21 **Keywords:** Particulate biogenic barium; Carbon remineralisation; North Atlantic; Biological pump

22 **Abstract**

23 The remineralisation of sinking particles by prokaryotic heterotrophic activity is important for controlling oceanic
24 carbon sequestration. Here, we report mesopelagic particulate organic carbon (POC) remineralisation fluxes in the
25 North Atlantic along the GEOTRACES-GA01 section (GEOVIDE cruise; May-June 2014) using the particulate
26 biogenic barium (excess barium; Ba_{xs}) proxy. Important mesopelagic (100–1000 m) Ba_{xs} differences were observed
27 along the transect depending on the intensity of past blooms, the phytoplankton community structure and the physical
28 forcing, including downwelling. The subpolar province was characterized by the highest mesopelagic Ba_{xs} content (up
29 to 727 pmol L⁻¹), which was attributed to an intense bloom averaging 6 mg Chl-*a* m⁻³ between January and June 2014
30 and by an intense 1500 m-deep convection in the central Labrador Sea during the winter preceding the sampling. This
31 downwelling could have promoted a deepening of the prokaryotic heterotrophic activity, increasing the Ba_{xs} content.

32 In comparison, the temperate province, characterized by the lowest Ba_{xs} content (391 pmol L⁻¹), was sampled during
33 the bloom period and phytoplankton appear to be dominated by small and calcifying species, such as coccolithophorids.
34 The Ba_{xs} content, related to an oxygen consumption, was converted into a remineralisation flux using an updated
35 relationship, proposed for the first time in the North Atlantic. The estimated fluxes were in the same order of magnitude
36 than other fluxes obtained by independent methods (moored sediment traps, incubations) in the North Atlantic.
37 Interestingly, in the subpolar and subtropical provinces, mesopelagic POC remineralisation fluxes (up to 13 and 4.6
38 mmol C m⁻² d⁻¹, respectively) were equalling and occasionally even exceeding upper ocean POC export fluxes, deduced
39 using the ²³⁴Th method. These results highlight the important impact of the mesopelagic remineralisation on the
40 biological carbon pump of the studied area with a near-zero, deep (> 1000 m) carbon sequestration efficiency in spring
41 2014.

42 1. Introduction

43 The ocean represents the largest active CO₂ sink (Sabine et al., 2004) partly materialized by the oceanic biological
44 carbon pump (BCP), which controls the export of carbon and nutrients to the deep ocean through the production of
45 biogenic sinking particles (Boyd and Trull, 2007; Sigman and Boyle, 2000; Volk and Hoffert, 1985). The North
46 Atlantic sustains one of the most productive spring phytoplankton bloom of the world's ocean (Esaias et al., 1986;
47 Henson et al., 2009; Longhurst, 2010; Pommier et al., 2009). The high primary productivity in combination with the
48 water mass formation there as part of the thermohaline circulation (Seager et al., 2002), results in a particularly efficient
49 BCP in the North Atlantic (Buesseler et al., 1992; Buesseler and Boyd, 2009; Herndl and Reinthaler, 2013; Honjo and
50 Manganini, 1993; Le Moigne et al., 2013b), estimated to contribute up to 18% of the global oceanic BCP (Sanders et
51 al., 2014). However, the magnitude of the carbon transfer to the deep ocean depends on many factors including the
52 efficiency of bacterial remineralisation within the mesopelagic layer (100–1000 m depth layer). In this layer, most of
53 the particulate organic carbon (POC) exported from the upper mixed layer is respired or released to the dissolved phase
54 as dissolved organic carbon (DOC; Buesseler et al., 2007; Buesseler and Boyd, 2009; Burd et al., 2016; Herndl and
55 Reinthaler, 2013; Lampitt and Antia, 1997; Martin et al., 1987). Mesopelagic remineralisation has been often reported
56 to balance or even exceed the carbon supply from the surface (i.e. POC and DOC; Aristegui et al., 2009; Baltar et al.,
57 2009; Burd et al., 2010; Collins et al., 2015; Fernández-castro et al., 2016; Giering et al., 2014; Reinthaler et al., 2006),
58 highlighting the impact of mesopelagic processes on bathypelagic carbon sequestration. Unfortunately, studies
59 focusing on the mesopelagic layer are scarce, and the remineralisation process in this part of the water column remains
60 poorly constrained. A variety of methods have been used to assess deep remineralisation. The attenuation of the
61 particulate organic matter concentration with depth can be deduced from POC fluxes recorded by bottom tethered or
62 free-floating neutrally buoyant sediment traps (e.g., Buesseler et al., 2007; Honjo et al., 2008; Martin et al., 1987)
63 deployed at different depths. Bacterial respiration can be assessed by measuring the rate of dissolved oxygen
64 consumption, but this approach is usually limited to the upper 200 m of depth because of sensitivity issues (Aristegui
65 et al., 2005; Christaki et al., 2014; Lefèvre et al., 2008). However, sediment traps and direct respiration measurements
66 are insufficiently reliable for depths exceeding 200 to 500 m (i.e. the lower mesopelagic area). Earlier work has
67 revealed that the accumulation of particulate biogenic barium (excess barium; Ba_{xs}) in the mesopelagic water column
68 (100 – 1000 m) is related with organic carbon remineralisation. This biogenic Ba is essentially carried by barite

69 (BaSO₄) micro-crystals, which form inside oversaturated micro-environments, mostly aggregates of organic material
70 where prokaryotic activity is intense (Bishop, 1988; Collier and Edmond, 1984; Dehairs et al., 1980; Ganeshram et al.,
71 2003; Gonzalez-Munoz et al., 2003). Bacterial activity will result in the disruption of these aggregates, thereby
72 releasing the barite crystals in the ambient water. As a result, the concentration of Ba_{xs} relates with oxygen consumption
73 rate (Dehairs et al., 1997; Shopova et al., 1995) and can be converted into a remineralisation rate of POC in the
74 mesopelagic layer (Dehairs et al., 1997). Ba_{xs} has been successfully used as a proxy of POC remineralisation flux in
75 the Southern Ocean (Cardinal et al., 2005; Jacquet et al., 2008a, 2008b, 2011a, 2015; Planchon et al., 2013) and Pacific
76 Ocean (Dehairs et al., 2008).

