18 **Abstract**

19 We report here the results of total mercury (HgT) determinations along the 2014
20 GEOTRACES GEOVIDE cruise (GA01 transect) in the North Atlantic Ocean (NA) from
21 Lisbon (Portugal) to the Labrador coast (Canada). HgT concentrations in unfiltered
22 samples (HgT_{UNF}) were log-normally distributed and ranged between 0.16 and 1.54
23 pmol L⁻¹, with a geometric mean of 0.51 pmol L⁻¹ for the 535 samples analysed. The
24 dissolved fraction (< 0.45 µm) of HgT (HgT_F), determined on 141 samples, averaged 78
25 % of the HgT_{UNF} for the entire data set, and 84 % for open sea waters (below 100 m)
26 and 91 % if the Labrador Sea data, where the primary production was high (with a
27 winter convection down to 1400 m), are excluded. HgT_{UNF} concentrations increased
28 eastwards and with depth from Greenland to Europe and from sub-surface to bottom
29 waters. The HgT_{UNF} concentrations were similarly low in the Subpolar Gyre waters (~
30 0.45 pmol L⁻¹), whereas they exceeded 0.60 pmol L⁻¹ in the Subtropical Gyre waters.
31 The HgT_{UNF} distribution mirrored that of dissolved oxygen concentration, with highest

32 concentrations levels associated with oxygen-depleted zones. The relationship between
33 HgT_F and the apparent oxygen utilization confirms the nutrient-like behavior of Hg in
34 the NA. An extended Optimum Multiparameter Analysis allowed us to characterize
35 HgT_{UNF} concentrations in the different Source Water Types (SWTs) present along the
36 transect. The distribution pattern of HgT_{UNF} , modeled by mixing of SWTs, show Hg-
37 enrichments in Mediterranean Waters and North East Atlantic Deep Water, and low
38 concentrations in young waters formed in the Subpolar Gyre and Nordic seas. The
39 change in anthropogenic Hg concentrations in the Labrador Sea Water, during its
40 eastward journey, suggests a continuous decrease of Hg content in this water mass over
41 the last decades. Calculation of the water transport driven by the Atlantic Meridional
42 Overturning Circulation across the Portugal-Greenland transect indicates a northward
43 Hg transport within the upper limb, and a southward Hg transport within the lower limb,
44 with a resulting net northward transport of about $97.2 \text{ kmol yr}^{-1}$.

45

46 **1. Introduction**

47 The ocean plays a central role in the global mercury (Hg) cycle. It receives Hg mainly
48 from atmospheric deposition, whereas it disposes of it in deep marine sediments (e.g.,
49 Mason et al., 1994). In the meantime, the largest part of Hg is recycled in the
50 atmosphere, while a smaller fraction penetrates the ocean interior *via* thermohaline
51 circulation or the biological pump (see reviews by Mason and Sheu, 2002; Fitzgerald et
52 al., 2007 and Mason et al., 2012). Firstly, Hg reinjection to the atmosphere results from
53 the formation of volatile elemental Hg *via* photoreduction and microbiological reduction
54 of divalent Hg (e.g., Mason et al., 1995; Amyot et al., 1997). Secondly, the Hg

55 integration into thermohaline circulation involves its solubilization in surface waters
56 followed by the subduction of these water masses along isopycnals (e.g., Gill and
57 Fitzgerald, 1988). Thirdly, the biological pump consists of Hg sorption onto biogenic
58 particles produced in the euphotic zone, then its conveying at depth by sinking
59 materials, with a possible Hg remobilization, due to the particulate remineralization-
60 dissolution process (e.g., Mason et al., 1993). The shape of observed vertical oceanic
61 Hg profiles, characterized by increasing concentrations with depth, includes the marks
62 of these different routes and is akin to “nutrient-type” profiles (Gill and Fitzgerald,
63 1988; Cossa et al., 2004; Lamborg et al., 2014; Bowman et al., 2015, 2016). The Hg
64 cycle is also known as being highly perturbed by human activities (e.g., Mason et al.,
65 2012; Lamborg et al., 2014; Zhang et al., 2014; Amos et al., 2015). Modern Hg
66 concentrations in the global atmosphere are more than three times the pre-industrial Hg
67 concentrations, leading to increasing of the Hg concentrations in surface and
68 intermediate oceanic layers, which remains to be precisely estimated. Albeit these
69 advances in the knowledge of the Hg biogeochemical cycle, the key features of the Hg
70 distribution among the principal oceanic water masses are still poorly documented.
71 Recent enhancements in precision and accuracy of Hg analyses allow more reliable
72 vertical Hg profiles in the water columns (e.g., Cossa et al., 2011; Lamborg et al., 2014;
73 Heimbürger et al., 2015; Bowman et al., 2015, 2016; Munson et al., 2015; Cossa et al.,
74 2017a and b). In addition, an original approach for the estimation of the anthropogenic
75 fractions of Hg concentrations in oceanic waters has been proposed (Lamborg et al.,
76 2014). Owing to these last methodological breakthroughs, significant advances in
77 detailed Hg oceanic distributions are possible.

78 The North Atlantic Ocean (NA) plays an active role in the cycling of chemical
79 species in the ocean because it is a region where deep water formation drives the
80 Atlantic Meridional Overturning Circulation (AMOC) (Kuhlbrodt et al., 2007).
81 Particularly in the subpolar NA, chemical properties, including Hg, are transported to
82 the ocean interior; thus, NA offers a unique opportunity for studying the oceanic
83 response to changes in atmospheric Hg deposition. The GEOTRACES-GA03 zonal and
84 meridional transects, sampled in 2010 and 2011, covered the NA from East to West
85 between 18°N and 40°N, from Africa to USA coasts. Here, we report the results of the
86 GEOVIDE cruise, along the GEOTRACES-GA01 transect, which targeted the NA from
87 40°N to 60°N, from Portugal to Newfoundland, *via* the southern tip of Greenland (Fig.
88 1). This article provides (i) a high-resolution description of the HgT distribution in the
89 waters of Subpolar and Subtropical gyres of the NA, (ii) a characterization the HgT
90 concentrations of the main water masses of the NA, (iii) an estimate of the temporal
91 change of anthropogenic Hg in LSW, and (iv) a quantification the HgT transport
92 associated with the upper and lower limbs of the AMOC. These new data contribute a
93 refinement of the depiction of the Hg distribution in the NA waters and should allow
94 further improvements in the oceanic Hg modeling.

