170 collected from north slope, including 72 herbs and 18 woody plants; 105 on the  
171 south slope, covering 85 herbs and 20 woody plants.

172 Surface soils (0–5cm) were collected after removing the litter layer at each  
173 sampling site. At each location, one composite soil sample was prepared by  
174 combining six subsamples randomly taken within a radius of 20 m. Sample was used  
175 to determine soil index including  $\delta^{15}\text{N}$ , N content, silt/clay ratio, pH and particle size.  
176 In addition, at each sampling site, we also collected another three soil samples using

177 a ring, which were used to measure soil bulk density and moisture.

178

### 179 **2.3 Laboratory measurements**

180 Plant and soil samples were air-dried in the field and then in the laboratory. The soil

181 samples were sieved through a 2 mm sieve to remove stones and plant residues.

182 Plant leaves and about 5 g sieved soil samples were then ground into a fine powder

183 using a steel ball mixer mill MM200 (Retsch GmbH, Haan, Germany).  $\delta^{15}\text{N}$ , N and

184 C contents in leaves, and  $\delta^{15}\text{N}$  and N contents in soil were measured on a Delta<sup>Plus</sup>

185 XP mass spectrometer (Thermo Scientific, Bremen, Germany) coupled with an

186 automated elemental analyzer (Flash EA1112, CE Instruments, Wigan, UK) in a

187 continuous flow mode at the Stable Isotope Laboratory of the College of Resources

188 and Environmental Sciences, China Agricultural University. For this measurement,

189 we obtained standard deviations of less than 0.1% for C and N contents and less than

190 0.15‰ for  $\delta^{15}\text{N}$  among replicates of the same sample.

191 The measurements of soil pH and soil particle size (clay, silt and sand content)

192 were determined using the sieved soil samples. Soil pH was measured using the pH

193 electrode in soil water suspension, with soil to water ratio of 1:2.5 (10 g soil and 25

194 mL deionized water removing carbon dioxide). Soil particle size (clay, silt and sand

195 content) was analyzed using a particle size analyzer (Malvern Masterizer 2000, UK)

196 after removing the calcium carbonates and organic matter. Soil moisture and bulk

197 density were determined after oven drying at  $105 \pm 2$  °C to a constant weight. Soil

198 moisture of each sample was the difference between its wet and dry weight divided

199 by its dry weight. Soil bulk density was the dry weight divided by the certain volume  
200 of the ring.

201

## 202 **2.4 Statistical analysis**

203 The MAT and MAP data of each sampling elevation used in the statistical analyses  
204 were generated by interpolation based on the climatic data derived from the four  
205 meteorological observatories distributed along the altitudinal transect. Statistical  
206 analyses were conducted by SPSS software (SPSS for Windows, Version 20.0,  
207 Chicago, IL, USA). One-way analysis variance (ANOVA) was used to compare leaf  
208  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  between the north and south slopes. Leaf C/N was  
209 ln- transformed to improve data normality. The relationships between  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$   
210 and leaf  $\delta^{15}\text{N}$  were performed by the linear regression on the two slopes. Leaf and  
211 soil  $\delta^{15}\text{N}$  were firstly analyzed by multiple linear regressions against all potential  
212 influential factors using ordinary least square (OLS) estimation. The potential  
213 influential factors of leaf  $\delta^{15}\text{N}$  included MAP, MAT, leaf N content, leaf C/N, soil  
214  $\delta^{15}\text{N}$ , soil N content, silt/clay ratio, soil moisture, soil bulk density and soil pH. The  
215 potential influential factors of soil  $\delta^{15}\text{N}$  consisted of MAP, MAT, soil N content,  
216 silt/clay ratio, soil moisture and soil bulk density and soil pH. Finally, **both principal**  
217 **component analysis (PCA) and correlation analysis were conducted to explore the**  
218 **complicated relationship among these factors and leaf or soil  $\delta^{15}\text{N}$ .**