77 We examined mesopelagic POC remineralisation along the GEOTRACES-GA01 section during the GEOVIDE cruise
78 (15 May–30 June, 2014; R/V Pourquoi Pas?) by assessing particulate biogenic barium (excess barium; Ba_{xs}) contents.
79 This study is the first one to report the use of the Ba_{xs} proxy in the North Atlantic. Regional variations of the Ba_{xs}
80 distributions along the crossed biogeochemical provinces are discussed regarding the stage and intensity of the bloom,
81 the phytoplankton community structure and the physical forcing. We re-assessed the algorithm between Ba_{xs} content
82 and oxygen consumption developed for the Southern Ocean, adapting it for the North Atlantic. We compared the
83 remineralisation fluxes resulting from this new North Atlantic-specific algorithm with those obtained by other methods
84 in the same area. This comparison, in combination with surface primary production (PP) and POC export estimates
85 (Lemaitre et al., 2018; this issue), allowed us to evaluate the fate of POC to the deep ocean and to constrain the BCP
86 in the North Atlantic.

87 2. Methods

88 2.1. Study area

89 The GEOVIDE section (15 May–30 June 2014; R/V Pourquoi pas?) crossed different biogeochemical provinces in the
90 North Atlantic including the North Atlantic subtropical gyre (NAST; Stations 1 and 13), the North Atlantic drift
91 (NADR) covering the West European (Stations 21 and 26) and Icelandic (Stations 32 and 38) basins, and the Atlantic
92 Arctic (ARCT) divided between the Irminger (Stations 44 and 51) and Labrador (Stations 64, 69 and 77) Seas
93 (Longhurst, 1995; Fig. 1, 2).

94 The evolution of chlorophyll-*a* (Chl-*a*) concentrations from satellite imagery (Fig. 1) revealed the decline of the bloom
95 in the NAST and the Labrador Sea and the bloom period within the NADR province and the Irminger Sea. Indeed, the
96 highest daily PP rates were measured in the NADR and in the Irminger Sea (> 150 mmol C m⁻² d⁻¹; Fonseca-Batista et
97 al., 2018; this issue; Lemaitre et al., 2018; this issue). The phytoplankton community structure also varied regionally,
98 with diatoms dominating the ARCT province and the West European basin of the NADR, coccolithophorids
99 dominating the Icelandic basin of the NADR and cyanobacteria in the NAST province (Tonnard et al., 2018; this
100 issue). Finally, as described elsewhere (Daniault et al., 2016; García-Ibáñez et al., 2015; Kieke and Yashayaev, 2015;
101 Zunino et al., 2017; this issue), these provinces also differ in terms of their hydrographic features. The NADR province
102 is crossed by the sub-arctic front (SAF), which was located near Station 26 during GEOVIDE (Fig. 2). Strong currents
103 were observed near the Greenland margin (probably influencing Stations 51 and 64), and an intense 1500 m-deep
104 convection happened during the winter preceding GEOVIDE in the central Labrador Sea (Station 69) due to the

105 formation of the Labrador Sea Water (LSW) in winter (Fig. 2). These features influenced the magnitude of the carbon
106 export fluxes, as well as the export and transfer efficiencies along the transect (Lemaitre et al., 2018; this issue). The
107 highest POC export fluxes from the upper-ocean (calculated at the depth “z” ranging from 40 to 130 m at Station 44
108 and 32, respectively) were observed in the NADR province and in the Labrador Sea and reached up to 10 mmol C m⁻²
109 d⁻¹ at Station 69 (Lemaitre et al., 2018; this issue). Export efficiency (i.e., the ratio of the POC export over the PP)
110 was generally low (≈10%), except at Stations 1 and 69 where it reached 30%. The transfer efficiency (defined as the
111 ratio of the POC export at z+100 m over the POC export at z) was more variable, ranging from 30% at Station 69 to
112 92% at Station 26 (Lemaitre et al., 2018; this issue).

113 2.2. Sampling and analyses

114 For different objectives, during GEOVIDE, suspended particles were collected by different sampling techniques. The
115 main goal of the Niskin sampling was to derive Ba_{xs} concentrations and, thus, carbon remineralisation fluxes in the
116 mesopelagic zone (high resolution in the 100-1000 m layer) at stations where PP data and carbon export fluxes were
117 also determined. The goal of the Go-Flo sampling was, at first, dedicated to the determination of all dissolved and
118 particulate trace elements and their isotopes. Since particulate Ba and Al were determined on samples collected by
119 both sampling techniques, we took the opportunity to compare both datasets in order to assess the quality of our data.

120 1) Ba_{xs} concentrations measured in samples collected using a standard CTD rosette equipped with 12 L Niskin
121 bottles. At eleven station, 18 depths were generally sampled between the surface and 1500 m in order to cover a high
122 vertical resolution in the mesopelagic layer (Table S1).

123 Four to 8 L of seawater were filtered on acid-cleaned polycarbonate membranes of 0.4 μm porosity (Nuclepore®, 47
124 or 90 mm diameter). Filter membranes were rinsed with Milli-Q grade water (18.2 MΩ cm; ≤ 5 mL) to remove sea-
125 salt, dried at ambient temperature under a laminar flow hood and finally stored in clean petri slides until analysis in
126 the home based laboratory.

127 Filters were totally digested overnight with a concentrated tri-acid mixture (1.5 mL HCl / 1 mL HNO₃ / 0.5 mL HF;
128 all Merck suprapur grades) using clean Teflon vials (Savillex®) on a hot plate at 90°C. The acid solution was then
129 evaporated at 110°C until near dryness and the residue dissolved in 13 mL 0.32M HNO₃ (Merck; distilled Normapur).
130 The solutions were transferred to polypropylene tubes (VWR) and analysed for Barium (Ba), Aluminium (Al) and
131 other major and minor elements using an inductively coupled plasma-quadrupole mass spectrometer (ICP-QMS; X
132 Series 2 Thermo Fisher) equipped with a collision cell technology (CCT). We used a concentric quartz nebulizer (1
133 mL min⁻¹) and nickel sample and skimmer cones. During the analyses, internal standards (Ru, In, Re and Bi) were
134 added to samples in order to monitor and correct the instrumental drift and matrix-dependent sensitivity variations.

135 Two multi-element artificial standard solutions were prepared for external calibration. The first contained major
136 elements (Na, Mg, Al, Ca and Ti) and the second was prepared with minor elements (Sr, Ba, REEs, Th and U).
137 Standards were prepared by dilution of the multi-element mixed standard stock solutions to span the expected range
138 of sample concentrations, with concentrations in the standard curve spaced to cover potential sample variations.

139 The accuracy and precision of our analyses were assessed using the following Certified Reference Materials (CRM):
140 BHVO-1, JB-3, JGb-1 and SLRS-5 (Table 1).

