**Abstract.** The overall goal of OUTPACE (Oligotrophy to UlTra-oligotrophy PACific Experiment) was to obtain a successful representation of the interactions between planktonic organisms and the cycle of biogenic elements in the western tropical South Pacific Ocean across trophic and N<sub>2</sub> fixation gradients. Within the context of climate change, it is necessary to better quantify the ability of the oligotrophic ocean to sequester carbon through biological processes. OUTPACE was organized around three main objectives which were: (1) To perform a zonal characterization of the biogeochemistry and biological diversity of the western tropical South Pacific during austral summer conditions, (2) To study the production and fate of organic matter (including carbon export) on three contrasting trophic regimes (increasing oligotrophy) with a particular emphasis on the role of dinitrogen fixation, and (3) to obtain a representation of the main biogeochemical fluxes and dynamics of the planktonic trophic network. The international OUTPACE cruise took place between 18 February and 3 April 2015 aboard the RV *L'Atalante* and involved 60 scientists (30 onboard). The west-east transect covered ~4 000 km from the western part of the Melanesian Archipelago (New Caledonia) to the western boundary of the South Pacific gyre (French Polynesia). Following an adaptive strategy, the transect initially designed along the 19° S parallel was adapted along-route to incorporate information coming from satellite measurements of sea surface temperature, chlorophyll a concentration, currents, and diazotrophs quantification. After providing a general context and describing previous work done in this area, this introductory paper elucidates the objectives of OUTPACE, the implementation plan of the cruise, water mass and climatological characteristics, and concludes with a general overview of the other papers that will be published in this special issue.

## 1 General context

The additional carbon dioxide (CO<sub>2</sub>) in the atmosphere, mainly resulting from fossil fuel emissions linked with human activities (anthropogenic CO<sub>2</sub>), is the main cause of global warming (Fifth Assessment Report - Climate Change 2013 - IPCC). The ocean has acted thus far as a major sink of anthropogenic CO<sub>2</sub> (Sabine et al., 2004), preventing greater CO<sub>2</sub> accumulation in the atmosphere and therefore greater increase of the Earth's temperature. The biological pump (Fig. 1), the

process by which carbon (C) is transferred from the upper to the deep ocean by biological processes, provides the main explanation for the vertical gradient of C in the ocean. Its strength and efficiency depends upon the complex balance between organic matter production in the photic zone and its remineralisation in both the epipelagic and mesopelagic zones. Before present and for tens of thousands years, the biological pump was thought to be in an equilibrium state with an associated near-zero net exchange of CO<sub>2</sub> with the atmosphere (Broecker, 1991; Murnane et al., 1999). Climate alterations then started to disrupt this equilibrium and the expected modification of the biological pump will probably considerably influence oceanic C sequestration (and therefore global warming) in future decades (Sarmiento and Gruber, 2006). The long term decrease of phosphate availability, and the shift from previously nitrogen (N) to phosphorus (P) limited primary production associated with increasing inputs of N by dinitrogen (N<sub>2</sub>) fixation observed at the Hawaii Ocean Time Series (HOT) station in the north Pacific gyre (NPG) (Karl et al., 1997; Karl, 2014), appear as a first example of biological pump alteration.

The input of new N to the surface ocean through biological N<sub>2</sub> fixation represents a major link between the C and N biogeochemical cycles, relating upper ocean nutrient availability with the biological pump, and ultimately the ocean and climate. This link was recently shown to play a central role in previous natural climate changes over long time scales (Galbraith et al., 2013). It is nevertheless clear that expected climate change due to anthropogenic atmospheric CO<sub>2</sub> input may concern shorter time scales: the increase of atmospheric CO<sub>2</sub> over the past 200 years equals the increase of atmospheric CO<sub>2</sub> between glacial to interglacial periods, which took place over several thousands of years (Sarmiento and Gruber, 2006). Furthermore, enhanced stratification in the tropical and subtropical ocean resulting from global warming (Polovina et al., 2008) might decrease nutrient availability such as nitrate (NO<sub>3</sub><sup>-</sup>), potentially favouring N<sub>2</sub> fixation in surface waters. It may also decrease phosphate availability (Moutin et al., 2008), and in turn N<sub>2</sub> fixation, net primary production and export (Karl, 2014). McMahon et al. (2015) covering the past 1000 years, argue that N<sub>2</sub> fixation has increased since the industrial revolution, and might provide a negative feedback to rising CO<sub>2</sub>.

