12  
13 **Abstract**

14  
15 Organic carbon processing at the seafloor is studied by biogeochemists to  
16 quantify burial and respiration, by organic geochemists to elucidate  
17 compositional changes and by ecologists to follow carbon transfers within food  
18 webs. Here I review these disciplinary approaches and discuss where they agree  
19 and disagree. It will be shown that the biogeochemical approach (ignoring the  
20 identity of organisms) and the ecological approach (focussing on growth and  
21 biomass of organisms) are consistent on longer time scales. Secondary  
22 production by microbes and animals is identified to potentially impact the  
23 composition of sedimentary organic matter. Animals impact sediment organic  
24 carbon processing by microbes in multiple ways: by governing organic carbon  
25 supply to sediments, by aeration via bio-irrigation and by mixing labile organic  
26 matter to deeper layers. I will present an inverted microbial loop in which  
27 microbes profit from bioturbation rather than animals profiting from microbial  
28 processing of otherwise lost dissolved organic resources. Sediments devoid of  
29 fauna therefore function differently and are less efficient in processing organic  
30 matter with the consequence that more organic matter is buried and transferred  
31 from Vernadsky's biosphere to the geosphere.

32  
33  
34 **1 Introduction**

35  
36 The seawater-sediment interface represents one of the largest interfaces  
37 on earth and our knowledge of processes at and fluxes through this dynamic and  
38 understudied interface is rather limited. This interface extends a few cm-dm  
39 upwards into the water column, i.e. benthic boundary layer (Boudreau and  
40 Jørgensen, 1992), as well as few cm-dm into the sediments, i.e. the bioturbated,  
41 active surface layer (Bernier, 1980; Meysman et al., 2006; Aller, 2013). It serves  
42 as a habitat for organisms, governs the partitioning of material being buried or  
43 recycled and acts as a filter for the paleorecord (Rhoads, 1974). Processes in the  
44 surface sediment layer determine whether remains from organisms (organic  
45 matter, biogenic silica) are recycled within the biosphere (short-term cycle) or  
46 transferred to the geosphere (long-term cycle) and as such it functions as a key  
47 interface in the System Earth.

48 This pivotal role of the seafloor in processing material deposited has been  
49 studied by scientists from various disciplines with their own interests,

50 techniques and paradigms (Figure 1). Marine geologists and paleoceanographers  
51 study sediments with the primary aim to extract information on past  
52 environmental conditions using down-core measurements of substances that  
53 have survived the processing at the seafloor (Burdige, 2006; Bender, 2013).  
54 Biogeochemists quantify the fate of material delivered, in particular how much of  
55 that is eventually buried or processed, and determine when and in what form the  
56 remaining part is recycled as key nutrients to sustain primary production in the  
57 water column (Bernier, 1980; Aller, 1980, 2001, 2013; Soetaert et al., 2000).  
58 Organic geochemists investigate how organic matter delivered to the seafloor is  
59 degraded, transformed or preserved using changes in the composition at the  
60 molecular level (Hedges and Keil, 1995; Dauwe et al, 1999; Burdige, 2006;  
61 Bianchi and Canuel, 2011). Ecologists focus on the organisms, i.e. the actors  
62 consuming, producing and transporting the material deposited (Gage and Tyler,  
63 1992; Gray and Elliot, 2009; Herman et al., 1999; Krumins et al., 2013).

64 Although these disciplines often study the same topic, e.g. organic matter  
65 delivered to the seafloor, they focus on different aspects and usually  
66 underappreciate or do not incorporate key concepts, findings and approaches  
67 from other disciplines. For example, ecologists and biogeochemist studying  
68 carbon flows at the seafloor normally ignore detailed molecular information  
69 available from organic geochemistry (Bernier, 1980; Glud, 2008). Bioturbation,  
70 biological reworking of sediments (Meysman et al., 2006), is often ignored by  
71 paleoceanographers, and biogeochemists (Bernier, 1980; Boudreau, 1997) have  
72 developed advanced transport-reaction models in which the actors, the animals,  
73 mix the sediment but do so without consuming organic matter.

74 Here I present the existing views on organic carbon processing at the  
75 seafloor, discuss where they agree and disagree and aim to arrive at an  
76 integrated view of carbon processing at the seafloor that is consistent with  
77 recent views within the organic geochemical, biogeochemical and ecological  
78 research communities. This overview is necessarily and admittedly incomplete  
79 but rather covers personal interests and presents new concepts on this topic. It  
80 is a concise version of the Vernadsky Medal Lecture presented at the 2017 EGU  
81 meeting.