141 The detailed procedure for sample preparation and analysis is given in Cardinal et al. (2001).

142 2) Ba_{xs} concentrations measured in samples collected using the trace metal clean rosette, equipped with
143 twenty-two 12 L Go-Flo bottles at higher spatial resolution (31 stations) but with lower vertical resolution in the
144 mesopelagic layer. Details about filtration, sample processing and analyses can be found in Gourain et al. (2018; this
145 issue). Briefly, at each depth, two size fractions were investigated: 0.45–5 μm using polysulfone filters (Supor®) and
146 > 5 μm using mixed ester cellulose filters (MF, Millipore®). Between 2 and 5 L of seawater were filtered for the upper
147 water column (surface to 100 m) and 10 L for depths exceeding 100 m. Excess seawater from the filters was drawn off
148 and then the filters were frozen in acid-cleaned petri-dishes until home analysis. In the laboratory, filters were digested
149 with a solution of 8 M HNO_3 (Ultrapur grade, Merck) and 2.3 M HF (Suprapur grade, Merck). Vials were then refluxed
150 at 130 °C on a hotplate for 4 h. After gentle evaporation, the residue was redissolved with approximately 2 mL of 0.32
151 M HNO_3 spiked with 1 $\mu\text{g L}^{-1}$ of Indium. Solutions were analysed using a SF-ICP-MS (Element 2, Thermo) following
152 the method of Planquette and Sherrell (2012). Total Ba and Al concentrations were calculated by summing the two
153 size fractions. The accuracy and precision of these analyses were assessed using the BCR-414 CRM (see Gourain et
154 al., 2018; this issue).

155 For both Niskin and Go-Flo samples, the Ba_{xs} concentrations were calculated by subtracting the particulate lithogenic
156 barium (pBa-litho) from the total particulate barium (pBa). The pBa-litho was determined by multiplying the
157 particulate aluminium (pAl) concentration by the upper continental crust (UCC) Ba:Al molar ratio (0.00135 mol mol⁻¹;
158 Taylor and McLennan, 1985). Along the GEOVIDE section, the pBa-litho fraction represented less than 7 % of total
159 barium, except at Stations 1 and 53, close to the Iberian and Greenland margin where pBa-litho accounted for 28 and
160 44 % of total Ba, respectively. Because of the rather large uncertainty associated with the UCC Ba:Al ratio and because
161 of the high lithogenic particle loads at Stations 1 and 53, those stations were not considered further in this study.
162 Uncertainties on Ba_{xs} concentrations were estimated using error propagation and ranged between 6 and 25 %.

163 For stations where total pBa and pAl concentrations were available at similar depths, the regression of Ba_{xs}
164 concentrations (100-1000 m layer) from the Go-Flo samples vs. those of the Niskin samples was significant (regression
165 slope: 0.87; R^2 : 0.61; $p < 0.01$; $n = 66$; Fig. S1) despite some discrepancies, especially in the higher concentration domain.
166 Such discrepancies could have resulted from differences in the chemical protocols and most likely the filters used. The
167 Niskin samples collected on 0.4 μm polycarbonate filters were digested using a tri-acid mix (50% HCl/33% HNO_3 /17%
168 HF), while the Go-Flo samples collected on paired 0.45 μm polyestersulfone / 5 μm mixed ester cellulose filters were
169 digested using a 50% HNO_3 /10% HF acid mix. The use of different filter types has been shown to lead to different
170 concentrations, depending on the element of consideration, despite using the same digestion technique (Planquette and
171 Sherrell, 2012). The addition of HCl has been shown to not improve elemental recoveries of marine particles (Ohnemus
172 and Lam, 2014) but the larger HF concentration of the tri-acid mix used for digesting the Niskin samples, likely,
173 dissolved more of the refractory particles, explaining the slightly higher concentrations obtained for these samples.

174 In addition, filtered suspended matter was also analysed using a Field Emission Scanning Electron Microscope (FE-
175 SEM; JEOL JSM-7100F) to detect the presence of barite particles. Because of time consuming analyses, seven filters
176 from the different basins were scanned: six samples with high mesopelagic Ba_{xs} concentrations (Station 13 at 400 m;
177 Station 38 at 300 m; Station 44 at 300 and 700 m; Station 69 at 600 m and Station 77 at 300 m) and one sample with
178 high surface Ba_{xs} concentrations (Station 26 at 50 m). For each sample, a filter surface of 0.5 cm² was analysed.

179 To verify the relationship between Ba_{xs} and barite particles (see section 4.1), we evaluated the contribution of the barite
180 particles to Ba_{xs} concentrations for the sample collected at 600 m at Station 69 and which has a high mesopelagic Ba_{xs}
181 content (see Section 3). Using the FE-SEM, 0.003% of the total filter surface was scanned and size and volume of all
182 detected barite particles present in this surface area were assessed. To this aim, each barite particle was pictured using
183 a magnification setting between 12,000 and 15,000 \times . Images were then analysed with the software ImageJ and, for
184 each barite particle, the longest and shortest axes were measured and pixels were converted to nanometres. Barite
185 particles were then assimilated to ellipses to calculate their volume. Finally, the concentration of pBa of each barite
186 particle was calculated using Eq. (1):

$$187 \quad \text{pBa in barite} = \Sigma [V \times \mu_{BaSO_4} \times (M_{Ba} / M_{BaSO_4})] / V_{SW} \quad (1)$$

188 where V is the volume of the barite particle (between 0.01 and 3.96 μm^3), μ_{BaSO_4} is the density of barite (4.45 g cm^{-3}),
189 M_{Ba} / M_{BaSO_4} is the molar proportion of barium in $BaSO_4$ (0.59) and V_{SW} is the volume of seawater filtered (equivalent
190 to 0.2 mL for the portion of filter surface analysed).

191 3. Results

192 3.1. Particulate biogenic Ba_{xs} distribution

193 3.1.1. Section overview

194 The Ba_{xs} longitudinal section of concentrations (Fig. 4) shows elevated concentrations between 100 and 1000 m, in the
195 mesopelagic layer ($333 \pm 224 \text{ pmol L}^{-1}$; median \pm 1s.d.; $n=209$). In comparison, the surface ocean (depths < 100 m)
196 and the deep ocean (depths > 1000 m) are characterized by lower median values (94 and 114 pmol L^{-1} , $n=113$ and 199,
197 respectively). Exceptions can be observed for the upper waters at Stations 25 and 26 and bottom waters at Stations 29,
198 32, 36, 38 and 71 where high Ba_{xs} concentrations may be attributed to Ba assimilation by phytoplankton and sediment
199 resuspension, respectively (Gourain et al., 2018; this issue). Concentrations ranged from 4 (Station 11, 55 m) to 24643
200 (Station 26, 35 m) pmol L^{-1} in surface waters and from 7 (Station 71, 350 m) to 1388 (Station 15, 300 m) pmol L^{-1} in
201 the mesopelagic layer (100–1000 m). For the mesopelagic layer, where the maximum Ba_{xs} concentrations were
202 generally observed, the highest Ba_{xs} concentration was observed in the NAST province, reaching 1388 pmol L^{-1} at 300
203 m of Station 15. These maxima occurred between 200 and 600 m but were spread over larger depth intervals in the
204 ARCT province, where high Ba_{xs} values occurred until 1200 m depth at Station 69.