The ecosystem changes due to climate change are complex and it is therefore necessary to characterize in detail the interactions between N<sub>2</sub> fixation and the C cycle to obtain a precise representation of the N<sub>2</sub> fixation process in global biogeochemical models, leading eventually to predictions. Even if considerable scientific progress has been made over the last decades (see reviews from (Sohm et al., 2011; Zehr and Kudela, 2011), many questions remain regarding the impact of this process on biogeochemical cycles and C export.

## 2 The role of N<sub>2</sub> fixation in the oligotrophic ocean and an overview of previous cruises in the western tropical South Pacific Ocean (WTSP)

The efficiency of oceanic C sequestration depends upon many factors, among which is the availability of nutrients to support phytoplankton growth in the photic zone (Fig. 1). Large amounts of N are required for phytoplankton growth, as it is an essential component of proteins, nucleic acids and other cellular constituents. Fixed N in the form of NO<sub>3</sub><sup>-</sup> or ammonium (NH<sub>4</sub><sup>+</sup>) is directly usable for growth, but concentrations are low (<0.1 μmol L<sup>-1</sup>) in the oligotrophic ocean and often growth

limiting in most of the open ocean euphotic zone (Falkowski et al., 1998; Moore et al., 2013). Dissolved  $N_2$  gas concentrations in seawater are in contrast very high in the euphotic zone (ca.  $450 \mu\text{mol L}^{-1}$ ) and could constitute a nearly inexhaustible N source for the marine biota. However, only some prokaryotic organisms (Bacteria, Cyanobacteria, Archaea) hereafter referred to as ‘ $N_2$ -fixing organisms’ (or diazotrophs) are able to use this gaseous N source since they possess the  
5 nitrogenase enzyme that breaks the triple bond between the two N atoms of the  $N_2$  molecule, and converts it into a usable form (i.e.  $NH_3$ ) (Zehr et al., 1998). At the global scale, they provide  $140 \pm 50 \text{ Tg N}$  per year to the surface ocean, contributing more than atmospheric and riverine N inputs (Gruber, 2004).  $N_2$ -fixing organisms thus act as ‘natural fertilizers’, and contribute to sustain life and potential C export in coastal and oceanic environments.

Most of the ocean (60 %, Longhurst, 1998) is comprised of low-nutrient, low-biomass oligotrophic areas, which constitute  
10 the largest coherent ecosystems on our planet. They support a large part (40 %) of the photosynthetic C fixation in the ocean (Antoine et al., 1996). This C fixation is mainly performed by picoplankton (smaller than  $2\text{--}3 \mu\text{m}$  in diameter) that are generally thought to represent a negligible fraction of the total particulate organic C (POC) export flux due to their small size, slow individual sinking rates, and tight grazer control that leads to high rates of recycling in the euphotic zone. Consequently, the efficiency of the biological C pump in these oligotrophic systems has long been considered to be low as  
15 the greatest proportion of fixed C is thought to be recycled in the surface layer and rapidly re-exchanged with the atmosphere.

Recent studies have challenged this view and indicate that all primary producers, including picoplanktonic cells, contribute to export from the surface layer of the ocean at rates proportional to their production rates (Richardson and Jackson, 2007). Export mechanisms differ compared to larger cells as export of picoplankton is mainly due to packaging into larger particles  
20 via grazing and/or aggregation processes (Jackson, 2001; Lomas et al., 2010). More recently, Close et al. (2013) pointed out that 40–70 % of picoplanktonic cells are small enough to escape detection under the most common definition of suspended particulate organic matter (POM).