82

## 83 **2 Biogeochemists focus on quantification of burial and mineralization.**

84

85 Organic matter delivered to marine sediments is either mineralized and  
86 the metabolites (carbon dioxide and nutrients) accumulate in pore-waters and  
87 exchange with the overlying water, or buried through the steady accumulation of  
88 particles (Fig. 2). This biogeochemical view (Bernier, 1980; Boudreau, 1997;  
89 Aller, 2013) is highly simplified, but for that reason also quantitative and I  
90 believe instructive. The percentage of organic matter buried varies from less  
91 than one % to a few tens % and is closely and positively related with total  
92 sediment accumulation rate (Canfield, 1989, 1994; Middelburg et al., 1993).  
93 Since sediment accumulation rates are high in vegetated, coastal, deltaic, shelf  
94 and ocean-margin settings, the majority of organic matter burial occurs there,  
95 with organic carbon burial in deep-sea sediments accounting for <5 % of the  
96 total buried (Bernier, 1982; Duarte et al., 2005; Burdige, 2007). In the deep sea  
97 and other settings with low burial efficiency, almost all organic matter is  
98 degraded to inorganic carbon at rates that provide an excellent approximation

99 for organic matter deposition (Jørgensen, 1982; Cai and Reimers, 1995; Glud,  
100 2008). Organic matter degradation can be quantified via the consumption of  
101 oxygen, the production of dissolved inorganic carbon and through the use of  
102 pore-water data and diagenetic models (i.e. reaction-transport models for  
103 sediments). At steady state, sediment oxygen consumption provides an accurate  
104 measure for total sediment organic matter degradation, independent whether  
105 organic matter is degraded aerobically (i.e. with oxygen) or anaerobically (with  
106 alternative electron acceptors such as nitrate, metal oxides, sulphate), because  
107 almost all reduced metabolites released (ammonium, manganese (II), iron(II),  
108 hydrogen sulfide and methane) are re-oxidized (Jørgensen, 1977, 2006; Berner  
109 and Westrich, 1985; Aller and Rude, 1988; Soetaert et al., 1996; Boetius et al.,  
110 2000; Strous and Jetten, 2004; Raghoebarsing et al., 2006; Middelburg and Levin,  
111 2009).

112 Biogeochemists have adopted a transport-reaction modeling approach to  
113 accurately quantify organic matter processing (Berner, 1980; Boudreau, 1997;  
114 Burdige, 2006). The basic premise of these diagenetic models is that both  
115 particles and solutes are subject to transport and reaction, making them distinct  
116 from for instance groundwater transport-reaction models in which normally  
117 only solutes and gas phases are mobile (Lichtner, 1996; Appelo, 1996).  
118 Transport of solutes is due to molecular diffusion, pore-water advection and  
119 biologically mediated processes such as enhanced diffusion due to interstitial  
120 fauna (Aller and Aller, 1992) and bio-irrigation due to tube and burrow  
121 construction and flushing by macrofauna (Aller, 1980, 1984; 2001; Volkenborn  
122 et al., 2010; 2016; Kristensen et al., 2012). Particle transport is not only due to  
123 steady particle deposition but also due to sediment reworking by animals  
124 (bioturbation, Boudreau, 1997; Aller, 1994, 2013; Rice, 1986; Meysman et al.,  
125 2003, 2006, 2010). The reaction terms in these diagenetic models are normally  
126 limited to microbial and chemical reactions and are described using zero, first,  
127 second order kinetic relationships or Monod/Michaelis-Menten type kinetics  
128 (Bouldin, 1968; Berner, 1980; Soetaert et al., 1996; Boudreau, 1997). There is a  
129 major inconsistency in the basic conceptual model underlying the (numerical)  
130 diagenetic models: animals dominate transport processes via pore-water  
131 irrigation and particle mixing, but without consuming any organic matter. This  
132 inconsistency has not received much attention because the ruling paradigm  
133 within the biogeochemical research community is that animals contribute very  
134 little to total carbon processing. Multiple recent studies involving use of <sup>13</sup>C as  
135 deliberate tracers show that this premise does not hold on the short term (days  
136 to weeks; Blair et al., 1996; Moodley et al., 2002, 2005a; Woulds et al., 2009,  
137 2016). Moreover, detailed studies of oxygen consumption have revealed that  
138 animals contribute substantially to total sediment oxygen uptake; directly via  
139 their respiration as well as indirectly via particle and solute mixing (Glud, 2008).  
140 Nevertheless, diagenetic models can very accurately reproduce most  
141 observations (Soetaert et al., 1996; Berg et al., 2003).

142 Diagenetic models combined with solid-phase and pore-water depth  
143 profiles, sediment-water exchange fluxes and rate measurement have resulted in  
144 a consistent picture of organic matter degradation pathways in marine  
145 sediments (Berner, 1980; Boudreau, 1997; Aller, 2013). These models can  
146 predict where, when and why organic matter oxidation occurs aerobically or  
147 involves nitrate, metal oxides or sulphate as oxidants (Rabouille and Gaillard,

148 2001; Boudreau, 1996; Soetaert et al., 1996; Middelburg et al. 1996; van  
149 Cappellen and Wang, 1996; Archer et al., 2002; Meysman et al., 2003; Berg et al.,  
150 2003). They also resolve the re-oxidation of reduced products such as  
151 ammonium, manganese(II), iron (II), sulfide and methane (Fig. 2) and as such  
152 define the scope for aerobic and anaerobic organisms, including the distribution  
153 and activity of chemoautotrophs (Middelburg, 2011). Despite these advances,  
154 diagenetic models cannot predict organic carbon burial rates, nor do they  
155 provide much insight into why organic matter is buried, or why it is either labile  
156 (reactive) or refractory. For this we need to have a detailed look at the organic  
157 geochemistry of sediment organic carbon.

