

1. *Although the number of studies on trace gas fluxes from lowland tropical peatlands are steadily increasing, measurements are completely absent from some important large peatland areas. The peats in the foreland basin of Pastaza Marañon (PMFB) in Peru is an example of an important tropical peatland area from which we have no empirical studies on CH₄ and N₂O fluxes. As such, this study is timely and novel. The authors conducted chamber based CH₄ and N₂O fluxes stratified according to the four dominant vegetation types ranging from nutrient rich floodplains to nutrient poor bogs. While the spatial resolution of the sampling is good (see Table 1) the temporal resolution is restricted to four time sampling over a period of two years (sampling twice during the wet season and twice during a dry season). However, given the difficult accessibility and the fact that this is the first report on fluxes from this important peat area this is acceptable for this initial study. Furthermore, we do learn important controls since supporting variables were measured as well. Nevertheless if have several point that should be addressed before the manuscript can be accepted for publication.*

Authors' response: The authors would like to thank the referee for his/her thoughtful and insightful comments on our manuscript, and welcome the opportunity to improve the manuscript for the wider readership of *Biogeosciences*.

2. *In your introduction, I miss a section on the known controls of CH₄ and N₂O fluxes in peatlands. I think it is important to include this, since it is otherwise unclear why you measured the environmental variables that you did. Are there some potentially important factors that you did not measure and if so, why was that the case?*

Authors' response: This was an oversight on our part. In order to keep the paper succinct, we omitted a more detailed review of the literature on the factors regulating CH₄ and N₂O fluxes. We will provide a more through description of the process-based on controls on CH₄ and N₂O flux in the revised version of the manuscript.

With respect to potentially important factors that we did not measure; we did not quantify CH₄ fluxes from woody plants nor did we specifically seek to quantify ebullition. While plant-mediated fluxes are believed to be important in tropical wetland ecosystems (Pangala et al., 2013), we did not have enough data on floristic composition or individual plant identities within our plots to come-up with a sampling design that would adequately represent plant-mediated fluxes from our study sites. Likewise, ebullition is often characterized by high spatial and temporal variability. In order to develop a representative, spatially-stratified sampling design to quantify ebullition, using techniques such as the inverted "flux funnel" approach (Strack et al., 2005), more detailed information on spatial patterns in net CH₄ flux would be required; information that we did not have prior to the collection of the data presented here. As a consequence, we chose to omit specific measurements of ebullition from this study, with a wider view towards collecting these data at a later date.

For N₂O, even though inorganic N is thought to be one of the major drivers of N₂O flux, we did not collect data on inorganic N (NH₄⁺, NO₃⁻), because the relatively modest budget for this project did not accommodate costs for inorganic N analysis.

3. *In l.142 and l.147 you mention soil Ca, it remains a mystery in which form this Ca occurs. Please provide more details, is Ca an important environmental control on CH₄ or N₂O fluxes?*

Authors' response: The Ca in these systems occurs as dissolved inorganic Ca²⁺ associated with the soil or peat exchange complex, or Ca found in secondary minerals (Lahteenoja et al., 2009). As far as we are aware, Ca has no direct effect on CH₄ or N₂O fluxes, although Ca may indirectly influence trace gas exchange by influencing plant productivity and organic matter decay. We will revise the text to acknowledge this and remove any ambiguity from the manuscript.

4. *You describe your chambers as floating static chambers (l. 179). You furthermore write that chamber were placed on the soil surface from a distance of no closer than 2m to reduce the risk of ebullition (l. 186). For me it is hard to believe that ebullition was completely excluded and I also cannot understand how you can place these chambers at a distance of 2 m? Nobody has arms that long (at least I don't), so how was this done in detail? And, especially, how did you take the gas samples from your chambers using syringes without causing ebullition?*

Authors' response: The referee is correct that we were unable to entirely exclude ebullition from our dataset. We did in fact find evidence of ebullition, with 164 of the 1181 chamber observations (13.9 %) showing signs of ebullition (e.g. abrupt, non-linear changes in headspace concentrations). Of these 164 observations, 83 (7.0 %) showed net CH₄ efflux (or, net ebullition), while a further 81 (6.9 %) showed very high rates of net CH₄ uptake. The latter we termed "ebullition-driven CH₄ uptake," due to the fact that very high rates of CH₄ uptake were observed following a putative bubble event. For these data, ebullition fluxes were calculated in one of two ways: for chambers showing steep non-linear increases, we fitted the data to a quadratic regression equation ($P < 0.05$), and fluxes were determined from the steep initial rise in CH₄ concentrations. For chambers showing abrupt stochastic increases, fluxes were determined by calculating the total CH₄ production over the course of the bubble event, in-line with the approach used by the investigators in other studies (Teh et al., 2011). We decided to omit these data from the final dataset because we could not exclude the possibility that these fluxes were caused by sampling effects, despite the care we took (e.g. physical disturbance due to chamber placement or investigator movement; pressure effects caused by syringe sampling) led to ebullition. A summary of these ebullition data are presented in Supplementary Table 1 (below). We will revise the text to include a description of our data filtering procedure, and will also include the data shown in Supplementary Table 1, to provide more information to the reader on ebullition.