Besides submicron POM export, low  $\delta^{15}\text{N}$  signatures in particles from sediment traps at the HOT station suggest that at least part of the production sustained by  $N_2$  fixation is ultimately exported out of the photic zone (Karl et al., 2012; Karl et al.,  
25 1997; Scharek et al., 1999a; Scharek et al., 1999b). This may either be direct through sinking of diazotrophs, or indirect, through the transfer of diazotroph-derived N to non-diazotrophic plankton in the photic zone, that is subsequently exported. Karl et al. (2012) reported an efficient summer export flux of C (three times greater than the mean wintertime particle flux) at the HOT station that was attributed to the direct export of symbiotic  $N_2$ -fixing cyanobacteria associated with diatoms (hereafter referred to as diatom-diazotroph associations or DDAs), which have high sinking and low remineralization rates  
30 during downward transit. This result is in accordance with high export fluxes measured in the tropical North Atlantic when the diazotroph community is dominated by DDAs (Subramaniam et al., 2008; White et al., 2012). More recently, (Berthelot et al., 2015; Bonnet et al., 2016a) studied the fate of a bloom of unicellular diazotrophs from Group C (UCYN-C) during a

mesocosm experiment in the New Caledonia lagoon after a phosphate enrichment and revealed that ~10 % of UCYN-C from the water column was exported to the particle traps daily, representing as much as  $22.4 \pm 5.5$  % of the total POC exported at the height of the UCYN-C bloom. A  $\delta^{15}\text{N}$  budget performed in the mesocosms confirmed the high contribution of  $\text{N}_2$  fixation (56 %, Knapp et al., 2016) to export compared to other tropical and subtropical regions where active  $\text{N}_2$  fixation contributes 10 to 25 % to export production (e.g. Altabet, 1988; Knapp et al., 2005). Mechanistically, the vertical downward flux was enabled by the aggregation of the small ( $5.7 \pm 0.8$   $\mu\text{m}$ ) UCYN-C cells into large (100-500  $\mu\text{m}$ ) aggregates. In addition to direct export of diazotrophs, the use of nanoSIMS (nanoscale Secondary Ion Mass Spectrometry) enabled tracking the fate of  $^{15}\text{N}$  from both *Trichodesmium* (Bonnet et al., 2016b) and UCYN blooms (Berthelot et al., 2015; Bonnet et al., 2016c), and demonstrated that a significant fraction of N originating from  $\text{N}_2$  fixation is quickly transferred to non-diazotrophic plankton, in particular diatoms (i.e. efficient C exporters to depth, (Nelson et al., 1995) during *Trichodesmium* blooms (Bonnet et al., 2016b). This reveals that  $\text{N}_2$  fixation can fuel large-size non-diazotrophic plankton growth in the water column, suggesting an indirect export pathway of organic matter sustained by  $\text{N}_2$  fixation in the oligotrophic ocean. Most of the above-mentioned studies were performed in microcosms and mesocosms and further open ocean studies combining the set of complementary approaches described above are needed to better assess the fate of  $\text{N}_2$  fixation and its role on C export.