205 3.1.2. Individual Profiles

206 In this section, we only present Ba_{xs} concentrations obtained from Niskin bottles. This is because (i) both data sets
207 converge (regression slope: 0.87; R^2 : 0.61; $p<0.01$; $n=66$); (ii) Niskin casts had a better sampling resolution in the 100–
208 1000 m layer; and (iii) Niskin casts were also used for the determination of POC export using the 234-Th deficit
209 method (see Lemaitre et al., 2018; this issue).

210 All the vertical Ba_{xs} profiles (Fig. 5) show increased concentrations between 100 and 1000 m, followed by lower
211 concentrations deeper that tend to return to a background level of $180 \pm 54 \text{ pmol L}^{-1}$ ($n=10$) as average along the
212 GEOVIDE transect. This background value is quite characteristic for the deep ocean (> 1000 m) and is considered to

213 represent the residual Ba_{xs} left over after partial dissolution and sedimentation of Ba_{xs} produced during previous
214 phytoplankton growth events (Dehairs et al., 1997).

215 In the NAST province (Station 13), the Ba_{xs} concentrations steadily increased from the surface to 400 m, reaching 961
216 $pmol L^{-1}$, then decreased with depth, reaching the background level of $180 pmol L^{-1}$ at 1500 m.

217 In the West European basin of the NADR province, vertical profiles of Ba_{xs} were similar, yet concentrations in the
218 mesopelagic layer were smaller at Station 21 with Ba_{xs} peaking only at $524 pmol L^{-1}$. Ba_{xs} concentrations returned to
219 the background value at 1200 m. Ba_{xs} concentration in surface waters of Station 26 were the highest of the entire
220 section reaching $1888 pmol L^{-1}$ at 50 m (note that the value for the Go-Flo sample at 35 m reaches $24643 pmol L^{-1}$;
221 section 3.1.1). Below this depth, Ba_{xs} concentrations decreased back to the background level at 100 m, then increased
222 again, with a second peak of $451 pmol L^{-1}$ at 200 m. In the Icelandic basin of the NADR province, Ba_{xs} concentrations
223 were relatively high, reaching 646 and $711 pmol L^{-1}$ at 200 and 300 m at stations 32 and 38, respectively. Station 38
224 was also characterized by a double Ba_{xs} peak at 300 and 700 m. Below this second maximum, Ba_{xs} concentrations
225 decreased to the background level at 1000 m for both stations.

226 In the ARCT province, a similar double peak profile was observed at Station 44, in the Irminger Sea, with Ba_{xs}
227 concentrations reaching $750 pmol L^{-1}$ between 200 and 400 m and $820 pmol L^{-1}$ at 700 m. Then, Ba_{xs} concentrations
228 returned to the background value at 1100 m. Close to the Greenland margin (Station 51), Ba_{xs} concentrations reached
229 a maximum of $495 pmol L^{-1}$ at 300 m, which was lower than the maxima determined at the other stations of the ARCT
230 province.

231 The Ba_{xs} concentrations of Stations 44 and 51 were compared to those obtained at Station 11 ($63.5^{\circ}N-324.8^{\circ}E$) and
232 Station 5 ($56.9^{\circ}N-317.2^{\circ}E$) of the GEOSECS cruise, in summer 1970 (Brewer et al., unpublished results; Fig. 5). The
233 Ba_{xs} concentrations obtained at GEOSECS Station 11 vary over a similar range as those for GEOVIDE Station 44
234 ($173-658 pmol L^{-1}$ and $116-823 pmol L^{-1}$, respectively). Similar ranges were also observed between GEOSECS Station
235 5 and GEOVIDE Station 51 ($170-402 pmol L^{-1}$ and $127-359 pmol L^{-1}$, respectively).

236 In the Labrador Sea (Stations 64, 69 and 77), high Ba_{xs} concentrations ($> 450 pmol L^{-1}$ and up to $863 pmol L^{-1}$ at
237 Station 69) extended to at least 1000 m, without returning to the background level as compared to the other stations
238 outside the Labrador Sea. Results for Go-Flo samples indicated that Ba_{xs} concentrations decreased to the background
239 level ($180 pmol L^{-1}$) at 1300, 1700 and 1200 m for Stations 64, 69 and 77, respectively.

240 **3.2. Mesopelagic Ba_{xs}**

241 The Ba_{xs} concentrations were integrated (trapezoidal integration) over two depth intervals of the mesopelagic layer
242 (100–500 m and 100–1000 m; Table 2) to obtain depth-weighted average (DWA) Ba_{xs} values.

243 The DWA Ba_{xs} values between 100 and 500 m ranged from 399 to $672 pmol L^{-1}$ and from 315 to $727 pmol L^{-1}$ between
244 100 and 1000 m (Stations 51 and 69, respectively). The DWA Ba_{xs} values varied by less than a factor of 1.4 between
245 both modes of integration. Only for the Labrador Sea (Stations 64, 69 and 77) the DWA Ba_{xs} values for the 100–1000
246 m were larger than for the 100-500 m interval. For the latter stations, the Ba_{xs} inventories for the interval between 100
247 m and the depths where concentrations decreased to background level (1300, 1700 and 1200 m for Go-Flo casts at
248 Stations 64, 69 and 77, respectively) were somewhat smaller than for the inventories between 100–1000 m (up to 1.5

249 times in the case of Station 77). To facilitate inter-comparison between stations, we consistently considered Ba_{xs}
250 inventories over the 100-1000 m depth interval in the following discussion.

251 Within the NAST province, Station 13 was characterized by a relatively low DWA Ba_{xs} value of 419 pmol L^{-1} .
252 Similarly, low median DWA Ba_{xs} contents were observed within the NADR province ($403 \pm 34 \text{ pmol L}^{-1}$, $n=4$), with
253 the lowest DWA Ba_{xs} observed at Station 26 ($391 \pm 58 \text{ pmol L}^{-1}$).