95

96 **2. Oceanographic context**

97 A full description of the water masses along the GEOTRACES-GA01 transect can be
98 found in García-Ibáñez et al. (this issue). Briefly, the North Atlantic Current (NAC)
99 conveys the warm salty surface waters from subtropical regions northwards to the
100 subpolar regions, where they are cooled down by heat exchange with the atmosphere

101 (Fig. 1). The intermediate and deep waters formed this way fill up the Global Ocean,
102 initiating the southward-flowing limb of the AMOC (e.g., McCartney and Talley, 1984;
103 Lherminier et al., 2010). In addition, the general circulation pattern is characterized by
104 the subtropical and the subpolar gyres (Fig. 1).

105 In the Subtropical Gyre (Fig. 1), several water masses can be identified. Listing
106 them from top to bottom: (i) the mixed layer, (ii) the East North Atlantic Central Water
107 (ENACW), (iii) the Mediterranean Water (MW), (iv) the Labrador Sea Water (LSW)
108 and (v) the lower North East Atlantic Deep Water (NEADW_L), which contains about
109 30% Antarctic Bottom Water (AABW) (García-Ibáñez et al., 2015). The transformation
110 of ENACW leads to the formation of different mode waters including the Subpolar
111 Mode Waters (SPMWs) (McCartney and Talley, 1982; Tsuchiya et al., 1992; van Aken
112 and Becker, 1996; Brambilla and Talley, 2008; Cianca et al., 2009). SPMWs are the
113 near-surface water masses of the Subpolar Gyre of the NA characterized by thick layers
114 of nearly uniform temperature, often notated with a temperature as a subscript (SPMW₈
115 for example). SPMWs are formed during winter convection at high latitude, due to
116 atmospheric freshening of surface waters originating from the Subtropical Gyre
117 (McCartney, 1992). SPMWs participate in the upper limb of the AMOC and provide
118 much of the water that is eventually transformed into the several components of North
119 Atlantic Deep Water (NADW; Brambilla and Talley, 2008).

120 In the Subpolar Gyre, ocean-atmosphere interaction is particularly intense. The
121 cooling down of subtropical waters produces dense waters, triggering the deepening of
122 the mixed layer and further leading to deep convection. The main NA convection zones
123 are located in the Labrador (LS), Irminger (IrS) and Nordic seas (NS) (Fig. 1).

124 Convection in those zones leads to the formation of intermediate and deep waters such
125 as LSW, Denmark Strait Overflow Water (DSOW) and Iceland-Scotland Overflow
126 Water (ISOW). LSW and ISOW are the main components of NEADW, and the all three
127 are the components of the NADW, which constitutes the cold deep southward-flowing
128 limb of the AMOC, flowing towards the Southern Ocean in the western Atlantic basin.
129 LSW has been variably produced in the past fifty years depending on the intensity of
130 winter convection, linked to the intensity of the North Atlantic Oscillation (e.g., Rhein
131 et al., 2002; Cianca et al., 2009; Yashayaev and Loder, 2016). Depths of winter
132 convection in the LS vary from a few hundred meters (the early 2000s) to over 2000 m
133 (early 1990s). The LSW is a thick layer in the LS and thins out as it travels
134 southwestwardly. It spreads out into the entire NA, filling the Subpolar Gyre and
135 entering the Subtropical Gyre. Within the Subpolar Gyre, LSW is marked by a salinity
136 minimum above the ISOW. In both gyres, the well-ventilated LSW is noticeable by a
137 marked oxygen maximum.

138

139 **3. Material and methods**

140 **3.1. Sampling**

141 Water samples were collected during the French-led GEOVIDE cruise (GEOTRACES-
142 GA01 transect), on board the RV *Pourquoi Pas?* sailing from Lisbon (Portugal) on May
143 15th to arrive on June the 30th 2014 in St John's (Newfoundland, Canada) (Fig. 1).
144 Seventy-eight (78) stations (Table S1) were occupied for hydrographic profiles (CTD,
145 dissolved oxygen, nutrients), among which 29 included trace metal sampling. Sampling
146 and water treatment for HgT determination (Lamborg et al., 2012; Cutter et al., 2017)

147 were performed using ultra-trace techniques following the GEOTRACES
148 recommendations. During the GEOVIDE cruise, an epoxy-coated aluminum rosette,
149 equipped with 12 L GO-FLO (General Oceanics®) bottles initially cleaned following the
150 GEOTRACES procedures (Cutter and Bruland, 2012), was deployed on a 6 mm Kevlar
151 hydrowire. The rosette was also equipped with probes for pressure, conductivity,
152 temperature, dissolved oxygen, fluorometry and transmission measurements (titanium
153 SBE model 911-plus, Sea-Bird Electronics®). Specifically, for Hg determination, all
154 material in contact with the seawater samples was made of Teflon or Teflon coated, acid
155 cleaned and rinsed with ultrapure water (Milli-Q, Millipore®) prior to utilization.
156 Original vent fixture and sampling valves of the GO-FLO bottles were replaced with
157 Teflon (PTFE) ones. GO-FLO bottles were sub-sampled under a laminar flow bench
158 inside a trace metal clean container. The efficiency of the High-Efficiency Particulate
159 Air filter (HEPA, 0.3 μm) in the container was checked with a Coulter Counter during
160 the cruise. All subsequent sample treatments (including filtration) and Hg analyses were
161 also performed in class 100 clean containers. For sample filtrations, acid-washed 0.45
162 μm polycarbonate membranes (Nuclepore) were preferred to cellulose acetate or
163 polyethersulfone membranes proposed in the GEOTRACES protocols (Fig. S1). Sub-
164 samples were stored in Teflon bottles (FEP) until the onboard HgT analyses, which
165 occurred within 6 hours after sampling.