158

### 159 **3 Organic geochemists focus on the composition of organic matter** 160 **preserved**

161

162 Organic matter delivered to the seafloor is predominantly produced in the  
163 surface sunlit layer of the ocean (Fig. 3). This organic matter is rich in proteins,  
164 carbohydrates and lipids and generally follows Redfield stoichiometry (Sterner  
165 and Elser, 2002; Bianchi and Canuel, 2011). Organic matter processing leads to  
166 preferential degradation of the more labile components with the result that  
167 organic matter becomes less reactive (Jørgensen, 1979; Westrich and Berner,  
168 1984; Middelburg, 1989; Arndt et al., 2013) and organic matter composition  
169 changes (Fig. 1; Wakeham et al. 1997; Dauwe et al., 1999; Lee et al., 2000). The  
170 proportion of organic matter that can be characterized molecularly decreases  
171 with progressive degradation, i.e. with water depth or depth downcore  
172 (Wakeham et al., 1997; Hedges et al., 2000; Middelburg et al., 1999; Nierop et al.,  
173 2017). This molecularly uncharacterizable material increases to more than 70%  
174 of the total in deep-sea sediment organic matter. The organic geochemical  
175 approach to study organic matter processing is limited not only by our inabilities  
176 to characterize the majority of the sedimentary organic matter, but also by the  
177 simple fact that the degraded fraction cannot be easily studied and we have to  
178 base our knowledge on the small fraction of extensively processed organic  
179 material remaining.

180 The changes in organic matter composition due to organic matter  
181 processing have been utilized to estimate the lability-digestability or the  
182 refractory nature of organic matter with various proxies such as chlorophyll to  
183 bulk organic matter, fraction of nitrogen present as amino acids, and the  
184 contribution of proteins and carbohydrates to total organic matter (Cowie et al.,  
185 1992; Dell'Anno et al., 2000; Danovaro et al., 2001; Koho et al., 2013). The amino-  
186 acid based degradation index (Dauwe and Middelburg, 1998) is one of the most  
187 commonly used proxies to quantify the extent of degradation or the quality of  
188 the remaining particulate organic matter and is based on subtle changes in the  
189 amino acid composition due to organic matter processing (Dauwe et al., 1999;  
190 Keil et al., 2000).

191 The compositional changes have also been used to infer transformation of  
192 organic matter by bacteria (Cowie and Hedges, 1994; Dauwe et al., 1999;  
193 Grutters et al., 2001; Vandewiele et al., 2009; Lomstein et al., 2006, 2012), extent  
194 of degradation under oxic and anoxic conditions (Sinninghe Damsté et al., 2002;  
195 Huguet et al, 2008; Nierop et al., 2017) and the relative importance of bacteria  
196 and fauna for organic matter degradation (Sun et al., 1999; Woulds et al., 2012,

197 2014). Although some organic geochemical studies hint at the importance of  
198 secondary production (Hayes et al., 1989; Cowie and Hedges, 1994; Grutters et  
199 al., 2001; Lomstein et al., 2006, 2012), this aspect has received little attention in  
200 organic geochemistry, yet it is one of the main objectives within the ecological  
201 approach.

202

#### 203 **4 Ecologists focus on the dynamics of organisms using organic matter**

204

205 Benthic communities are usually partitioned into different size classes  
206 (e.g. macrofauna, meiofauna and microbes; Gage and Tyler, 1992; Gray and Elliot,  
207 2009; Herman et al., 1999), which are often studied by different research  
208 communities having distinct objectives, approaches and tools. Organic matter  
209 delivered to the seafloor fuels benthic food webs: i.e. it represents food for the  
210 animals and the energy substrate for heterotrophic microbes. Microbial  
211 ecologists study the growth of microbes on delivered organic matter (e.g.  
212 bacterial production) and subsequent microbial loss processes, including  
213 predation and viral lysis (Kemp, 1988; 1990; Danovaro et al., 2008, 2011, 2016).  
214 Microbial ecologists also study in detail the identities and activities of organisms  
215 involved in (an)aerobic respiration pathways and the re-oxidation of reduced  
216 metabolites produced during anaerobic organic matter degradation (Canfield et  
217 al., 2005). Animal ecologists focus on the response of fauna to food delivery, the  
218 diet and growth of animals and transfer of carbon up the food chain to top  
219 consumers (Krumins et al., 2013; Fig. 3). Interactions among food-web members  
220 are considered the key to understand carbon flows (Pimm et al., 1991; van  
221 Oevelen et al., 2010).