254 The highest median DWA Ba_{xs} value was observed in the ARCT province ($566 \pm 155 \text{ pmol L}^{-1}$, $n=5$). There, the DWA
255 Ba_{xs} contents were more variable between stations, ranging from 315 pmol L^{-1} at Station 51 to 727 pmol L^{-1} at Station
256 69, with a high DWA Ba_{xs} also observed at Station 44 (633 pmol L^{-1}).

257 4. Discussion

258 4.1. Barite is the main carrier of Ba_{xs}

259 Several barite particles were observed associated to or in close proximity to biogenic fragments such as coccoliths
260 (Fig. 3), suggesting they were originally formed inside biogenic microenvironments as proposed by others (Bishop,
261 1988; Dehairs et al., 1980; Stroobants et al., 1991). However, no barite crystals were observed in the surface waters at
262 Station 26 where very high Ba_{xs} concentrations were recorded (up to 1888 pM), most likely the result of Ba uptake
263 and/or adsorption by biota, as reported by Sternberg et al. (2005) for culture experiments. This result was expected as
264 it fits in the concept of barite formation proposed by Stroobants et al. (1991), showing that the barium sulphate in
265 biogenic aggregates of surface waters is not crystallized, whereas below this surface layer, when organic matter
266 degradation occurs, barite is present as discrete micron-sized particles.

267 Regarding the contribution of the barite particles to the Ba_{xs} concentration for the sample collected at 600 m of Station
268 69, we assumed that the small filter portion (only 0.003% of the total filter surface was analysed by FE-SEM) is
269 representative of the whole filter. The Ba concentration deduced from the FE-SEM particle sizing analysis and using
270 Eq. (1) is 1260 pmol L^{-1} . This is in the same order of magnitude, although 1.5 times larger, than the concentration of
271 total Ba_{xs} obtained by ICP-MS (831 pmol L^{-1}) after whole filter digestion. The similarity between both values is
272 remarkable considering the limitations of the FE-SEM procedure (the very small fraction of filter analysed). This also
273 confirms that Ba_{xs} in the mesopelagic layer is carried mostly by barite particles, as observed earlier (Dehairs et al.,
274 1980).

275 4.2. Factors influencing the DWA Ba_{xs} in the North Atlantic

276 4.2.1. Influence of the intensity and stage of the bloom

277 We compared our Ba_{xs} inventories with the average biomass development from January to June 2014 (Fig. 6), which
278 covers the entire productive period in the North Atlantic, starting from winter till the date of our sampling.

279 Along the GEOVIDE transect, the most productive area was clearly the Labrador Sea of the ARCT province, where
280 Chl-*a* concentrations averaged 6 mg m^{-3} (Fig. 6). This basin was sampled during the decline of the bloom (Fig. 1; Chl-
281 *a* concentration was $> 3 \text{ mg m}^{-3}$ one month before the sampling, and PP and nutrient concentrations were low during
282 sampling). The high DWA Ba_{xs} observed in this area (Table 2) likely results from the large biological activity during
283 the period preceding sampling. The West European basin of the NADR province, and in particular the area around

284 Station 21, was also characterized by a high phytoplankton biomass between January and June (Fig. 6), though lower
285 than in the Labrador Sea. Here, the bloom started in May (Fig. 1; Chl-*a* concentration $\approx 3 \text{ mg m}^{-3}$, one month before
286 the sampling) and was still in progress during the sampling, as indicated by the high PP ($135 \text{ mmol C m}^{-2} \text{ d}^{-1}$). These
287 features can explain the lower DWA Ba_{xs} observed at Station 21 (Table 2) compared to the Labrador Sea. The other
288 stations of the NADR (Stations 26, 32 and 38) were sampled during the bloom development (Fig. 1) with high PP
289 reaching $174 \text{ mmol m}^{-2} \text{ d}^{-1}$ at Station 26. The latter stations were characterized by lower DWA Ba_{xs} values compared
290 to other stations, pointing to a time lag between the phytoplankton bloom and the build-up of the Ba_{xs} signal. However,
291 this was not the case for Station 44, in the Irminger Sea of the ARCT province, which was sampled during the bloom
292 (high PP, high Chl-*a* and high nutrient concentrations during the sampling period) and characterized by one of the
293 highest DWA Ba_{xs} , possibly reflecting an important past bloom.

294 As also indicated by others, the mesopelagic Ba_{xs} signal builds-up during the growth season and therefore integrates
295 effects of past surface production (Dehairs et al., 1997; Cardinal et al., 2001, 2005). The large regional and temporal
296 variability of the bloom development stage thus results in a large variability of the mesopelagic Ba_{xs} signal in the North
297 Atlantic.

298 4.2.2. Influence of water masses/physical forcing

299 The Labrador Sea (Stations 64, 69 and 77) had the largest Ba_{xs} inventory coinciding with the presence of the Labrador
300 Sea Water (LSW; potential temperature between 2.7 and 3.8 °C and salinity below 34.9; Harvey, 1982; Yashayaev,
301 2007) in the upper 1500 m. The LSW formation takes place in the central Labrador Sea, where convection reached
302 $\sim 1700 \text{ m}$ during the winter preceding GEOVIDE (Fig. 2; Kieke and Yashayaev, 2015). The deepening of the mixed
303 layer has been recently shown to represent a major mechanism to convey organic carbon to the mesopelagic zone (from
304 23 % to $> 100 \%$ in high latitude regions; Dall’Olmo et al., 2016), supporting the carbon demand of the mesopelagic
305 food web (Burd et al., 2010; Aristegui et al., 2009). Moreover, the highest mesopelagic prokaryotic heterotrophic
306 abundance during GEOVIDE was observed in the central Labrador Sea (Station 69), reaching $896 \text{ cells } \mu\text{L}^{-1}$ at 500 m,
307 while the median values at the other stations for which bacterial cell numbers were available for the mesopelagic zone
308 (Stations 13, 21, 26, 32 and 38), reached only $258 \pm 60 \text{ cells } \mu\text{L}^{-1}$ at the similar depth (J. Laroche, J. Ratten and R.
309 Barkhouse, personal communication). Therefore, the LSW subduction area appears to reinforce the microbial loop by
310 increasing the layer in which the bacteria can thrive feeding on increased food supplies. This condition appears to
311 increase the Ba_{xs} inventory.