166 **3.2. Chemical analyses**

167 In order to access all Hg species, the release of Hg from its ligands was achieved by a
168 BrCl solution (50 μL of a 0.2 N solution is added to a 40-mL sample), and then the Hg
169 was reduced with an acidic SnCl₂ solution (100 μL of a 1 M solution is added to a 40-

170 mL sample). Potassium bromide (Sigma Aldrich, USA) and potassium bromate (Sigma
171 Aldrich, USA) were heated for 4 h at 250°C to remove Hg traces before making up
172 BrCl solution with freshly double-distilled HCl (Heimbürger et al., 2015). The
173 generated Hg vapor was amalgamated into a gold trap and then released by heating into
174 an atomic fluorescence spectrometer (AFS). We used two AFS systems in parallel
175 (Tekran® Model 2500, Brooks® Model 3), both calibrated against the NIST 3133
176 certified reference material. This technique, initially described by Bloom and Crecelius
177 (1983) and subsequently improved by Gill and Fitzgerald (1985), is now an
178 authoritative procedure officialised by the US-EPA as method 1631 (EPA, 2002). The
179 definitions of detection limit (DL), reproducibility and accuracy given here are adopted
180 from Taylor (1987) and Hewitt (1989). Using a mirrored quartz cuvette (Hellma®)
181 allowed for an “absolute DL”, defined as two times the electronic noise magnitude, as
182 low as 1.7 femtomoles. However, in practice for trace measurements, the DL is
183 governed by the reproducibility of the blank values, and calculated as 3.3 times the
184 standard deviation of blank values. The blank was determined on a purged Hg-free
185 seawater sample spiked with reagents (i.e., BrCl and SnCl₂). The mean (\pm standard
186 deviation) of blanks measured during the GEOVIDE cruise was 3.2 ± 1.0 femtomoles.
187 Thus, for a 40-mL seawater aliquot, the DL expressed in HgT concentration was 0.07
188 pmol L⁻¹. The reproducibility (coefficient of variation of six replicate measures) varied
189 according to the concentration level between 5 and 15 %. The accuracy of HgT
190 measurements was tested using ORMS-5 certified reference material (CRM) from the
191 National Research Council of Canada (<http://www.nrc-cnrc.gc.ca/>), as spike addition to
192 a purged Hg-free seawater sample. Measurements were always within the given

193 confidence interval. To ensure good data quality, and as a continuity of previous efforts
194 (Cossa and Courau, 1990; Lamborg et al., 2012), we organized the 2014 GEOTRACES
195 intercalibration exercise for total HgT and methyl Hg as a part of the GEOVIDE cruise.
196 The intercalibration sample was taken on June 22nd, 2014 in the LS at 49.093°W,
197 55.842°N, and 2365 m-depth. The sample was sent out to 10 participating laboratories.
198 This station was also planned as crossover station within the 2015 Arctic GEOTRACES
199 effort (Canadian cruise) but has been changed subsequently to another location. Our
200 results compare well with the consensus values, $\text{HgT} = 0.63 \pm 0.12 \text{ pmol L}^{-1}$, $n = 8$. We
201 measured the 2014 GEOTRACES intercalibration sample twice for HgT and obtained 0.51
202 (22nd June 2014, on board) and 0.58 pmol L^{-1} (30th October 2014, home lab).

203 **3.3. *Extended Optimum Multiparameter analysis***

204 We used an extended Optimum Multiparameter (eOMP) analysis to characterize the
205 water mass HgT_{UNF} concentrations along the GEOTRACES-GA01 transect (García-Ibáñez
206 et al., 2015, this issue). The eOMP analysis quantifies the proportions of the different
207 Source Water Types (SWTs) that contribute to a given water sample. The HgT_{UNF}
208 concentration of each SWT, $[\text{HgT}_{\text{UNF}}]_i$, was estimated through an inversion of the SWT
209 fractions given by the eOMP analysis. Such an approach was successfully applied to
210 dissolved-organic-carbon water mass definitions in the NA (Fontela et al., 2016) and for
211 evaluating the impact of water mass mixing and remineralization on the N_2O
212 distribution in the NA (de la Paz et al., 2017). Here, we performed an inversion of a
213 system of 430 equations (HgT_{UNF} samples) and 11 unknowns ($[\text{HgT}_{\text{UNF}}]_i$). Samples for
214 which the difference between the observed HgT_{UNF} and the predicted HgT_{UNF} values by
215 the multiple linear regression (Eq. 1 below) was three times greater than the standard

216 deviation were removed from the analysis. Nine samples were concerned: Sta. 2 (125
 217 m), Sta. 11 (793 m), Sta. 11 (5242 m), Sta. 13 (1186 m), Sta. 15 (170 m), Sta. 19 (99
 218 m), Sta. 26 (97 m), Sta. 32 (596 m), and Sta. 38 (297 m). The SWTs were characterized
 219 by potential temperature, salinity, and macronutrients. The eOMP was restricted to
 220 depths below 75 m in order to avoid air-sea interaction effects. The eOMP gave us the
 221 fractions of the 11 SWTs, and we resolved the following expression to estimate the
 222 $[HgT_{UNF}]_i$:

$$223 \quad [HgT_{UNF}]_j = \sum_{i=1}^{11} SWT_i^j * [HgT_{UNF}]_i + \epsilon_j \quad (j = 1 \dots 430) \quad (1)$$

224 where $[HgT_{UNF}]_j$ represents the measured HgT_{UNF} concentration for each sample “j”,

225 SWT_i^j the proportion of SWT “i” to sample “j” (obtained through the eOMP),

226 $[HgT_{UNF}]_i$ the HgT_{UNF} concentration for each SWT “i” (unknown), and ϵ_j the residual.