222 During the last two decades, <sup>13</sup>C-labeled phytodetritus addition  
223 experiments have been performed to identify the organisms involved in the  
224 immediate processing of organic matter delivered to the seafloor (Middelburg,  
225 2014). These studies often covered all size classes (animals and microbes) and  
226 could show that respiration was the major fate of added phytodetritus and that  
227 all size classes directly profited from recently deposited organic matter (Blair et  
228 al., 1996; Moodley et al., 2002, 2005a; Woulds et al., 2007, 2009, 2016; Witte et  
229 al., 2003; Nomaki et al., 2005; Sweetman and Witte, 2008). In other words,  
230 heterotrophic microbes and small and big animals compete for the same food.  
231 Van Nugteren et al. (2009b) have shown that the spatial distribution of resources  
232 is a key factor governing the relative use of phytodetritus by bacteria vs. animals.  
233 Moreover, the relative share of organisms in the processing of organic matter  
234 was in some systems and for some consumers proportional to the biomass of the  
235 benthic size class, but not always (Moodley et al., 2005a; Woulds et al., 2009,  
236 2016). For instance, foraminifera and amoebid protozoa, sometimes contribute  
237 disproportionately to short-term carbon processing reflecting high turn-over of an  
238 active community (Moodley et al., 2002; Woulds et al., 2007).

239

240

#### 241 **5 Towards a synthesis**

242

243 The above discussion on conceptual views within different research disciplines  
244 highlights a few discrepancies and gaps in our knowledge. Secondary production  
245 by animals and microbes is often not included in the biogeochemical view that

246 focuses on preservation versus mineralization. It is also largely absent from the  
247 organic geochemical literature. Consumption of organic matter is restricted to  
248 microbes in the biogeochemical view, while the non-fed animals move organic  
249 matter, microbes and particles around and enhance solute transfer by bio-  
250 irrigation activities. The consumption of organic matter eventually results in  
251 compositional changes of the organic matter remaining but there is little  
252 information that the identity of the organism matters much. Whole ecosystem  
253 labeling experiments revealed direct flow from detritus to most benthic  
254 consumers and to the dissolved inorganic carbon pool, but these short-term  
255 experimental results cannot directly be compared to the long-term natural  
256 processing of deposited organic matter because long-term transfers within the  
257 food web and eventual carbon preservation cannot be resolved experimentally.  
258

### 259 **5.1 On the consistency of food-web carbon processing and the** 260 **biogeochemical burial-respiration partitioning**

261  
262 Food-web models describe the exchange of matter (e.g. carbon or energy) among  
263 different compartments (organisms) within an ecosystem (Pimm et al., 1991; de  
264 Ruiten et al., 1995) and usually lump respiration losses (Cole et al., 2006; van  
265 Oevelen et al, 2010; Fig. 3 left). Experimental studies using <sup>13</sup>C labelled  
266 phytodetritus as a tracer of sediment carbon processing showed that animals  
267 and microbes both can assimilate labile carbon directly and confirmed that  
268 respiration is the largest sink (Moodley et al, 2005a; Buhning et al., 2006;  
269 Andersson et al. 2008; Woulds et al. 2009, 2016). The biogeochemical budgeting  
270 approach basically distinguishes only between (refractory) carbon preserved  
271 and buried versus labile organic carbon that is respired to carbon dioxide (Aller,  
272 2013; Fig. 3 right). These ecological and biogeochemical concepts can be  
273 consistent depending on the timescale considered. On the time scale of days to  
274 month deposited carbon is processed by the benthic organisms, a small part is  
275 assimilated and the majority is respired. On longer time scales and when  
276 considering steady-state conditions, i.e. constant faunal and microbial biomass,  
277 there is transfer from the detritus pool to the living biomass pool, but these  
278 secondary producers die and their remains are returned to the detritus pool for  
279 another cycle with the result that eventually all labile organic matter is respired.  
280

### 281 **5.2 Secondary production and the formation of molecularly** 282 **uncharacterizable organic matter.**

283  
284 The mere presence of living organisms in sediments clearly indicates that  
285 secondary production is omnipresent. Microbes usually dominate living biomass,  
286 but not always, and living biomass typically contributes a few % to the standing  
287 stock of total organic carbon in coastal sediments (Herman et al., 1999). The  
288 importance of microbial biomass relative to total biomass increases with  
289 increasing water depth (Rex et al., 2006; Danovaro et al., 2014, 2015). Moreover,  
290 living biomass may contribute substantially to total carbon stocks in coarse-  
291 grained sandy sediments with low background organic carbon contents (Herman  
292 et al., 1999; Evrard et al., 2012). Various types of experimental evidence have  
293 shown that carbon flow through the living compartment is much higher than  
294 through the non-living sediment organic matter pool. Short-term, in situ