The western tropical south Pacific (WTSP) is an ideal location to study this question, as it is considered a hot spot of  $\text{N}_2$  fixation in the world ocean (Bonnet et al., In Rev.). While average  $\text{N}_2$  fixation rates range from 20-200  $\mu\text{mol N m}^{-2} \text{d}^{-1}$  in the tropical North Atlantic (Benavides and Voss, 2015) and Pacific (Böttjer et al., 2017; Dore et al., 2002), they reach 30-5400  $\mu\text{mol N m}^{-2} \text{d}^{-1}$  (average ~800  $\mu\text{mol N m}^{-2} \text{d}^{-1}$ ) in the Solomon Sea (western part of the WTSP) (Berthelot et al., Submitted; Bonnet et al., 2009; Bonnet et al., 2015), which is in the upper range of rates reported in the global  $\text{N}_2$  fixation MAREDAT database and even surpassed its upper rates (100-1000  $\mu\text{mol N m}^{-2} \text{d}^{-1}$ ) (Luo et al., 2012). High rates ranging from 151 to 703  $\mu\text{mol N m}^{-2} \text{d}^{-1}$  have also been reported off New Caledonia (Garcia et al., 2007), with seasonal variations closely linked with phosphate availability (Moutin et al., 2005; Van Den Broeck et al., 2004). The seasonal distribution of  $\text{N}_2$  fixation is corroborated by *in situ* and satellite observations (Dupouy et al., 2011) of recurrent large *Trichodesmium* blooms during austral summer conditions (January-March) over the 1998-2010 period in the Melanesian archipelago (MA: New Caledonia, Vanuatu, Fiji Islands). In addition to *Trichodesmium* which dominates the diazotroph community in the WTSP (Moutin et al., 2005; Berthelot et al., Submitted; Bonnet et al., 2015), very high abundances of UCYN-B (up to 106-107 nifH copies  $\text{L}^{-1}$ ) have been reported (Bonnet et al., 2015; Campbell et al., 2005; Moisander et al., 2010). The uncultivated UCYN-A (Zehr et al., 2008) also displays high abundances (105-106 nifH copies  $\text{L}^{-1}$ , (Bonnet et al., 2015; Moisander et al., 2010) around the MA, but they seem to have different ecological niches compared to *Trichodesmium* and UCYN-B (Bonnet et al., 2015; Moisander et al., 2010).

When going eastward towards the South Pacific gyre (GY), Halm et al. (2012) have reported rates of 12-190  $\mu\text{mol N m}^{-2} \text{d}^{-1}$  on the western border of the gyre and Raimbault and Garcia (2008) and Moutin et al. (2008) reported rates of  $60 \pm 30$   $\mu\text{mol}$

$\text{N m}^{-2} \text{ d}^{-1}$  in the central gyre, indicating a decreasing gradient of  $\text{N}_2$  fixation from west to east and low  $\text{N}_2$  fixation rates relative to other ocean gyre ecosystems. The organisms responsible for these fluxes are different from common autotrophic diazotrophs such as *Trichodesmium* or UCYN-B, and are mainly affiliated with heterotrophic proteobacteria and low abundances of UCYN-A (Bonnet et al., 2008; Halm et al., 2012).

- 5 The west to east zonal gradient of  $\text{N}_2$  fixation and the distinct diversity of  $\text{N}_2$ -fixing organisms along this gradient together provide a unique opportunity to study how production, mineralisation and export of organic matter depends upon  $\text{N}_2$  fixation in contrasting oligotrophic regimes (from oligotrophy to ultra-oligotrophy). Comparisons between different systems along a zonal gradient of trophic status and  $\text{N}_2$  fixation will provide new insights for identifying and understanding fundamental interactions between marine biogeochemical C, N, P, silica (Si), and iron (Fe) cycles in oligotrophic ecosystems.

### 10 3 Objectives of OUTPACE

The overall goal of OUTPACE was to obtain a precise representation of the complex interactions between planktonic organisms and the cycle of biogenic elements (C, N, P, Si, Fe), considering a variety of scales, from single-cell processes to the whole WTSP Ocean. To meet this goal, the three specific objectives of OUTPACE were the following:

- 1) To perform a zonal characterization of the biogeochemistry and biological diversity of the WTSP during the strongest stratified period (austral summer),
- 15 2) To study the production and fate of organic matter (including C export) of three contrasting environments (from oligotrophy to ultra-oligotrophy) with a particular emphasis on  $\text{N}_2$  fixation,
- 3) To obtain a satisfactory representation of the main biogeochemical fluxes (C, N, P, Si, Fe) and the dynamics of the planktonic trophic network, both *in situ* and by using microcosm experiments.
- 20 The detailed study of biological production and its subsequent fate at a given site implied a combination of adaptive and Lagrangian strategies. Indeed, as pointed out by d'Ovidio et al. (2015), the spatiotemporal domain of an oceanographic cruise is also one in which horizontal stirring generated by ocean circulation at the mesoscale induces strong variability in biogeochemical tracers' distributions. Consequently, ephemeral and local gradients due to mesoscale activity can easily mask the large-scale gradients. Following d'Ovidio et al. (2015), this problem can be overcome by adopting an adaptive sampling
- 25 strategy (described in Sect. 4.1.) based on information on sea surface temperature (SST), chlorophyll a (chl *a*) concentrations and currents provided by satellite products analyzed in real time during the entire cruise.