227 The 430 ϵ_j s of the inversion presented a null mean and a standard deviation of 0.085

228 pmol L^{-1} ($R = 0.84$).

229 **3.4. Mercury transport calculation**

230 Velocity fields across the GEOTRACES-GA01 transect were calculated using inverse

231 model constrained by Doppler current profiler velocity measurements (Zunino et al.,

232 this issue) an overall mass balance of 1 ± 3 Sv to the North (Lherminier et al., 2007,

233 2010). The volume transport per SWT was computed by combining these velocity fields

234 with the results of the eOMP (García-Ibáñez et al., this issue). Finally, the HgT_{UNF}

235 transports per water mass were calculated through Eq. (2):

$$236 \quad T_{HgT_{UNF}} = \sum_{i=1}^{11} T_{SWT_i} * [HgT_{UNF}]_i * \rho_i \quad (2)$$

237 where T_{SWTi} is the volume transport of SWT “ i ”, $[HgT_{UNF}]_i$ is the HgT_{UNF} concentration
238 for each SWT “ i ” (from Eq. 1), and ρ_i is the density of the SWT “ i ”.

239 The inverse model configuration for the GEOVIDE cruise data is described in Zunino
240 et al. (this issue). The inverse model is based on the least-squares formalism, which
241 provides errors on the velocities and associated quantities such as the magnitude of the
242 AMOC (estimated in density coordinate) and the heat flux (Lherminier et al., 2010). The
243 inverse model computes the absolute geostrophic transports orthogonal to the section.
244 The Ekman transport is deduced from the wind fields averaged over the cruise period and
245 added homogeneously in the upper 40 m (Mercier et al., 2015). The transport estimates
246 of the inverse model across the section have been validated by favorable comparisons
247 with independent measurements (Gourcuff et al., 2011; Daniault et al., 2011; Mercier et
248 al., 2015).

249

250 **4. Results**

251 Distributions of potential temperature, salinity, dissolved oxygen and silicic acid are
252 given in García-Ibáñez et al. (this issue), and reproduced on figure S2.

253 HgT_{UNF} concentrations along the GEOTRACES-GA01 transect ranged from 0.16 to
254 1.54 pmol L^{-1} ($n = 535$), these data being log-normally distributed, positively skewed
255 (Skewness = 1.1; Kurtosis = 2.1; Fig. S3) and with 97 % of the values lower than 1.00
256 pmol L^{-1} . The geometric mean and the median were 0.51 pmol L^{-1} , whereas the
257 arithmetic mean and standard deviation were 0.54 and 0.19 pmol L^{-1} , respectively.
258 These concentrations are within the range found along the GEOTRACES-GA03 transect

259 (0.09–1.89 pmol L⁻¹, n = 605) that crossed the NA within the subtropical gyre from
260 18°N to 40°N (Bowman et al., 2015), but lower than the range and the unusually high
261 arithmetic mean determined in the South Atlantic along the GEOTRACES-GA10 transect
262 (0.39–3.39 pmol L⁻¹, n = 375; Bratkič, personal communication, and 1.45 ± 0.60 pmol
263 L⁻¹; Bratkič et al., 2016, respectively).

264 The overall distribution of the HgT_{UNF} concentrations along the GEOTRACES-
265 GA01 transect is represented in Fig. 2. The main feature of HgT_{UNF} concentrations is an
266 eastward increase, from Greenland to Europe, and downward increase, from sub-surface
267 to bottom waters. In addition, lowest and highest (most variable) HgT_{UNF} values were
268 encountered in surface/sub-surface waters, where Hg evasion to the atmosphere and
269 high particulate matter concentrations may generate low and high HgT_{UNF}
270 concentrations, respectively. Out of the 141 filtered samples that were analysed,
271 altogether, the filtered fraction of Hg (HgT_F) represents, on average, 78% (range: 36–
272 98%) of the HgT_{UNF} (Fig. 3). Excluding the upper 100 m, where the biogenic suspended
273 particles are usually abundant, and the stations located on the shelf and slope, where
274 particulate matter from continental sources are usually present, the HgT_F fraction
275 represents, on average, 84 % (range: 72–98%) of the HgT_{UNF}. In addition, in the LS,
276 HgT_F / HgT_{UNF} mean ratios were rather low ranging 62–92 %, with a mean of 76 %. In
277 fact, the primary production was high in spring 2014 in LS, and the winter convection,
278 which reached 1400 m, conveyed surface particles at depth (Yashayaev et al., 2015;
279 Lemaitre et al., this issue). If we exclude the LS from the HgT_F mean computation, we
280 obtain a mean percentage HgT_F / HgT_{UNF} ratio of 91%, which is similar to values (~
281 90%) obtained along the GEOTRACES-GA03 zonal and meridional transects (Bowman et

282 al., 2015). In the following sub-sections, detailed descriptions of the HgT_{UNF} profiles for
283 the five following oceanographic environments are given: LS, IrS, Iceland basin (IcB),
284 Eastern North Atlantic basin (ENAB) and Iberian abyssal plain (IAP).

285 **4.1. Labrador Sea (Stas. 61 to 78)**

286 In the LS, the HgT_{UNF} concentrations ranged from 0.25 to 0.67 pmol L⁻¹, with a mean (\pm
287 standard deviation) of 0.44 ± 0.10 pmol L⁻¹ (n = 113). Distribution, source, and cycling
288 of Hg in the LS have been described and discussed in detail in a companion paper
289 (Cossa et al., 2017b). In summary: highest HgT_{UNF} concentrations were found in the
290 waters of the Labrador Current (LC) receiving freshwaters from the Canadian Arctic
291 Archipelago, and in the waters over the Labrador shelf and continental rise. In the LSW
292 formed during the 2014 winter convection, HgT_{UNF} concentrations were low ($0.38 \pm$
293 0.05 pmol L⁻¹, n = 23) and increased gradually with depth (up to > 0.5 pmol L⁻¹) in the
294 Northeast Atlantic Deep Waters.