295 experiments using  $^{13}\text{C}$  and/or  $^{15}\text{N}$  labelled organic matter (e.g. phytodetritus)  
296 revealed rapid incorporation of  $^{13}\text{C}/^{15}\text{N}$  in physically separated organisms  
297 (macro- and meiofauna and foraminifera) and microbes, the latter via  
298 incorporation of tracers in biomarkers specific for certain microbial groups  
299 (Middelburg et al., 2000; Boschker and Middelburg, 2002; Veuger et al., 2007;  
300 Oakes et al., 2012; Woulds et al., 2007, 2016) Similarly, ammonium isotope  
301 dilution studies have shown that net ammonification (ammonium release) is  
302 only a fraction of the total ammonium regeneration because a substantial part of  
303 the ammonium liberated is re-assimilated by the microbial community  
304 (Blackburn and Henriksen, 1983). Clearly the microbes and animals living in  
305 sediment assimilate carbon and synthesize new biomass (Veuger et al., 2012).  
306 How can this be reconciled with the biogeochemical and organic geochemical  
307 views in which organic matter is either preferentially degraded to carbon dioxide  
308 or selectively preserved (Fig. 1, 3). These two apparently inconsistent views are  
309 consistent if most of the newly produced organic matter is eventually degraded.

310 Detailed investigations of organic matter composition might in principle  
311 resolve this issue as microbial and animal processing of organic matter results in  
312 the formation of distinct compounds (Bradshaw et al., 1990; Sun et al., 1999;  
313 Thomas and Blair, 2002; Woulds et al., 2012, 2014). There are few issues with  
314 this approach: (1) most sedimentary organic matter is molecularly  
315 uncharacterizable and the origin (imported from the water column vs. newly  
316 produced within the sediment) can thus not directly be investigated, (2)  
317 microbes living within (the guts) of animals may mask the animal signatures  
318 (Woulds et al., 2012, 2014) and (3) different analytical windows (amino acids vs.  
319 lipids) may result in different inferences. On one hand, the accumulation of  
320 bacterial derived non-protein amino acids and peptidoglycan derived D amino  
321 acids are clear signs that extensively modified organic matter contains a major  
322 fraction that is derived from (heterotrophic) bacteria (Cowie and Hedges, 1994;  
323 Dauwe et al., 1999; Grutters et al., 2001; Lomstein et al., 2006; Keil and Fogel,  
324 2001; Keil et al., 2000). Using fatty acids, Gong and Hollander (1997) also  
325 identified a substantial microbial contribution to sedimentary organic matter. On  
326 the other hand, using a combined lipid-isotope approach Hartgers et al. (1994)  
327 reported only a minor contribution of bacteria to sedimentary organic carbon  
328 pools.

329 Secondary production has potentially major consequences for the  
330 interpretation of sedimentary records. If microbial reworking of deposited  
331 organic matter represents a major carbon flow and part of the material is  
332 preserved, then one would expect that bulk organic matter properties such as C,  
333 N, P elemental ratios and nitrogen and carbon isotopes would reflect this.  
334 Degradation of organic matter initially results in the preferential release of  
335 nitrogen and phosphorus relative to carbon. Microbes normally have lower C:N  
336 ratios than their substrate (Sternner and Elser, 2002) implying that secondary  
337 production and accumulation of microbial derived organic matter should  
338 eventually result in a net decrease of sediment C:N ratios (Müller, 1977). In  
339 contrast, the C:P ratio of heterotrophic microbes is rather variable because P  
340 demands depends on the growth rate (Sternner and Elser, 2002) and slowly  
341 growing benthic microbes may have high C:P ratios (Steenbergh et al., 2013).  
342 Moreover, microbial P storage also depends on redox conditions with the  
343 consequences that sedimentary C:P ratios are highly variable (Algeo and Ingall,

344 2007). Sediment  $\delta^{15}\text{N}$  values often show a post-depositional shift towards  
345 heavier values in alternating oxic/anoxic settings (Moodley et al., 2005b). Such a  
346 shift is to be expected because regenerated ammonium is either transformed  
347 into nitrite/nitrate (nitrification) or re-assimilated by the microbial community.  
348 During oxic conditions nitrification occurs with preference for  $^{14}\text{N}$  and the  
349 remaining ammonium available for re-assimilation by microbes will be relatively  
350 rich in  $^{15}\text{N}$ , while during anoxic conditions oxidation of ammonium is less  
351 important or absent, and the ammonium re-assimilated will have similar  $\delta^{15}\text{N}$   
352 values as that regenerated. Secondary production within sediment may also  
353 impact the interpretation of bulk stable carbon isotope records (Hayes et al.,  
354 1998) and paleorecords of microbial biomarkers (Schouten et al., 2010).