### 4 Implementation of the OUTPACE cruise

- The OUTPACE cruise was conducted during austral summer conditions from 18 February to 3 April 2015, aboard the RV *L'Atalante*. We performed a ~4,000 km zonal transect from the North of New Caledonia to the western part of the GY, finally reaching French Polynesia (Fig. 2). Along this transect, two types of stations were sampled: 15 SD "short duration" (8

h) stations dedicated to a large-scale description of biogeochemical and biodiversity gradients; and three LD “long duration” (7 days) stations for Lagrangian process studies.

#### 4.1 Adaptive strategy

5 Following the planned adaptive strategy, the initial transect designed to approximately follow 19° S was modified along-route thanks to the information coming from satellite images, as follows. The regions along the vessel route were first characterized at large scale through the analysis of satellite (Altimetry, SST, Ocean color) data. These data were automatically retrieved and processed to derive Eulerian and Lagrangian diagnostics of ocean circulation and biogeochemistry: Okubo-Weiss parameter maps, Lagrangian Coherent Structures (LCS), and chl *a* maps (d'Ovidio et al.,  
 10 2015).

The satellite data was treated in near real time on land and the obtained data were transmitted on board together with a daily bulletin containing the analysis of remote sensing information, along with suggestions for LD station positions (the complete series of the 42 bulletins is available on the OUTPACE website at <https://outpace.mio.univ-amu.fr>, section “Adaptive Strategy”).

15 Two main criteria were adopted in suggesting LD station positions:

- 1) The areas for the LD A and LD B (LD C) stations were characterized by local maxima (minima) of sea surface chl *a* concentration to sample MA (GY) conditions, and
- 2) Local minima of surface current intensity for all LD stations, to increase the chance of sampling a homogeneous water mass.

20 Once the suggested positions for LD stations were relayed via the daily bulletin, at one of these locations real time analysis of water samples by quantitative Polymerase Chain Reaction (qPCR) was conducted to measure abundances of six groups of diazotrophs (Stenengren et al., this issue). In this way, we located regions with diazotrophs, while also resolving the contrasting role *Trichodesmium* spp. or UCYN-dominated diazotroph communities have on biogeochemical cycles.

Finally, the exact locations of the three LD stations were then determined on board in real time from a rapid survey using a

25 Moving Vessel Profiler (MVP) equipped with conductivity-temperature-depth (CTD) and fluorimeter sensors, accompanied by the hull-mounted thermosalinograph and acoustic Doppler current profiler.

During this rapid survey, it was planned to follow two different sampling routes: a cross of about 40 km each side, followed by a Zig-Zag route covering an area of 25 km each side at the centre of the cross. This strategy was applied as planned for the LD A and LD C stations.

30 The LD A station was performed east of the northern extremity of New Caledonia in an anticyclonic recirculation characterized by a relative high surface chl *a* concentration. The LD C station was performed in a cyclonic eddy in the most oligotrophic part of the OUTPACE transect (GY) close to Cook Islands.

The severe meteorological conditions due to the development of tropical cyclone Pam (a category 5 storm) that hit the Vanuatu Islands, obliged us to perform the LD B station at a more easterly location than initially planned. Satellite imagery allowed for the targeting of a large filament of high surface chl *a* concentration close to Niue Island. Due to the circulation patterns associated with the bloom, the rapid survey strategy was adapted in order to perform four sections across the structure (see details in de Verneil et al., this issue).