219

## 220 **3 Results**

### 221 **3.1 Comparisons of $\delta^{15}\text{N}$ in leaf and soil between the north and the south slopes**

222 On Mount Tianshan, for all species pooled together, the arithmetic mean (mean  $\pm$  SE)  
223 of leaf  $\delta^{15}\text{N}$  were  $0.5 \pm 0.2\text{‰}$  and  $2.0 \pm 0.2\text{‰}$  for the plants grown on the north and  
224 the south slopes, respectively. One-way ANOVA suggested a significant difference  
225 for leaf  $\delta^{15}\text{N}$  between the north and south slopes ( $P < 0.001$ ) (Fig. 2a). The mean soil  
226  $\delta^{15}\text{N}$  of the north and south slope were  $4.1 \pm 0.4\text{‰}$  and  $5.0 \pm 0.8\text{‰}$ , respectively.  
227 One-way ANOVA showed that sampling slope exerted no significant effect on soil  
228  $\delta^{15}\text{N}$  ( $P = 0.290$ ) (Fig. 2b). The mean  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  was  $-3.6 \pm 0.3\text{‰}$  for the north  
229 slope and  $-2.4 \pm 0.3\text{‰}$  for the south slope, and one-way ANOVA suggested a  
230 significant difference in  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  between the two slopes ( $P = 0.003$ ) (Fig. 2c). In  
231 addition, this study showed that  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  was positively related to  $\delta^{15}\text{N}_{\text{leaf}}$  on the  
232 two slopes ( $P < 0.001$ , Fig. 3).

233 Fig. 2

234 Fig. 3

235

### 236 **3.2 The relationships between leaf $\delta^{15}\text{N}$ and potential influential factors**

237 A multiple regression of leaf  $\delta^{15}\text{N}$  against potential influential factors including soil  
238  $\delta^{15}\text{N}$ , MAT, MAP, leaf N content, leaf C/N, soil N content, soil moisture, soil pH,  
239 soil bulk density and silt/clay was conducted. The statistical analyses showed that  
240 45.8% and 23.4% of the variability in leaf  $\delta^{15}\text{N}$  on the north slope and south slope  
241 could be explained as a linear combination of all 10 independent variables,  
242 respectively ( $P < 0.001$  for the north slope and  $P = 0.005$  for the south slope) (Table

243 2). Among these influential factors, MAT, leaf N content correlated positively and  
244 leaf C/N, MAP, soil moisture and silt/clay ratio correlated negatively with leaf  $\delta^{15}\text{N}$   
245 on the north slope (Table 3). The results of PCA also showed that leaf N content had  
246 strong positive while leaf C/N had negative effects on leaf  $\delta^{15}\text{N}$ , MAT and MAP also  
247 exerted influences on leaf  $\delta^{15}\text{N}$ , however, soil factors almost did not affect leaf  $\delta^{15}\text{N}$   
248 except silt/clay ratio and soil moisture (Fig. 4a). Whereas on the south slope, only  
249 leaf C/N was found to have a negative effect on leaf  $\delta^{15}\text{N}$ , MAP correlated  
250 marginally and negatively with leaf  $\delta^{15}\text{N}$  (Table 4). Besides, on the south slope, PC1  
251 and PC2 could almost represent soil conditions and plant traits, respectively, leaf  
252  $\delta^{15}\text{N}$  was affected strongly by leaf C/N (Fig. 4b).

253 Table 2

254 Table 3

255 Table 4

256 Fig. 4

257

### 258 3.3 The relationships between soil $\delta^{15}\text{N}$ and potential influential factors

259 Multiple regressions analysis with soil  $\delta^{15}\text{N}$  as a dependent variable and MAT, MAP,  
260 soil N content, silt/clay ratio, soil moisture, soil bulk density and soil pH as  
261 independent variables were conducted separately for the north slope and south slope.  
262 The statistical analyses showed that the regressions were very significant on both  
263 slopes ( $P < 0.001$  for the both slopes). The seven factors in total accounted for 55.2%  
264 and 72.7% of soil  $\delta^{15}\text{N}$  variance on the north and south slope, respectively (Table 2).

265 Considering the potential link between soil N and plant N, new multiple regressions  
266 including leaf  $\delta^{15}\text{N}$ , leaf N and leaf C/N were performed on the two slopes.  
267 Compared to the old multiple regressions, the new regressions did not exhibit  
268 changes in  $R^2$  and  $P$  values on both slopes (in the new regressions  $P < 0.001$  and  $R^2$   
269  $= 0.563$  for the north slope,  $P < 0.001$  and  $R^2 = 0.738$  for the south slope).  
270 Furthermore, compared to the adjusted  $R^2$  values derived from the old regressions  
271 (adjusted  $R^2 = 0.513$  for the north slope, adjusted  $R^2 = 0.708$  for the south slope), the  
272 values of the new regressions were smaller or almost unchanged (adjusted  $R^2 =$   
273  $0.506$  for the north slope, adjusted  $R^2 = 0.709$  for the south slope) (Table 2). Thus,  
274 the new multiple regressions indicated no effect of leaf nutrient traits on soil  $\delta^{15}\text{N}$ .  
275 Among these factors, MAT, MAP, soil moisture and silt/clay were found to be  
276 significantly related to the soil  $\delta^{15}\text{N}$  of the north slope (Table 3). **The PCA showed**  
277 **that both MAT and MAP had large loadings on soil  $\delta^{15}\text{N}$ , meanwhile, soil  $\delta^{15}\text{N}$**   
278 **increased with decreasing silt/clay ratio and increasing soil moisture (Fig. 4a).**  
279 However, on the south slope, only MAP and soil moisture were found to play a  
280 significant and negative role in soil  $\delta^{15}\text{N}$  (Table 4, **Fig. 4b**).