312 The LSW was also present in the Irminger Sea between 500 and 1000 m at Station 44 (Fig. 2). In the Temperature-
313 Salinity plot, the high Ba_{xs} concentrations of the second peak (823 pmol L^{-1} at 700 m; Fig. 5) are clearly associated
314 with the presence of LSW (Fig. 7a), suggesting that this second deeper Ba_{xs} maximum represents an advected signal.
315 We calculated the DWA Ba_{xs} without taking into account the 2nd peak (100-600 m depth interval) subtracted it from
316 the total DWA Ba_{xs} (100-1000 m depth interval) to estimate the advected signal. At Station 44, the advected Ba_{xs} signal
317 represents some 89 pmol L^{-1} , 14 % of the total signal, which is within the uncertainty of the remineralisation flux
318 calculation (see later below). Similarly, at Station 32 the Temperature-Salinity plot (Fig. 7b) points out that the second
319 Ba_{xs} peak (at 450 m; Fig. 5) was related to the presence of the Subarctic Intermediate water (SAIW; temperature of 5.6
320 $\pm 0.1 \text{ }^\circ\text{C}$ and salinity of 34.70 ± 0.02 ; Alvarez et al., 2004), which contributes to 14 pmol L^{-1} (3 % of the total signal).

321 Association of Ba_{xs} maxima with water masses is not always clear, as it is evident from the case of Station 38 where
322 the second Ba_{xs} maximum at 700 m (Fig. 5) does not coincide with a specific water mass (Fig. 7). In this case, the deep
323 Ba_{xs} maximum may possibly result from remineralisation generated by larger or heavier organic aggregates reaching
324 greater depths. At the remaining stations there was no evidence of water mass influence. Overall, lateral transport
325 influencing the local Ba_{xs} distributions was observed at two stations during GEOVIDE but did not significantly modify
326 the magnitude of the local mesopelagic Ba_{xs} inventory. However, the subduction occurring in the Labrador Sea resulted
327 in larger mesopelagic DWA Ba_{xs} , probably due to high organic export and associated prokaryotic heterotrophic activity
328 in these areas.

329 4.2.3. Influence of the phytoplankton community structure

330 The different Ba_{xs} inventories may also be influenced by the differences in phytoplankton community compositions.
331 The ARCT province was dominated by diatoms (median value: 63 ± 19 % of the total phytoplankton community taxa;
332 Tonnard et al., 2018, this issue) and was characterized by the highest DWA Ba_{xs} values while the NAST and NADR
333 provinces were characterized by higher abundance of haptophytes (median value: 43 ± 16 % of the total phytoplankton
334 community taxa; Tonnard et al., 2018, this issue) and by lower Ba_{xs} inventories. Coccolithophorids are part of the
335 haptophyte family and their dominance was confirmed by visual observations on filters (surface down to 400 m) by
336 FE-SEM. Calcifiers, such as coccolithophorids, have been shown to be more efficient in transferring carbon to the
337 deep ocean compared to diatoms (Francois et al., 2002; Klaas and Archer, 2002; Lam et al., 2011). This difference
338 could result from the low compaction or the high fluffiness of diatom aggregates, the high degree of degradability of
339 organic compounds within diatom aggregates, the greater density of calcite, the resistance of calcite to grazing and the
340 more refractory nature of the exported organic matter associated to calcite (Bach et al., 2016; Francois et al., 2002;
341 Klaas and Archer, 2002; Lam et al., 2011; Le Moigne et al., 2013a; Ragueneau et al., 2006). Therefore, enhanced
342 particle degradation when diatoms are predominant seems to increase the mesopelagic DWA Ba_{xs} .

343 4.3. Relationship between Ba_{xs} and carbon remineralisation in the North Atlantic

344 In previous studies focusing on the Southern Ocean, Ba_{xs} based-mesopelagic carbon remineralisation fluxes were
345 estimated using Eq. (2), which relates the accumulated mesopelagic Ba_{xs} inventory to the rate of oxygen consumption
346 (Shopova et al., 1995; Dehairs et al., 1997):

$$347 \text{Mesopelagic } Ba_{xs} = 17200 \times JO_2 + Ba_{\text{residual}} \quad (2)$$

348 where *Mesopelagic* Ba_{xs} is the depth-weighted average in the mesopelagic layer (DWA; in pmol L^{-1}), JO_2 is the rate
349 of oxygen consumption (in $\mu\text{mol L}^{-1} \text{d}^{-1}$), and Ba_{residual} is the deep-ocean Ba_{xs} value observed at zero oxygen
350 consumption (or Ba_{xs} background signal), which was determined to reach 180 pmol L^{-1} (Dehairs et al., 1997).

351 The oxygen consumption JO_2 can be converted into a C remineralisation flux through Eq. (3):

$$352 \text{POC mesopelagic remineralisation} = Z \times JO_2 \times (C:O_2)_{\text{Redfield Ratio}} \quad (3)$$

353 where the *POC mesopelagic remineralisation* is in $\text{mmol C m}^{-2} \text{ d}^{-1}$, Z is the thickness of the layer in which the
354 mesopelagic Ba_{xs} is calculated, JO_2 is the rate of oxygen consumption given by Eq. (2) and $(\text{C}:\text{O}_2)_{\text{Redfield Ratio}}$ is the
355 stoichiometric molar ratio of carbon to dioxygen (127/175; Broecker et al., 1985).

356 However, it is of interest to investigate if this relationship can be applied in the North Atlantic. Therefore, we
357 determined the oxygen utilization rate (OUR; $\mu\text{mol kg}^{-1} \text{ yr}^{-1}$), which is obtained by dividing the apparent oxygen
358 utilization (AOU, in $\mu\text{mol kg}^{-1}$) by the water mass age (Table S1). From the Iberian coast to Greenland, the age
359 calculation was based on the CFC-12 distribution (when available, otherwise CFC-11) determined in 2012 (OVIDE
360 CARINA cruise, de la Paz et al., 2017). For the Labrador Sea, the mean age of LSW has been estimated by Rhein et
361 al. (2015) based on a 25 year record of CFC contents. The OUR was then integrated over the 100–1000 m layer. The
362 resulting regression between DWA Ba_{xs} and OUR is as follows (see Fig. 8):

$$363 \quad \text{Mesopelagic } \text{Ba}_{\text{xs}} = 23391 (\pm 6368) \times \text{JO}_2 + 247 (\pm 61) \quad (4)$$

364 where *Mesopelagic* Ba_{xs} and JO_2 are defined in Eq. 2. Here, $\text{Ba}_{\text{residual}}$ is 247 pmol L^{-1} .

365 This regression is significant ($R^2 = 0.63$; $p\text{-value} = 0.006$) when Station 44 is excluded. This latter station was located
366 in the Irminger Gyre (Zunino et al., 2017; this issue) and it is possible that the gyre system induced an accumulation
367 and retention of mesopelagic Ba_{xs} , which then no longer reflects remineralisation associated with the present growth
368 season.