295 **4.2. Irminger Sea (Stas. 40–60)**

296 HgT_{UNF} concentrations in the IrS waters varied from 0.22 to 0.76 pmol L⁻¹, with a mean
297 of 0.45 ± 0.10 pmol L⁻¹ (n = 103). In the IrSPMW, which was encountered in the
298 upper 1000 m near the East Greenland and the upper 500 m in the rest of the IrS (Fig. 4a
299 in García-Ibáñez et al., this issue), HgT_{UNF} values span between 0.29 and 0.42 pmol L⁻¹
300 (Fig. 2). Deeper, HgT_{UNF} increased up to 0.50 and 0.63 pmol L⁻¹ in LSW (~1000 m) and
301 ISOW (~2500 m), respectively. Lower HgT_{UNF} concentrations (0.40–0.50 pmol L⁻¹)
302 were associated with DSOW in the very bottom waters (Sta. 42-44, Fig. 2).

303 **4.3. Iceland Basin (Stas. 34–38)**

304 HgT_{UNF} concentrations in the IcB ranged from 0.18 to 0.65 pmol L⁻¹, with a mean of
305 0.46 ± 0.10 pmol L⁻¹ (n = 51). In the top 100 m of the water column, HgT_{UNF}
306 concentrations were quite variable (0.25-0.62 pmol L⁻¹) probably as a result of the
307 counteracting importance of Hg evasion to the atmosphere and high particulate matter
308 and/or complexing substance concentrations. West of the IcB (Sta. 38), contrasting
309 HgT_{UNF} levels were found on both sides at 500 m, characterized by a thermohaline
310 gradient (Fig. 2a and b in García-Ibáñez et al., this issue). In the top waters, HgT_{UNF}
311 levels were depleted to 0.18 pmol L⁻¹, whereas, below 500 m, they were much higher
312 and converge to values close to what we found, at the same depths in the adjacent IrS
313 (~0.60 pmol L⁻¹, Sta. 40). In the bottom waters, constituted by more than 50% of ISOW
314 (García-Ibáñez et al., this issue), HgT_{UNF} concentrations reached values > 0.50 pmol L⁻¹.

315 **4.4. Eastern North Atlantic Basin (Stas. 17–32)**

316 The HgT_{UNF} concentrations in the ENAB varied from 0.18 to 1.14 pmol L⁻¹, with a
317 mean of 0.61 ± 0.18 pmol L⁻¹ (n = 174). The ENAB, also named Western European
318 Basin, is characterized by a complex vertical stratification of the water column. The
319 HgT_{UNF} vertical profiles at all the stations of the ENAB were characterized by a
320 complex but reproducible pattern depicting (i) two maxima peaks (the upper at
321 subsurface, the lower within the intermediate waters), and below, (ii) a HgT_{UNF}
322 enhancement starting from 2500 m towards the bottom (Fig. 2). The position and
323 intensity of the peaks vary with longitude. The upper peak, which occurs within the top
324 200 m, is only 0.48 pmol L⁻¹ at Sta. 29, but reaches 1.14 pmol L⁻¹ at Sta. 19 (Fig. 2).
325 The vertical position of maxima of the lower peak and deepens eastwards, from 200 m
326 down to 800 m, concurrently with an increase of its magnitude (Fig. 2). The position of

327 the upper peaks suggests a relation with position of the fluorescence maximum (data not
328 shown), whereas the position of the lower peaks, which is close to the maximum of
329 Apparent Oxygen Utilization (AOU) that rose above $70 \mu\text{mol L}^{-1}$ (Fig. 2), suggests a
330 dependence on the organic matter remineralization (see Discussion below). Between
331 1400 and 2500 m, in the layer corresponding to LSW, HgT_{UNF} concentrations were
332 quite uniform, with a mean concentration of $0.54 \pm 0.04 \text{ pmol L}^{-1}$ ($n = 18$). HgT_{UNF}
333 concentration increased from 3000 m downwards to the sea bottom, consisting of
334 NEADW_L, where it reaches 0.95, 0.97, 1.03 and 1.13 pmol L^{-1} at Sta. 21, 19, 25 and 23,
335 respectively.

336 **4.5. Iberian Abyssal Plain (Stas. 1–15)**

337 In the IAP, HgT_{UNF} concentrations ranged from 0.19 to 1.54 pmol L^{-1} , with a mean of
338 $0.69 \pm 0.23 \text{ pmol L}^{-1}$ ($n = 94$). The highest HgT_{UNF} concentrations were measured in the
339 upper 100 m near the shelf slope. At Sta. 2, the only station on the European shelf
340 (bottom at 152 m), the HgT_{UNF} concentrations increased from 10 m to the bottom, from
341 0.38 to 0.86 pmol L^{-1} , but did not differ from the open NA ocean levels. Off-shore, at
342 Sta. 1, 11, 13 and 15 (Fig. 2), the vertical distributions of HgT_{UNF} presented a certain
343 similarity with those of the eastern ENAB, but with an additional third deep peak. As in
344 the eastern ENAB, the upper peak is associated with subsurface waters, and the second,
345 centered around 800 m, is associated with the oxygen minimum of SPMW₈. The third
346 peak, centered around 1100-1200 m, is associated with the salinity maximum of the
347 core of MW (Fig. S2). The presence of a HgT_{UNF} peak in the MW was still visible
348 westwards, at Sta. 17, 19 and 23, near 1100 m, as a shoulder of the main peak at 800 m
349 (Fig. 2). Deeper in the water column, HgT_{UNF} increased gradually from 2000 m (LSW)

350 to 3000 m (ISOW), 3500 m and below (NEADW_L), where HgT_{UNF} concentrations
351 reached 0.87 to 1.04 pmol L⁻¹ depending on the station.