281

## 282 **4 Discussion**

### 283 **4.1 Differences in leaf $\delta^{15}\text{N}$ , soil $\delta^{15}\text{N}$ and $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$ between the south and the** 284 **north slopes**

285 On Mount Tianshan, leaf  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  both showed higher values on the  
286 south slope than the north slope; soil  $\delta^{15}\text{N}$  of the south slope was also more positive

287 than that of the north slope although the difference was not significant. The results  
288 confirmed our hypothesis that, for a given mountain, the leaf  $\delta^{15}\text{N}$ , soil  $\delta^{15}\text{N}$  and  
289  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  of the south slope could differ from those of the north slope. Greater leaf  
290  $\delta^{15}\text{N}$  on the south slope than north slope suggested that the south slope had higher  
291 soil N availability and higher soil N transformation rates (N mineralization or  
292 nitrification rates) (Garten and Van Miegroet, 1994; McLauchlan et al., 2007).  
293 Increasing soil N transformation rates led to an increase in soil available N.  
294 Meanwhile, increasing soil N transformation rates could result in more  $^{15}\text{N}$   
295 enrichment in soil available N sources, and consequently plant  $\delta^{15}\text{N}$  increased,  
296 because N transformation processes discriminate against  $^{14}\text{N}$ .

297  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  was greater on the south slope than the north slope. This result also  
298 suggested that the south slope has higher N availability and N mineralization or  
299 nitrification rates relative to the north slope, because previous studies reported that  
300  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  increased with increasing soil N transformation rates (N mineralization  
301 or nitrification rates) and N availability (Garten and Van Miegroet, 1994; Kahmen et  
302 al., 2008; Cheng et al., 2010).

303 Amundson et al. (2003) suggested that  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  could be interpreted as the  
304 isotopic composition of plant-available N provided that isotopic discrimination does  
305 not occur during plant uptake and assimilation. In the present study, we found a  
306 highly correlation between leaf  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  on each slope, which was  
307 consistent with the result observed by Craine et al. (2009). Additionally, leaf  $\delta^{15}\text{N}$   
308 has been widely considered as a good approximation to  $\delta^{15}\text{N}$  of soil available

309 nitrogen sources in natural ecosystems (Virginia and Delwiche, 1982; Cheng et al.,  
310 2010; Craine et al., 2015a), because N isotopic discrimination would be negligible  
311 during nitrogen uptake and assimilation due to limited soil available N in most  
312 natural ecosystems (Högeberg et al., 1999). Thus, the significant correlated  
313 relationship between leaf  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  could provide a powerful support for  
314 the suggestion in Amundson et al. (2003).

315

#### 316 **4.2 Influences of various factors on leaf $\delta^{15}\text{N}$ and soil $\delta^{15}\text{N}$ : south slope versus** 317 **north slope**

318 The regression and correlation analyses showed that each factor did not exert  
319 completely identical effect on leaf  $\delta^{15}\text{N}$  and soil  $\delta^{15}\text{N}$  across the two slopes, this  
320 provided powerful support for our argument that the influences of environmental  
321 factors on leaf  $\delta^{15}\text{N}$  and soil  $\delta^{15}\text{N}$  are **localized**.