369 Figure 8 also shows the oxygen consumption related to the GEOVIDE Ba_{xs} values using the Southern Ocean regression
370 (Eq. 2). It appears that for a given mesopelagic Ba_{xs} inventory the oxygen consumption is smaller when using the
371 Southern Ocean regression. However, both regressions are not significantly different when taking into account the
372 errors associated with the slope and intercept of the regression in Eq. 4. The Southern Ocean regression appears to
373 represent a lower limit that seems to over-estimate the remineralisation fluxes. Furthermore, the relationship here
374 deduced for the North Atlantic is sensitive to potential errors. Indeed, calculation of OUR has been shown to under-
375 estimate the ocean respiration because of the non-proportional diffusive mixing of AOU and water mass age resulting
376 in an excess loss of AOU versus age (Koeve and Kähler, 2016). This would decrease the mismatch between the
377 Southern Ocean and North Atlantic regressions. Errors can also be directly associated with the CFC-based age values
378 of the water masses, which would appear especially critical for LSW. Indeed, the severe winter preceding the cruise
379 (2013/2014) appeared to have strongly ventilated LSW with a mixed layer depth exceeding 1700 m (Kieke and
380 Yashayaev, 2015), indicating that the mean age (4 years) estimated by Rhein et al. (2015) may have over-estimated
381 the real LSW age (P. Lherminier, personal communication). Moreover, in the Labrador Sea, the residence time of LSW
382 strongly varies between the central Labrador Sea (4–5 years) and the boundary currents off the Greenland and
383 Newfoundland coasts (a few months; Deshayes et al., 2007; Straneo et al., 2003). An over-estimation of these ages
384 leads to under-estimating OUR, resulting in reducing the apparent discrepancy between the both North Atlantic and
385 Southern Ocean regressions.

386 In the following discussion, carbon remineralisation fluxes are estimated for the North Atlantic (GEOVIDE and
387 GEOSECS cruises) using Eq. (4) and (3).

388 4.4. Comparison of remineralisation fluxes

389 4.4.1. Remineralisation from the Ba_{xs} proxy

390 The GEOVIDE remineralisation fluxes are compared with values reported for the World Ocean and also based on Ba_{xs}
391 inventories (Table 3; Fig. 9). In the North Atlantic, the fluxes obtained during the GEOVIDE and GEOSECS
392 (symbolized by stars in Fig. 9) cruises are of the same order of magnitude, highlighting a relatively constant
393 remineralisation over the last 44 years. The remineralisation fluxes reported for the Southern and Pacific Oceans are
394 similar to those in the NAST and NADR provinces of the North Atlantic. However, the fluxes in the ARCT province
395 are clearly higher, highlighting an important remineralisation in the northern part of the North Atlantic compared to
396 other oceans.

397 4.4.2. Remineralisation from direct measurements

398 In the North Atlantic, carbon respiration rates were also deduced from surface drifting sediment traps and associated-
399 shipboard incubations (Fig. 9). Collins et al. (2015) determined very high respiration rates reaching 39 and 72 mmol
400 $C\ m^{-2}\ d^{-1}$ at sites located in the NADR and in the ARCT provinces, respectively. Nevertheless, these high fluxes were
401 deduced in the upper mesopelagic layer (50–150 m) where respiration is larger compared to the lower mesopelagic
402 layer (100–1000 m). This difference in depth interval could thus explain the lower remineralisation rates in our study.
403 Also using surface drifting sediment traps and associated-shipboard incubations but supplemented by measurements
404 of zooplankton respiration, Giering et al. (2014) determined respiration rates in the NADR province (PAP site)
405 reaching 7.1 mmol $C\ m^{-2}\ d^{-1}$ during summer. This flux, determined over the 50–1000 m depth interval, is of the same
406 order of magnitude as our estimates for the NADR province.

407 4.4.3. Remineralisation from the deep sediment traps

408 The remineralisation flux in the mesopelagic layer can also be derived from the difference between a deep POC export
409 flux and a surface POC export flux. Honjo et al. (2008) compiled deep POC fluxes from bottom tethered sediment
410 traps and calculated the corresponding export production (upper-ocean POC export flux) using an ecosystem model
411 (Laws et al., 2000) for most world ocean provinces. Then, by difference, the authors estimated an annual average of
412 carbon remineralisation fluxes in the mesopelagic layer, which were converted into daily average fluxes.
413 Remineralisation fluxes reached values of 34 mmol $C\ m^{-2}\ d^{-1}$ in the ARCT province, 9 mmol $C\ m^{-2}\ d^{-1}$ in the NADR
414 province and 4 mmol $C\ m^{-2}\ d^{-1}$ in the NAST province (Fig. 9). Noteworthy, the flux in the ARCT province was one of
415 the highest mesopelagic remineralisation fluxes estimated worldwide, confirming the occurrence of important
416 remineralisation in the northern part of the North Atlantic as compared to other oceans. The values published by Honjo
417 et al. (2008) for the North Atlantic are quite similar to our median values obtained during GEOVIDE. Indeed,
418 mesopelagic remineralisation fluxes based on the Ba_{xs} proxy were similar to the value reported by Honjo et al. (2008)
419 for the NAST province, while they were respectively 2 and 4 fold lower in the NADR and in the ARCT provinces.
420 Overall, the remineralisation fluxes deduced from the Ba_{xs} proxy are in concordance with those obtained by the other
421 methods, confirming the order of magnitude of the mesopelagic remineralisation fluxes determined in this study of the
422 North Atlantic (Fig. 9).

423 **4.5. The biological carbon pump in the North Atlantic**

424 In order to investigate the efficiency of the biological carbon pump in the North Atlantic, we examined the daily PP
425 (Fonseca-Batista et al., 2018; this issue; Lemaitre et al., 2018; this issue), the upper-ocean POC export (Lemaitre et
426 al., 2008; this issue) and the POC remineralisation in the mesopelagic layer (Table 3; Fig. 10).

427 During GEOVIDE, low ($\leq 12\%$) export efficiencies (i.e., the ratio between PP and POC export) were observed at most
428 stations indicating an accumulation of biomass in surface waters or a strong turn-over of the exported organic matter
429 due to important remineralisation occurring in the upper water column (< 100 m). Furthermore, mesopelagic POC
430 remineralisation fluxes were relatively high, equalling or exceeding the POC export fluxes at some stations. This
431 highlights a strong mesopelagic remineralisation with little or no material left for export to the deep ocean, but above
432 all, it involves an imbalance between carbon supplies and mesopelagic remineralisation.