355 To reconcile the strong experimental evidence for preferential  
356 degradation (Middelburg, 1989), selective preservation (Tegelaar et al., 1989)  
357 and formation of new compounds by secondary producers (Lomstein et al, 2012;  
358 Braun et al, 2017) I present a new integral concept (Fig. 4). Phytodetritus  
359 delivered to sediments is preferentially degraded with the result that new  
360 biomass is formed and that some compounds are selectively preserved. The  
361 newly formed biomass is after death of the organism added to the pool of  
362 degraded detritus and subject to further microbial processing. After multiple  
363 cycles of processing by benthic heterotrophs most of the remaining organic  
364 matter becomes molecularly uncharacterizable. This conceptual model is  
365 consistent with the ruling paradigms of preferential degradation and selective  
366 preservation as well as with the occurrence of secondary production and  
367 formation of molecular uncharacterizable organic matter, but the next step is to  
368 quantify this conceptual view. One approach would be to use proxies for organic  
369 matter degradation state such as fraction of total nitrogen present as amino acid,  
370 non-protein amino acids accumulation and the degradation index (Cowie and  
371 Hedges, 1994; Dauwe and Middelburg, 1998; Dauwe et al., 1999). Lomstein et al.  
372 (2012) and Braun et al. (2017) used amino acid racemization to quantify  
373 turnover of living microbial biomass as well as of bacterially derived organic  
374 matter (necromass) in the deep biosphere. Veuger et al. (2012) executed a  
375  $^{13}\text{C}/^{15}\text{N}$  tracer experiment and followed the isotope labels into carbohydrates,  
376 amino acids and lipids and basically showed that most of the deliberately added  
377 heavy isotopes were recovered from the molecularly uncharacterizable pool  
378 within a few weeks and remained in that pool till the end of the experiment (> 1  
379 year). Their study provided direct evidence for rapid formation of new microbial  
380 biomass and subsequent transfer of microbial biomass to the pool of molecular  
381 uncharacterizable organic matter. Moreover, the efficient retention of label was  
382 indicative of recycling of molecules (or parts thereof) by microbes rather than de  
383 novo synthesis, consistent with findings for archaeal lipids in marine sediments  
384 (Takano et al., 2010, Lipsewiers et al., 2017) and bacteria in soils (Dippold and  
385 Kuzyakov, 2016).

386

387

### 388 **5.3 Animals and carbon supply to sediments**

389

390 Marine sediments are often considered donor-controlled systems, i.e. organic  
391 matter is delivered via settling of organic matter produced in the sunlit upper  
392 part of the ocean (Fig. 3) and the consuming sediment communities have no

393 control on its carbon delivery (Fig. 5). It is only on the time-scale of ocean  
394 bottom-water renewal (100-1000 years) that nutrient regenerated by benthic  
395 organisms may impact primary producers in the sunlit upper part of the ocean  
396 (Soetaert et al., 2000). This is obviously different for sediments in the photic  
397 zone that make up about 1/3 of the coastal ocean (Gattuso et al., 1996) because  
398 animals can directly graze and consume the benthic primary producers at the  
399 sediment surface (Middelburg et al., 2000; Evrard et al., 2010, 2012; Oakes et al.,  
400 2012; Fig. 5). Donor and consumer controlled food webs have intrinsically  
401 different dynamics.

402 Animals living in sediments below the photic zone can in multiple ways  
403 impact carbon processing within marine sediments (Fig. 5). Deposit-feeding  
404 animals mix particles (and thus particulate organic carbon) as a consequence of  
405 their activities. In the case of constant organic carbon delivery (donor-control)  
406 bioturbation stimulates organic carbon processing at depth (Herman et al.,  
407 1999). In coastal systems, organic matter delivery is more complex because of  
408 multiple deposition-resuspension events and lateral transport pathways. Rice  
409 and Rhoads (1989) showed that in this case (with constant organic carbon  
410 concentration in the top layer) more sediment reworking will increase the  
411 organic matter flux into the sediment. Moreover, organic carbon gradients with  
412 depth are steeper for high-quality than low-quality material and particle mixing  
413 thus results in transfer of high-quality organic matter to (micro-)organisms  
414 living at depth. Animals living in permeable sediment can via surface sediment  
415 topography (bioroughness) induce pore-water flows resulting in the trapping of  
416 phytoplankton (Huettel et al., 2014).

417 Tropical and cold-water corals, coastal and deep-sea sponges, suspension  
418 feeding bivalves and other marine forests communities utilize particulate  
419 organic matter suspended in the water (Herman et al., 1999; Roberts et al., 2006;  
420 Rossi et al., 2017). This organic carbon is used for maintenance respiration and  
421 growth, but part is excreted as faeces or pseudofaeces and becomes then  
422 available for consumers in the sediments. This can result in local hotspots of  
423 biodiversity and microbial activity in the sediments (Herman et al., 1999;  
424 Gutierrez et al., 2003; Cathalot et al., 2015). Moreover, the physical structures  
425 built by these ecosystem engineers impact hydrodynamics with consequences  
426 for local and distant carbon deposition rates. Soetaert et al. (2016) reported  
427 elevated carbon deposition to ocean margin sediments due to cold-water corals  
428 reefs at very large distances.