322 Leaf C/N may play a role in regulating biogeochemical cycles of carbon and  
323 nitrogen in natural ecosystems (Luo et al., 2004), or, conversely, soil  
324 biogeochemistry and plant physiology also cause the shifts in leaf C/N  
325 stoichiometric characters (Reich and Oleksyn, 2004; Yang et al., 2011). In this study,  
326 leaf C/N was negatively correlated with leaf  $\delta^{15}\text{N}$  on both slopes of Mount Tianshan.  
327 The result was similar to the finding by Pardo et al. (2006), in which leaf  $\delta^{15}\text{N}$  and  
328 root  $\delta^{15}\text{N}$  both decreased with forest floor C/N. A negative correlation between leaf  
329 C/N and  $\delta^{15}\text{N}$  was also reported for the fine roots in Glacier Bay (Hobbie et al.,  
330 2000). Two possible reasons were responsible for the pattern observed in the present

331 study. First, the increase in leaf C/N might be caused by enhanced photosynthesis,  
332 which would aggravate the limit in nitrogen nutrients and result in a decrease in  
333 nitrogen availability. As we all know, when soil N availability is high and N nutrient  
334 is rich, soil N transformations, such as  $\text{NH}_3$  volatilization and  $\text{NO}_x$  emission are  
335 enhanced, consequently, more  $^{14}\text{N}$  losses from soil. This causes  $^{15}\text{N}$  enrichment in  
336 soil, subsequently, plant  $\delta^{15}\text{N}$  is more positive. Conversely, plants have more  
337 negative  $\delta^{15}\text{N}$  values when soil N is limited because of weak soil N transformations  
338 and less  $^{14}\text{N}$  loss. Thus, an increase in leaf C/N caused a decrease in nitrogen  
339 availability and  $^{15}\text{N}$ -depletion in plants. Second, leaf C/N usually was considered to  
340 be negatively correlated with leaf N contents because leaf C contents always keep  
341 relative stable (Tan and Wang, 2016). The relative stability of leaf C was also  
342 observed in this study. The negative relationship between leaf C/N and leaf  $\delta^{15}\text{N}$   
343 might be caused by the positive relationship between leaf N content and leaf  $\delta^{15}\text{N}$ ,  
344 which has been reported by many studies (Chen et al., 2015; Zhang et al., 2015;  
345 Craine et al., 2012; Pardo et al., 2006; Craine et al., 2009; Martinelli et al., 1999).  
346 This study also found a positive relationship between leaf N content and leaf  $\delta^{15}\text{N}$  on  
347 the north slope of Mount Tianshan.

348 MAP was observed to be significantly and negatively correlated with leaf  $\delta^{15}\text{N}$  on  
349 the north slope; however, on the south slope the relationship was just marginally  
350 significant. A negative relationship between leaf  $\delta^{15}\text{N}$  and MAP was reported in  
351 many previous studies (Austin and Sala, 1999; Handley et al., 1999; Robinson, 2001;  
352 Amundson et al., 2003; Craine et al., 2009). The decrease in leaf  $\delta^{15}\text{N}$  with

353 increasing precipitation could be associated with decreased gaseous N loss in wetter  
354 regions (Houlton et al., 2006).

355 MAT played a positive effect in the leaf  $\delta^{15}\text{N}$  of the north slope, which was  
356 consistent with many previous studies (Amundson et al., 2003; Craine et al., 2009);  
357 whereas on the south slope the effect of MAT was not observed. The probable  
358 explanation for the observations was that climate on the north slope is very cold (the  
359 average MAT = -1.85 °C), temperature is the key growth-limiting factor for plants.  
360 Previous studies consistently suggested that the key factor limiting plant growth  
361 generally also plays a dominant role in plant isotope discrimination (McCarroll and  
362 Loader, 2004; Winter et al., 1982; Xu et al., 2015), thus, temperature exerted an  
363 effect on leaf  $\delta^{15}\text{N}$ . However, on the south slope, climate is relatively warm except  
364 those sites with higher altitudes, and usually, temperature does not limit plant growth,  
365 thus, leaf  $\delta^{15}\text{N}$  was not related to temperature. With respect to the positive effect of  
366 temperature on the north slope, the mechanism might be that higher temperature  
367 favors more complete plant nitrogen assimilation and transformation, this might  
368 decrease isotopic fractionation during N assimilation and transformation, then cause  
369  $^{15}\text{N}$  enrichment in plants.

370 On Mount Tianshan, soil  $\delta^{15}\text{N}$  increased with increasing MAP on the north slope,  
371 while decreased with increasing MAP on the south slope. Soil  $\delta^{15}\text{N}$  could be  
372 determined by the balance of the N input or output processes and corresponding  
373 isotopic fractionation factors (Brenner et al., 2001; Bai and Houlton, 2009; Wang et  
374 al., 2014). Considering that the leaching loss could be neglected on both slopes

375 because of the dry environment, soil  $\delta^{15}\text{N}$  can be estimated by the following  
376 equation:

$$377 \quad \text{Soil } \delta^{15}\text{N} = \delta^{15}\text{N}_{\text{input}} + \varepsilon_{\text{G}} \times f_{\text{G}} + \varepsilon_{\text{P}} \times f_{\text{P}} \quad (1)$$