SD station positions were chosen in relation to the LD stations, so that they were roughly equidistant from each other, respected territorial waters, and incorporated the changing conditions during the cruise.

#### 4.2 General programme at each station

Every station (Table 1) was investigated from the surface to 2000 m.

##### SD stations

Each of the 15 SD stations was investigated for 8 h. Specific operations during the SD station occupation consisted of:

- (1) Two 0-200 m CTD casts and Niskin bottle sampling and one 200-2000 m CTD cast and Niskin bottle sampling using the classical SBE 9+ CTD-Rosette (C-R) for measurements of core parameters (dissolved oxygen, dissolved inorganic carbon, total alkalinity, nutrients, chl *a*, Particulate and dissolved organic C, N, P and Si) and some more specific ones (for example primary production rates, N<sub>2</sub> fixation rates and diazotroph abundance). A Marine Video Profiler (UVP) was attached to the CTD-rosette to quantify and visualize suspended particulate material;
- (2) One 0-500 m CTD cast and bottle sampling using the Trace Metal Clean SBE 9+ CTD-Rosette (TM-R) equipped with 24 teflon-lined GoFlo bottles to sample for trace metals analyses;
- (3) Optical sensors casts: Integrated measurements of bio-optical properties and pigments were made with instruments measuring hyperspectral radiometry in the UV-Visible domain with UV-VIS Trios spectroradiometers, and a MicroPro free-fall profiler (Satlantic) was used for downward irradiance measurements.
- (4) Hauls for phytoplankton and zooplankton sampling with specific nets; and
- (5) A profile of turbulence measurements using a VMP1000 equipped with microsenors for temperature and shear that enable accurate estimates of the eddy diffusion coefficient K<sub>z</sub>.

The specific configurations of the two CTD-Rosettes are available here: <https://outpace.mio.univ-amu.fr/spip.php?article137>.

##### LD stations

Each of the three LD stations was investigated with a drifting array (see below) that was deployed for 7 days. A series of CTD (C-R) casts (0-500 m) were performed every 3 h near the actual position of the drifting array while numerous specific operations (see below) were carried out in between CTD casts.

A total of 13 Surface Velocity Program (SVP) drifters anchored at 15 m depth were deployed in order to study relative surface dispersion. The drifters were launched with three at LD A, six at LD B and four at LD C. A drifting array (equipped

with three PPS5 sediment traps, current meters, specific oxygen sensors, and specific high frequency temperature sensors; please consult <https://outpace.mio.univ-amu.fr/spip.php?article75> for details) was then deployed at the chosen station position to start the process study. The drifting array was recovered at the end of each LD station occupation, immediately following the last CTD cast. An additional CTD cast from surface to bottom (5000 m) was undertaken at the LD B station.

5 Specific operations during LD stations were identical to those performed at SD stations, along with other operations like *in situ* production measurements, *in situ* particulate material sedimentation measurements, trace metal clean pumping for process experiments, and profiles of current measurements. Finally, at each LD station, a drifting Provor-type ARGO float (ProBio equipped with sensors to measure chl *a* (fluorescence), CDOM (fluorescence), PAR, Irradiance at 3 wavelengths, backscattering and dissolved oxygen (optode)), was deployed (Table 2).

10 The following color code was proposed to present data from the different LD stations: LD A green; LD B red; and LD C blue.

All details regarding the OUTPACE cruise are available on the OUTPACE web site: <https://outpace.mio.univ-amu.fr/>.