429 Some invertebrates have the capability to take up dissolved organic  
430 carbon and in particular sponges can assimilate substantial quantities and  
431 transform it into biomass (de Goeij et al., 2013; Fiore et al., 2017; Hoer et al.,  
432 2017). This sponge tissue and in particular its detritus can be consumed by  
433 benthic organisms. This sponge loop (de Goeij et al., 2013; Rix et al., 2016) is  
434 another example how animals can manipulate the transfer of organic carbon  
435 from the water-column to the sediments (Fig. 5).

436  
437

#### 438 **5.4 Animal stimulation of microbes: An inverted microbial loop?**

439

440 The microbial loop is a key concept in ocean biogeochemistry (Pomeroy,  
441 1974; Azam et al., 1983). Dissolved organic matter released by phytoplankton,

442 zooplankton or viral lysis of bacteria, archaea and algae is consumed by  
443 heterotrophic microbes. These heterotrophs are in turn consumed by flagellates,  
444 ciliates and other small consumers that are predated upon by zooplankton  
445 (Azam et al., 1983; Jumars et al. 1989). Energy shunted into the large,  
446 heterogeneous dissolved organic matter pool is in this way made available again  
447 for animals (Fig. 6).

448 After discovery of this loop in the surface ocean water, research has been  
449 executed to identify and quantify it in sediments (Kemp, 1988, 1990). This  
450 required substantial investment in developing new methods: these studies  
451 basically revealed that predation on sedimentary bacteria was not that  
452 important (Kemp, 1990; Hondeveld et al., 1992; Hamels et al., 2001; Guilini et al.,  
453 2009). Van Oevelen et al., (2006) made a detailed study on the fate of bacterial  
454 production using in situ <sup>13</sup>C labelling of bacteria. They observed that 8% was lost  
455 by physical processes, 27% was consumed by animal predation, while bacterial  
456 mortality accounted for 65%. Viruses are the most important loss term for  
457 sedimentary microbes (Danovaro et al, 2009, 2011, 2016) and the viral lysis  
458 products (dissolved organic matter) are consumed by microbes. This results in a  
459 dissolved organic carbon-microbes cycle (Fig. 6). This benthic microbial cycle  
460 represents a dead end in terms of food web topology, because there is little  
461 transfer to higher trophic levels and most carbon is eventually respired as  
462 needed for mass-balance closure on the long term (Fig. 3).

463 In fact, the benthic microbial cycle represents more an *inverted microbial*  
464 *loop*: rather than animals profit from the microbial loop sensu Azam et al. (1983),  
465 it appears that benthic microbes profit from animals mixing labile organic matter  
466 downwards into the sediments (Fig. 6). Labile organic matter delivered to the  
467 sediment surface is mixed by animals inhabiting the sediments (Fig. 5). The  
468 transfer of high quality organic matter to deeper sediment layer may prime  
469 sediment microbial communities and in this way stimulate degradation of  
470 indigenous organic matter (Canfield, 1994; van Nugteren et al, 2009a, Bianchi,  
471 2011; Hannadis & Aller, 2017). Moreover, tube construction and ventilation by  
472 animals brings dissolved oxygen to deeper sediment layers and will in this way  
473 stimulate organic matter mineralization (Canfield, 1994; Kristensen et al., 1995;  
474 Dauwe et al., 2001). Bio-irrigation activities may be intermittent (Volkenborn et  
475 al., 2016) and cause oscillations in oxygen availability that stimulate organic  
476 matter degradation (Aller and Aller, 1998). This inverted microbial loop is a  
477 prime example how animals as ecosystem engineers impact sediment carbon  
478 processing (Meysman et al., 2006).

479  
480

## 481 **5.5 Imagine a world without animals.**

482

483 An ocean floor inhabited solely by microbes and without animals was likely the  
484 reference state during the first four billion of years of Earth's history (Canfield,  
485 2014; Lenton and Watson, 2011). Moreover, in modern systems with anoxic  
486 bottom waters benthic animals are absent (Rhoads and Morse, 1971; Diaz and  
487 Rosenberg, 1995, 2008; Levin, 2003; Levin et al, 2009). In these systems, organic  
488 matter degradation pathways are different not only because of a lack of oxygen  
489 and use of alternative electron acceptors, but also because bio-irrigation and  
490 sediment reworking are absent (Aller and Aller, 1998; Levin et al., 2009;