378 where  $\delta^{15}\text{N}_{\text{input}}$  is the input  $\delta^{15}\text{N}$ ;  $f_{\text{G}}$  and  $f_{\text{P}}$  are the fraction of gas losses and net plant  
379 N accumulation out of total N losses (%), respectively;  $\varepsilon_{\text{G}}$  and  $\varepsilon_{\text{P}}$  are the  
380 fractionation factors of corresponding N losses processes, respectively. And

$$381 \quad f_{\text{G}} + f_{\text{P}} = 1 \quad (2)$$

382  $\varepsilon_{\text{G}}$  varies from 16‰ to 30‰ (Handley et al., 1999; Robinson, 2001);  $\varepsilon_{\text{P}}$  is between 5‰  
383 and 10‰ (Handley et al., 1999; Evans, 2001), thus, in general,  $\varepsilon_{\text{G}} > \varepsilon_{\text{P}}$ , and soil  $\delta^{15}\text{N}$   
384 is correlated positively with  $f_{\text{G}}$  and negatively with  $f_{\text{P}}$  based on eqn. (1) and (2). On  
385 the north slope, rainfall event may accelerate the gas losses (nitrification and  
386 denitrification processes) more than plant N uptake, while it may be opposite on the  
387 south slope. On the north slope, with increase in MAP,  $f_{\text{G}}$  increases and causes  $^{15}\text{N}$   
388 enrichment in soil; on the south slope,  $f_{\text{P}}$  increases with MAP, and results in  $^{15}\text{N}$   
389 depletion in soil.

390 The effects of silt/clay ratio on soil  $\delta^{15}\text{N}$  might be driven by the indirect effects of  
391 silt/clay ratio on soil moisture and soil oxygen concentrations. The north slope is  
392 wetter than the south slope, and the north slope will prefer denitrification, while  
393 nitrification will be favored on the south slope. On the north slope, with increase in  
394 silt/clay ratio, soil oxygen concentration increases and this inhibits soil  
395 denitrification, consequently,  $^{15}\text{N}$  depletion in soil would be resulted in, thus silt/clay  
396 ratio showed a negative relationship with soil  $\delta^{15}\text{N}$ .

397

## 398 **5 Conclusion**

399 We sampled plants and soils on the south slope and north slope of Mount Tianshan  
400 and measured their  $\delta^{15}\text{N}$ . South slope differs significantly in climate and  
401 environment from north slope. In the present study, leaf  $\delta^{15}\text{N}$  and  $\Delta\delta^{15}\text{N}_{\text{leaf-soil}}$  (leaf  
402  $\delta^{15}\text{N}$  – soil  $\delta^{15}\text{N}$ ) of the south slope were more positive than that of the north slope,  
403 soil  $\delta^{15}\text{N}$  of the south slope was also higher than that of the north slope although the  
404 difference between the two slopes was not significant. The results suggested that the  
405 south slope has higher soil N transformation rates and soil N availability relative to  
406 the north slope. In addition, among the potential influential factors, MAP, leaf C/N,  
407 soil moisture and silt/clay ratio had negative effects while MAT and leaf N content  
408 had positive effects on leaf  $\delta^{15}\text{N}$  of the north slope; however, on the south slope, only  
409 leaf C/N played a negative role in leaf  $\delta^{15}\text{N}$ . For soil  $\delta^{15}\text{N}$ , the significant influential  
410 factors were MAT, MAP, soil moisture and silt/clay ratio on the north slope, whereas  
411 on the south slope, MAP and soil moisture exerted significant effects. Interestingly,  
412 MAP was found to exert contrary effects on soil  $\delta^{15}\text{N}$  between the two slopes. This  
413 indicated that environmental influences on leaf  $\delta^{15}\text{N}$  and soil  $\delta^{15}\text{N}$  are  
414 local-dependent.

655 *Note: In the model-1, independent variables were MAT, MAP, leaf N content, leaf C/N, soil  $\delta^{15}\text{N}$ ,*  
656 *soil N content, silt/clay, soil moisture, soil bulk density and soil pH. In the model-2, independent*  
657 *variables were MAT, MAP, soil N content, silt/clay, soil moisture, soil bulk density and soil pH.*  
658 *In the model-3, besides all variables in Model-2, leaf  $\delta^{15}\text{N}$ , leaf N content and leaf C/N were also*  
659 *included in independent variables.*