352 In summary, the HgT_{UNF} mean concentrations were low and similar in the basins
353 of the Subpolar Gyre (0.44, 0.45 and 0.46 pmol L⁻¹ for LS, IrS, and IcB respectively),
354 whereas they exceeded 0.60 pmol L⁻¹ in the Subtropical Gyre (0.61 and 0.69 pmol L⁻¹ for
355 ENAB and IAP, respectively). On the other hand, the profiles were rather homogenous
356 in the Subpolar Gyre compared to the multipeak vertical distribution observed in the
357 Subpolar Gyre (Fig. 2). A multipeak pattern was also observed in 1994 in the Eastern
358 Atlantic slope water column in the Celtic Sea (Cossa et al., 2004). The shape of the Hg
359 profiles exhibited the same peaks in the same water masses as the ones observed in this
360 study (i.e., SPMW and MW). However, HgT_{UNF} concentration levels, measured 20
361 years ago, were much higher varying mostly often from 0.3 pmol L⁻¹ in sub-surface
362 waters to more than 2.0 pmol L⁻¹ at depth.

363

364 5. Discussion

365 5.1. Biogeochemical and hydrographical controls on HgT distribution

366 Main paths of the Hg cycle in the open ocean can be briefly summarized as follows.
367 Direct atmospheric deposition is the dominant source of Hg for the oceans, most of the
368 deposited Hg is re-emitted in the atmosphere, and a minor Hg fraction is drawn down to
369 the ocean interior with downwards convecting waters or associated with sinking
370 particles. At depth, the dissolution of particulate matter, produced as a result of organic
371 matter microbiological remineralization, remobilizes Hg from particles produced in the

372 euphotic zone. The biological pumping/regeneration process results in a relationship
373 between Hg concentrations and nutrient or dissolved oxygen concentration (or AOU),
374 which are proxies of the organic matter remineralization (mainly the microbial
375 respiration) that the sample has experienced since it was last in contact with the
376 atmosphere. Such a biogeochemical behaviour, which is qualified of “nutrient-like”
377 behaviour, is observed in the present study (Fig. 4). The correlation coefficient (R)
378 between Hg_{TF} and the AOU, obtained from *in situ* measurements of dissolved oxygen
379 and temperature, reached the highly statistically significant value of 0.87 ($n = 141$, $p <$
380 0.01). Similar behaviour was already observed in the water column near the shelf edge
381 of the western European margin (Cossa et al., 2004), and elsewhere in the NA
382 (Lamborg et al., 2014; Bowman et al., 2015). Thus, present results confirm that
383 biological uptake and regenerative processes appear to control a large part of the
384 oceanic Hg distribution in the Subpolar and Subtropical gyres of the NA.

385 Hydrological circulation may also impact the Hg distribution in the NA. We
386 estimated the Hg_{UNF} (and AOU) values of each SWT using eOMP (Table 1). The
387 correlation coefficient between observed and predicted (eOMP-based) values through
388 Eq. (1) (Material and Methods section) for Hg_{UNF} is 0.71. The estimated Hg_{UNF}
389 concentrations vary significantly between SWTs from 0.32 ± 0.03 to 1.04 ± 0.02 pmol
390 L^{-1} , for the IrSPM to the NEADWL, respectively. However, a large part of the Hg_{UNF}
391 between SWTs is due to the regeneration process as suggested by the correlation
392 coefficient ($R = 0.82$) of the linear relationship of Hg_{UNF} versus AOU (Fig. 5). Based
393 on this model ($Hg_{UNF} = 0.0043 * AOU + 0.3547$), we calculated mean “corrected”
394 Hg_{UNF} concentrations for each identified SWT for a zero AOU concentration.

395 “Corrected” mean values range from 0.22 to 0.61 pmol L⁻¹ in IrSPMW and NEADW,
396 respectively (Table 1). This variation should result from the origin, the route and the
397 age of each SWT. The “corrected” HgT_{UNF} values of IrSPMW-PIM-SPMW-DSOW-
398 LSW, which are formed in the Subpolar gyre and in the NS during the last winter,
399 present very low and similar values 0.22-0.31 (Table 1). Even, the IrSPMW is the
400 youngest SPMW formed in the IrS as a result of air-sea interaction of the waters
401 transported northwards by the NAC (e.g., McCartney and Talley, 1984); the low
402 HgT_{UNF} value found in the IrSPMW may result from a net Hg evasion in this region,
403 consistently with the conclusion that Western and Central NA are a net source of Hg for
404 the atmosphere (Mason et al., 2017). On the contrary, on the Eastern NA side, where Hg
405 deposition and evasion are rather similar (Mason et al., 2017), the ENACW shows
406 higher “corrected” HgT concentration (0.41 pmol L⁻¹, Table 1). The highest “corrected”
407 HgT_{UNF} mean concentration is calculated for NEADW_L (0.61 pmol L⁻¹, Table 1), which
408 is the dominant water mass in the bottom IAP, with its main core below ~3500 m-depth
409 and spreading down to the bottom (see figure 4 in García-Ibáñez et al., this issue). This
410 water mass presents a significant component from Southern Ocean (AABW), which is
411 known to be Hg-rich (HgT_{AABW} = 1.35 ± 0.39 pmol L⁻¹, Cossa et al., 2011). The same
412 rationale can be drawn for the “corrected” HgT_{UNF} concentration in MW (0.41 pmol L⁻¹,
413 Table 1). Indeed, recent measurements in the waters of the Western Mediterranean give
414 HgT_{UNF} values varying between 0.53 and 1.25 pmol L⁻¹ within the layer that flows out
415 of the Mediterranean Sea at the Strait of Gibraltar (Cossa and Coquery, 2005; Cossa et
416 al., 2017a).

417 In summary, the distribution pattern of HgT_{UNF} along the GEOTRACES-GA01
418 transect, modeled by mixing of SWTs (Fig. S4), stresses the importance of Hg
419 scavenging by plankton and organic matter regeneration, but also show that a part of
420 Hg-enrichment in certain SWTs, among which MW and NEADW, is due to preformed
421 Hg outside the NA. This type of results, characterizing the Hg concentrations in
422 principal oceanic water masses, should contribute to the refinements in model
423 formulation and predictability.