491 Middelburg and Levin, 2009). Consequently, microbe-fauna interactions  
492 (enhanced carbon delivery, Fig. 5; animal stimulation of microbes, Fig. 6) are  
493 impeded.  
494 While organic matter mineralization in the presence of oxygen may be more  
495 efficient than in anoxic environments (Canfield, 1994; Kristensen et al., 1995;  
496 Dauwe et al. 2001) , the lack of animal stimulation of microbes may also  
497 contribute to burying organic carbon more efficiently in sediments underlying  
498 anoxic bottom waters (Hartnett et al., 1998; Hartnett and Devol, 2003;  
499 Middelburg and Levin, 2009; Jessen et al., 2017). Moreover, the organic matter  
500 buried in hypoxic and anoxic settings is usually less degraded (Cowie, 2005,  
501 Cowie et al., 2009; Vandewiele et al., 2009; Koho et al., 2013; Jessen et al., 2017).  
502 This presence of animals and all their interactions with organic matter and  
503 microbes has consequences for organic carbon processing in marine sediments  
504 and thus the global carbon cycle. It is obvious for any terrestrial microbiologist  
505 that a world with trees and other macrophytes would be different than one  
506 without. Moreover, biological oceanographers and limnologists agree that  
507 zooplankton and other metazoan consumers contribute to biogeochemical cycles  
508 (Vanni, 2002; Vanni and McIntyre, 2016), and I hope that colleagues studying  
509 marine sediments are aware that BIO in sediment biogeochemistry is more than  
510 just microbiology.

511

#### 512 *Acknowledgement*

513 This paper presents my acceptance lecture for the Vladimir Ivanovich Vernadsky  
514 Medal 2017 of the European Geosciences Union. I thank the colleagues that  
515 nominated me for this award and the many colleagues, students and  
516 postdoctoral fellows with which I have had the pleasure to interact and  
517 collaborate over the years. In particular, the late Carlo Heip who was  
518 instrumental for getting some more realistic BIO into my biogeochemistry and  
519 my long-term collaborators in modelling benthic ecosystems (Karlina Soetaert,  
520 Peter Herman, Filip Meysman and Bernie Boudreau), in food-web studies (Dick  
521 van Oevelen, Leon Moodley), in organic geochemistry (Jaap Sinnighe Damsté and  
522 Stefan Schouten) and in coastal biogeochemistry (Jean-Pierre Gattuso and Carlos  
523 Duarte). Ton Marcus is thanked for graphic support. Don Canfield, Roberto  
524 Danovaro and one anonymous referee are thanked for constructive feedback.  
525 This is a contribution to the Netherlands Earth System Science Centre supported  
526 by the Dutch ministry of Education and Science.

Figure 1. Different views, approaches and interests on carbon processing in marine sediments. Paleoceanographers focus on the sedimentary record, biogeochemists quantify carbon burial and recycling, organic geochemists study alteration of organic matter and ecologists focus on carbon as food for organisms living in the sediment. The red-orange-yellow fractions of organic matter have a different lability.

Figure 2. Conceptual model of organic matter (OM) degradation and re-oxidation pathways (based on Middelburg and Levin, 2009). The red arrows reflect the fate of (energy-rich) substrates released during anaerobic mineralization.

Figure 3. Carbon processing in marine sediments on the short-term (left) and the long-term (right). Organic matter produced in the sunlit layer of the ocean and delivered to the sediments is either consumed by organisms or buried. The organic matter consumed by organisms is used to synthesize biomass or metabolized to carbon dioxide and nutrients. On the long-term or at steady-state, i.e. the biomass of benthic organisms does not change, the benthic community can be considered a black box diverting organic matter either into metabolites or into the geosphere (burial).

Figure 4. Conceptual diagram showing the relationships between molecular uncharacterizable organics, deposited phytodetritus and secondary production. Phytodetritus is degraded preferentially and new biomass is formed, which after death of the organisms is added to the pool of detritus and subject to degradation. Multiple cycles of organic matter processing eventually results in the formation of molecular uncharacterizable organic matter. The red-orange-yellow fractions of organic matter have a different lability.

Figure 5. Organic matter supply to sediments. 1. The traditional view of organic matter settling passively from the water column (donor control). 2. Sediments in the photic zone are inhabited by benthic microalgae that produce new organic matter in situ and grazing animals can impact the growth of these primary producers. 3. Bioturbating animals transfer labile carbon from the sediment surface layer to deeper layers in the sediments. (Vertical axis is depth, horizontal is concentration) 4. Suspension feeding organisms enhance the transfer of suspended particulate matter from the water column to the sediments (biodeposition). 5. Sponge consume dissolved organic carbon and produce cellular debris that can be consumed by benthic organisms (i.e. the sponge loop).

Figure 6. The microbial and inverted microbial loop. In the water column dissolved organic carbon derived from phytoplankton, zooplankton or microbes (via viral loop) is consumed by heterotrophic microbes, which in turn are consumed by protists and small animals with the consequence that carbon flowing through dissolved organic carbon pools eventually can be used by larger animals (microbial loop). In sediments, the dissolved organic carbon (from viral lysis and other sources) is also consumed by heterotrophic microbes but this carbon is inefficiently transferred to animals. The engineering activities of animals are key in delivering labile organic matter (phytodetritus) to microbes living in the subsurface (inverted microbial loop).