With respect to chamber placement; this was achieved by using a 2-m long pole to lower the flux chambers onto the water or saturated soil. Gas samples were collected with syringes using >2 m lengths of Tygon[®] tubing, after thoroughly purging the dead volumes in the sample lines. The text will be revised to provide these additional details on chamber placement and sampling technique.

5. *Ebullition is relatively easy to detect e.g. if you start with very high concentrations or if you detect abrupt increases in CH₄ concentration. Can you give us information on how you dealt with such data and how many of your chamber measurements were potentially affected by ebullition? Is there a correlation of flux strength and the potential occurrence of ebullition? You also mention in your discussion that you measured occasionally high CH₄ uptake values (l. 477). Is it possible that this was related to high CH₄ concentrations at the beginning of chamber closure, potentially caused by ebullition? Did you find a correlation between initial CH₄ concentration and calculated CH₄ uptake values? I was also wondering whether the contrasting seasonal emission patterns that you discuss (l. 417 and further) could be related to ebullition. As you see, I think you don't give use sufficient information about the potential occurrence of ebullition and you should clearly improve this.*

Authors' response: Please see point 4 above. We did in fact see evidence of greater ebullition in higher emission environments. For example, ebullition was more common in Mixed Palm Swamp and *M. flexuosa* palm swamp (12.2 and 16.7 % of observations for those vegetation types, respectively), which are the two vegetation types that showed the highest CH₄ fluxes. In contrast, forested (short pole) and forested vegetation, which showed the lowest CH₄ fluxes, saw the lowest occurrence of ebullition (i.e. 6.9 and 10.5 % of observations, respectively). We also observed greater ebullition fluxes in the wet season, though the trend for ebullition-driven uptake was less clear. Due to the high variance in both ebullition and ebullition-driven uptake fluxes, we did not observe statistically significant differences in either of these rates among vegetation types, or between seasons. The text will be revised to include these data.

Regarding chambers that showed high oxidation rates; these high fluxes were in fact related to high initial concentrations, and we cannot exclude the possibility that these chambers could have been affected by ebullition, even if we did not see empirical evidence for this over the course of our chamber measurements (e.g. ebullition could have occurred immediately after chamber placement and before the first sample was taken). We will revise the discussion to recognise this possibility.

6. *I have no problem with the fact that you measured negative N₂O fluxes, since we see more and more evidence that globally this is quite an important process. However, some of the negative fluxes seem to be quite high in your figure 2. How do your N₂O uptake rates compare to other published values and is it possible that this may also somehow related to ebullition? Also, here I would be interested if your negative values correlate with the initially measured concentration in your chambers. If ebullition played a role for negative Ch₄ and N₂O fluxes, you may expect that both strong CH₄ uptake and N₂O uptake would occur in the same chamber measurement. Did you check this?*

Authors' response: Relative to other environments we have studied elsewhere in Peru (e.g. Kosñipata Valley, Manu National Park) and in the literature from upland environments, these uptake fluxes are very low; at least one order of magnitude lower than uptake fluxes observed in upland ecosystems (Teh et al., 2014). We believe it is highly unlikely that ebullition caused these trends, because we saw very little evidence of ebullition-driven N₂O

fluxes (only 3 out of 1181 observations, or 0.3 %), and these data were filtered to remove these three observations from the analysis presented here. We also saw no evidence that strong CH₄ uptake was correlated with N₂O uptake.

7. You probably measured your fluxes at different time of the day. Did you find any diurnal pattern in GHG fluxes? If yes, what could explain these observed differences and how would this affect your estimate of emission strength?

Authors' response: We did in fact conduct a study to investigate if gas fluxes showed evidence of diurnal variability, but did not find strong evidence of diurnal trends in fluxes. We will discuss this in the revised version of the manuscript.

8. The potential role of CH₄ oxidation is remarkable absent from your discussion. Why is that the case? Do you think this is not important for the total measured CH₄ fluxes?

Authors' response: For sake of brevity, we did not go discuss the potential role of gross CH₄ oxidation in modulating net CH₄ efflux. This is not because we did not believe gross CH₄ oxidation was unimportant; rather, it was because we did not have the tools or the experimental design to make clear inferences about what proportion of produced CH₄ was consumed prior to atmospheric egress. We do in fact believe that gross CH₄ oxidation is very important, as demonstrated by past work in tropical systems that have used isotope tracers to deconvolve gross CH₄ production and oxidation fluxes (von Fischer and Hedin, 2002; von Fischer and Hedin, 2007; Teh et al., 2005). For example, work by the lead author has demonstrated that gross methanotrophy may consume upwards of 48 % of produced CH₄ in tropical soils (Teh et al., 2005). Follow-up experiments at these study sites could explore this question in the future. We will revise the manuscript to include this information.

9 The version of the map in Fig. 1 that I saw did not have a very good quality. Can you provide a map where the four vegetation types that you used for stratification are included? The impression of Fig. 1 is that the total peat area is larger than what can be seen in the map. Can you adjust Fig. 1 in such a way that we see all of (or most of) the PMFB peatland area?

Authors' response: In the revised manuscript, we will provide a higher quality image than the one shown here, and will endeavour to include the information that the referee has requested.