424 **5.2. Change in anthropogenic Hg in LSW**

425 Evidence for a decrease in the Hg anthropization in the NA waters can be
426 obtained from the comparison of the present results with those obtained twenty years
427 ago with similar clean sampling and analytical techniques. In a companion paper (Cossa
428 et al., 2017b), we have already compared the present findings for the convection layer in
429 the LS with the results of the 1993 International Oceanographic Commission cruise
430 (Mason et al., 1998). Between 1993 and 2014 the decrease in HgT_{UNF} concentrations
431 would have been more than a factor of two ($1.14 \pm 0.36 \text{ pmol L}^{-1}$ versus 0.40 ± 0.07
432 pmol L^{-1}). However, bearing in mind the uncertainty of the accuracy of early numbers,
433 this magnitude of the decrease cannot be taken for granted. To circumvent the difficulty,
434 the approach to estimate the anthropogenic Hg (Hg_{Anth}) concentrations in subsurface
435 waters, proposed by Lamborg et al. (2014), can be used. Hg_{Anth} is inferred from the
436 difference between measured HgT_{UNF} concentrations and the concentrations predicted
437 based on a worldwide relationship between deep ocean Hg concentrations and
438 remineralised phosphate (Lamborg et al., 2014), with a Redfield ratio of 141 between
439 AOU and remineralized phosphate (Minster and Boulahdid, 1987) a more representative

440 value for the NA than the global value of 170 proposed by Anderson and Sarmiento
441 (1994). The LSWs take less than 20 years (Doney et al., 1997) to flow eastward more
442 than 3000 km from the LS eastward to the Subtropical Gyre of the NA. Along its path,
443 LSW bears the record of Hg incorporation at the time of their formation, thus sampling
444 along its flow path allows the observation of decadal variations in anthropogenic Hg
445 inputs to the NA. In the NA, estimation of Hg_{Anth} concentrations in the core of LSW,
446 defined within potential density of 27.74 and 27.82, account for 36 ± 0.07 % of the
447 $Hg_{T_{UNF}}$, and are one third lower for younger waters (LS and IrS: 0.16 ± 0.11 pM) than
448 for older waters (IcB and ENAB: 0.24 ± 0.06 pM) (Fig. 6). This 30%-decrease in Hg
449 concentrations are consistent (i) with the observations of a temporal decrease of Hg in
450 the marine boundary layer of the NA (Sprovieri et al., 2010; Weigelt et al., 2014) over
451 the last two decades, and with (ii) the estimated decline in Hg concentrations in
452 subsurface waters of the NA estimated by models during the last decades (e.g.,
453 Soerensen et al., 2012).

454 This means that LSW formed in the 1990s' in the LS, and currently present in the
455 ENAB, received more Hg_{Anth} from the atmosphere than the $LSW_{2014-2015}$ "vintage".
456 These results contrast with what can be deduced from the vertical profile of $Hg_{T_{UNF}}$ in
457 the LS, where the Hg regeneration in the water column is sufficient to account for the
458 Hg increase between the shallow LSW layer ($LSW_{2014-15}$) and the deep LSW layer
459 ($LSW_{1987-94}$) (Cossa et al., 2017b). This discrepancy between these two deductions
460 suggests that LSW, which are present in the Eastern NA, is likely older (and more
461 imprinted by legacy Hg_{Anth}) than the LSW currently present in the LS.

462 **5.3. Latitudinal transport of Hg**

463 The transport of HgT_{UNF} per unit of water mass, calculated with Eq. (2) (Material and
464 Methods section), are given in Table 2. We also applied Eq. (2) separately to the upper
465 and lower limbs of the AMOC and computed the transports of HgT_{UNF} per water mass
466 for the two limbs. The velocity fields across the Portugal-Greenland transect was
467 calculated using inverse model constrained by Doppler current profiler velocity
468 measurements (Zunino et al., this issue). The volume transport per SWT was computed
469 by combining this velocity fields with the results of the eOMP (García-Ibáñez et al., this
470 issue).

471 The mean (velocity-weighted) HgT_{UNF} concentration of the water advected
472 northwards within the upper limb of the AMOC is 0.55 pmol L^{-1} , whereas the one
473 advected southwards within the lower limb of the AMOC is 0.40 pmol L^{-1} . Across the
474 Portugal-Greenland transect, there is a northward HgT_{UNF} transport within the upper
475 limb of the AMOC ($10.20 \text{ mmol s}^{-1}$), and a southward HgT_{UNF} transport within the
476 lower limb (7.12 mmol s^{-1}), resulting in a net northward transport of $97.2 \text{ kmol yr}^{-1}$.
477 Most of the HgT_{UNF} southward transport is due to IrSPMW and ISOW displacements,
478 whereas HgT_{UNF} northward transport is associated with ENACW and SPMW
479 displacements (Table 2). The Hg exchange across the LS section can be roughly
480 estimated at 133 kmol yr^{-1} , using the mean southward water transport of the shelf edge
481 LC is at the Seal Island transect (Hamilton Bank near Stas. 77 and 78) which is 7.5 Sv ,
482 according to Han et al. (2008) and a mean HgT concentration of 0.56 pmol L^{-1} (Cossa et
483 al., 2017b). Thus, from our “snap shot” study, the net Hg exchange across the GEOVIDE
484 transect, which crosses the LS and the NA from Portugal and Greenland, would be an
485 Arctic loss of 36 kmol yr^{-1} . In comparison, Soerensen et al. (2016), based on a mass

486 balance budget, estimated that “Arctic seawater is enriched in total Hg relative to
487 inflowing waters from the North Atlantic and North Pacific Oceans at all depths
488 resulting in a 26 Mg a^{-1} (i.e., 130 kmol a^{-1}), net loss from the Arctic *via* circulation”.