433 This imbalance can result from the differences between the time windows over which the PP, POC export and POC
434 remineralisation fluxes are integrated. Indeed, the measurements of PP represent a snapshot (24h incubations) while
435 measurements of export (^{234}Th) integrate several weeks (Benitez-Nelson et al., 2001; Buesseler et al., 1992) and
436 remineralisation (from the Ba_{xs} proxy) probably integrates much longer time scales. Moreover, previous studies in the
437 Southern Ocean showed that mesopelagic processing of exported organic carbon, as reflected by Ba_{xs} , has a phase lag
438 relative to the upper-ocean processes (Dehairs et al., 1997; Cardinal et al., 2005). Thus, we do not expect mesopelagic
439 Ba_{xs} to be in phase with coinciding amplitude of PP and subsequent export. Because of the observed high
440 remineralisation fluxes relative to the export fluxes, particularly in the ARCT province, it is likely that particulate
441 organic matter sank out of the surface waters and became subject to mineralisation in the mesopelagic layer during the
442 period preceding the specific time windows for POC export and PP. Such discrepancies between fluxes can be
443 amplified by the spatial and temporal variability of the phytoplankton blooms in this province, generating sudden high
444 export events and associated remineralisation. In contrast to the above, at Station 32 in the NADR province, a large
445 fraction of exported POC (50%; Table 4), appears to escape remineralisation. The more efficient POC transfer through
446 the mesopelagic layer of this province may be explained by the fact that sampling took place in an early stage of the
447 bloom and/or by the presence of calcified phytoplankton species, ballasting aggregates thereby increasing their settling
448 velocity (see Section 4.1).

449 Overall, the remineralisation in the mesopelagic layer is an important process that needs to be taken into account as
450 our results point to the poor capacity of specific areas within the North Atlantic to sequester carbon at depths below
451 1000 m in spring 2014.

452 **5. Conclusion**

453 We investigated mesopelagic carbon remineralisation fluxes in the North Atlantic during the spring 2014 (GEOVIDE
454 section) using for the first time the particulate biogenic barium inventories measured for this area. The excess biogenic
455 barium (Ba_{xs}) inventories in the mesopelagic layer varied between the different provinces of the North Atlantic. The
456 largest Ba_{xs} inventory was observed in the ARCT province, where also high carbon production rates were observed
457 earlier in the season. The regional variations of the Ba_{xs} inventory may also result from differences with phytoplankton
458 community composition encountered along this trans-Atlantic section. Lower mesopelagic Ba_{xs} contents occurred
459 where smaller calcified phytoplankton species dominated, such as in the NADR province. Finally, the ARCT province

460 was also characterized by important water mass subduction, generating a large transport of organic matter to the deep
461 ocean, which might have resulted into an important Ba_{xs} accumulation in the mesopelagic layer.
462 Using the OUR method, we confirmed that the mesopelagic Ba_{xs} inventory can be related to the oxygen utilisation rate,
463 but the relationship between both parameters is slightly different compared to the relationship proposed elsewhere for
464 the Southern Ocean. A new relationship is thus proposed for the North Atlantic. This proxy approach provided
465 estimations of mesopelagic remineralisation fluxes of similar magnitude as those obtained by others using independent
466 methods (free-floating and moored sediment traps, incubations) in the North Atlantic.
467 Overall, in spring 2014, the mesopelagic remineralisation balanced or exceeded POC export in the subtropical and
468 subpolar provinces of the North Atlantic, highlighting the important impact of the mesopelagic remineralisation on the
469 biological carbon pump and indicating that little to none organic matter was transferred below 1000 m in this region.

470 **Acknowledgements**

471 We would like to thank the captain and the crew of the R/V Pourquoi Pas?, as well as Fabien Perault and Emmanuel
472 De Saint Léger from the CNRS DT-INSU for their help during the CTD deployments. Pierre Branellec, Floriane
473 Desprez de Gésincourt, Michel Hamon, Catherine Kermabon, Philippe Le Bot, Stéphane Leizour and Olivier Ménage
474 are also acknowledged for their technical help during the cruise. We acknowledge Lorna Foliot, Raphaëlle Sauzède,
475 Joséphine Ras, Hervé Claustre and Céline Dimier for the sampling and analysis of pigments. We would like to thank
476 the co-chief scientists Pascale Lherminier and Géraldine Sarthou. We also express our thanks to Pascale Lherminier,
477 Herlé Mercier, Monika Rhein, Julie Deshayes and Claude Talandier for providing useful help on the characteristics of
478 the Labrador Sea Water. Satellite chlorophyll-a data and visualizations used in this study were produced with the
479 Giovanni and the Ocean Color (Ocean Biology Processing Group; OBPG) online data system, developed and
480 maintained by the NASA.

804

805
 806 **Figure 8:** Regression of DWA mesopelagic Ba_{xs} (pmol L⁻¹) versus O₂ consumption rate (μmol L⁻¹ d⁻¹) using the Southern
 807 Ocean transfer function from Dehairs et al. (1997; red circles) and the transfer function obtained here for the North Atlantic
 808 (black circles). Station 44 (triangle) was excluded from the regression. If station 44 is included, R²=0.33 and p-value= 0.07.

809
 810
 811

812
 813 **Figure 9:** Summary of published POC remineralisation fluxes (in $\text{mmol C m}^{-2} \text{d}^{-1}$) in the World's Ocean. The
 814 remineralisation fluxes for the Pacific Ocean (Dehairs et al., 2008) and the Southern Ocean (Cardinal et al., 2005; Jacquet
 815 et al., 2008a, 2008b, 2011b, 2015; Planchon et al., 2013) were calculated based on the Ba_{ss} inventories. Insert shows data for
 816 the North Atlantic: sites indicated by circles lined in black are from the present study; at sites labelled with # symbols
 817 remineralisation was deduced from POC fluxes recorded by moored sediment traps (Honjo et al., 2008); at sites labelled by
 818 ° remineralisation was obtained from on-board incubations (Collins et al., 2015; Giering et al., 2014); sites labelled with *
 819 are GEOSECS sites for which we calculated remineralisation from existing Ba_{ss} profiles (Brewer et al., unpublished results).
 820 Data were plotted using the ODV software (Schlitzer, 2017).

821

822

823

824 **Figure 10:** General schematic of the biological carbon pump in the NAST, NADR and ARCT provinces during GEOVIDE.
 825 Primary production (PP) data from Fonseca-Batista et al. (2018; this issue) and Lemaitre et al. (2018; this issue); particulate
 826 organic carbon (POC) export fluxes from Lemaitre et al. (2018; this issue) and POC remineralisation fluxes from this study.
 827 The dominating phytoplankton communities and the stage of the bloom are also indicated.

828