489

490 **6. Summary and conclusions**

491 HgT_{UNF} concentrations in the waters along the GEOTRACES-GA01 transect, which
492 crossed the NA from 40°N to 60°N (Portugal to Canada), ranged from 0.16 to 1.54
493 pmol L^{-1} , but with 97 % of the values lower than 1.00 pmol L^{-1} and a geometric mean of
494 0.51 pmol L^{-1} ($n = 535$). The dissolved fraction ($< 0.45 \mu\text{m}$) of HgT , determined on 141
495 samples, averaged 78 % of the HgT_{UNF} for the entire data set, 84 % for deep open sea
496 waters, and 91 % if the Labrador Sea data, where the primary production was high, are
497 excluded. HgT_{UNF} concentrations increased eastwards and downwards. The HgT_{UNF}
498 concentrations were similarly low in the Subpolar Gyre waters ($\sim 0.45 \text{ pmol L}^{-1}$),
499 whereas they exceeded 0.60 pmol L^{-1} in the Subtropical Gyre waters, especially within
500 NEADW_L. The relationship between HgT_{F} and AOU, which indicates a nutrient-like
501 behavior for Hg in the NA, attests to the influence of organic matter regeneration on
502 HgT mobilization. The distribution pattern of HgT_{UNF} along the transect, modeled by
503 mixing of SWTs, show Hg-enrichments in MW and NEADW, and low Hg
504 concentrations in younger water masses formed during the last winter at high latitudes.
505 Using the HgT_{UNF} fraction unexplained by regeneration processes as a proxy for Hg_{Anth} ,
506 we observed geographical trend in the Hg_{Anth} in the LSW along its eastward journey in
507 the NA, characterized by an eastward increase, which suggests that Hg incorporation in
508 the downwelling waters of the LS has decreased over the last 20 years, in parallel with

509 the decrease of Hg concentrations in the NA troposphere. By combining the velocity
510 fields with the results of the eOMP, a net northward Hg transfer of $97.2 \text{ kmol yr}^{-1}$ across
511 the Portugal-Greenland transect can be calculated as a result of the AMOC. Taking into
512 account the southern Hg export with the LC, the net Hg exchange along the entire
513 GEOVIDE transect would be an Arctic loss of 36 kmol yr^{-1} .

750 **Figure caption**

751 **Figure 1.** Schematic view of the water circulation in the North Atlantic Ocean adapted
752 from García-Ibáñez et al. (2015) and Danialt et al. (2016). Red lines indicate the
753 circulation in surface, while blue lines indicated circulation at depth. Black lines
754 represent the GEOVIDE cruise transects (GEOTRACES-GA01). Main geographical
755 features, water masses and currents are indicated: Newfoundland (NFL), United
756 Kingdom (U.K.), United States of America (U.S.A.); Denmark Straight Overflow Water
757 (DSOW), Iceland-Scotland Overflow water (ISOW), Labrador Sea Water (LSW),
758 Lower North East Atlantic Deep water (NEADW_L), Mediterranean Water (MW), and
759 North Atlantic Deep Water (NADW), Deep Western Boundary Current (DWBC),
760 Eastern Greenland Current (EGC), Labrador Current (LC), North Atlantic Current
761 (NAC), Western Greenland Current (WGC).

762 **Figure 2.** Distribution of unfiltered total mercury (HgT_{UNF}) concentrations along the
763 GEOTRACES-GA01 transect. LS: Labrador Sea; IrS: Irminger Sea; IcB: Iceland basin;
764 ENABw: west part of Eastern North Atlantic basin; ENABe: east part of Eastern North
765 Atlantic basin; IAP: Iberian Abyssal Plain.

766 **Figure 3.** Mercury concentrations in filtered (HgT_F) vs unfiltered (HgT_{UNF}) samples (n
767 = 141) collected along the GEOTRACES-GA01 transect.

768 **Figure 4.** Total Hg in filtered samples (HgT_F) vs apparent oxygen utilization (AOU)
769 relationship along the GEOTRACES-GA01 transect.

770 **Figure 5.** Total Hg in unfiltered samples (HgT_{UNF}) vs apparent oxygen utilization
771 (AOU) relationship within the various Source Water Types.

772 **Figure 6.** Anthropogenic HgT (HgT_{Anth}) concentration distribution in the core of the
773 Labrador Sea Water (LSW) ($S = 34.9$, $\sigma_\theta = 27.74\text{--}27.82$, 1200–2000 m) between the
774 Labrador Sea and the Eastern North Atlantic basin. HgT_{Anth} values were obtained
775 according to the model by Lamborg et al. (2014). Young LSW corresponds to the
776 “2014-vintage” (LSW₂₀₁₄) formed during winter 2013–2014. The insert shows the Hg
777 concentration decrease in the troposphere over the North Atlantic during the last 20
778 years according to Soerensen et al. (2012).

779 **Tables**

780

781 **Table 1.** Total Hg in unfiltered samples (HgT_{UNF}) vs apparent oxygen utilization (AOU)
 782 concentrations of each source water type (SWT), calculated according to eOMP (Eq. 1)
 783 (see also García-Ibáñez et al., this issue). “Corrected” HgT_{UNF} is a theoretical HgT
 784 concentration for a AOU concentration equal to zero, using the equation from figure 5.
 785 ENACW₁₂: East North Atlantic Central Water of 12°C; SPMW₈ and SPMW₇: Subpolar
 786 Mode Waters of the Iceland basin of 7 and 8°C; IrSPMW: Subpolar Mode Water of the
 787 Irminger basin; LSW: Labrador Sea Water; MW: Mediterranean Water; ISOW: Iceland-
 788 Scotland Overflow Water; NEADW_L: lower North East Atlantic Deep Water; DSOW:
 789 Denmark Strait Overflow Water; PIW: Polar Intermediate Water; and SAIW₆: Subarctic
 790 Intermediate Water of 6°C.