The general scheduled and realized programmes are available here: [http://www.obs-vlfr.fr/proof/php/outpace/outpace\\_log\\_and\\_basic\\_files.php](http://www.obs-vlfr.fr/proof/php/outpace/outpace_log_and_basic_files.php)

## 15 5 General characteristics of the upper water masses in the WTSP

Water characteristics (temperature, salinity, density, chl *a* fluorescence) for the upper 700 m as measured by the C-R are presented in Fig. 3. The deep CTD casts from all SD and LD stations are presented subsequent to post-cruise processing using Sea-Bird Seasoft software adopting the TEOS-10 standard. The upper surface layer (0-30 m) observed during the OUTPACE transect was characterized by warm waters, with temperatures between 26.18 and 29.93 °C (Fig. 3a), and relatively low salinity, i.e. absolute salinity between 35.03 and 35.81 g kg<sup>-1</sup> (Fig. 3b). Density anomalies of 21.72-22.91 kg.m<sup>-3</sup> between 0-30 m increased gradually between 30 and 200 m to reach 24.89-25.38 kg m<sup>-3</sup> (Fig. 3c). The salinity increase of subsurface waters (100-200 m) from 187°W longitude (Fig. 3b) indicated the geographical border between waters under the influence of the MA (SD1 to SD12) and waters from the GY (SD13 to SD15, LD C). LD B was not classified here and required a further analysis (de Verneil et al., this issue). The classification between MA and GY waters will be helpful to describe general biogeochemical and biological features. Between 200 and 700 m, a decreasing gradient of temperature and salinity indicated the presence of permanent thermocline waters. Temperature fell from 19.27-22.08 °C at 200 m to 5.48-6.91 °C at 700 m (Fig. 3a). Absolute salinities of 35.76-36.21 g kg<sup>-1</sup> at 200 m decreased to 34.49-34.61 g kg<sup>-1</sup> (Fig. 3b). The density anomalies of 24.89-25.38 kg m<sup>-3</sup> at 200 m increased largely to 26.97-27.13 kg m<sup>-3</sup> at 700 m (Fig. 3c). The maximum fluorescence depth, considered here as the main indicator of the trophic state, increased from ~100 m depth in the MA waters to ~115-150 m depth in the GY waters, which allowed us to sample the oligotrophic to ultraoligotrophic transition in the WTSP for the purpose of the OUTPACE project.

## 6 The climatological context of the campaign

The OUTPACE cruise took place in the WTSP, a region impacted by the El-Niño Southern Oscillation (ENSO), known to be the most important mode of SST variability on inter-annual to decadal time scales (Sarmiento and Gruber, 2006). ENSO-related SST anomalies are caused by a combination of changes in ocean circulation (mainly changes in the strength and source of equatorial upwelling) and anomalous local air-sea heat exchanges. The most dramatic effects of ENSO in the surface ocean are well documented in the Eastern Tropic Pacific, where seasonal upwelling conditions can be suppressed with severe economic consequences for fisheries (Chavez et al., 2003). During El-Niño phases (negative Southern Oscillation Index (SOI), defined below), the warm pool normally positioned in the Western Pacific is found farther east, resulting in the aforementioned suppression of upwelling conditions off Peru. La Niña, the opposite phase with positive SOI, reverses this situation. After decades of intense study, ENSO is still an active field of research (Takahashi et al., 2011).

Given the known importance of ENSO for the Tropical South Pacific, it is worthwhile determining in which climatological conditions the cruise was performed. To achieve this goal, we identified years of opposing ENSO phase and analyzed the corresponding WTSP conditions with available satellite data. ENSO phases were identified using the monthly time series of Southern Oscillation Index (SOI) provided by NCEP (<http://www.cpc.ncep.noaa.gov/>, downloaded 5 December 2016). The SOI metric uses differences in standardized sea level air pressure between Papeete (Tahiti) and Darwin (Australia) to represent ENSO phase as previously mentioned. The OUTPACE region lies between these two locations (Fig. 2), highlighting again ENSO's possible influence on the cruise.

WTSP conditions were estimated with SST and surface chl *a* concentration measured by the MODIS Aqua satellite mission and available at the NASA Ocean Color Data website (<https://oceandata.sci.gsfc.noaa.gov/>, downloaded 14 December 2016). Global annual and monthly (March) averages of both SST and chl *a* were provided by NASA at level 3 (i.e. mapped) with 4 km satellite pixel resolution, resulting in four separate datasets from 2003 to present. The data within the OUTPACE region, defined between 25° S, 155° E, and 15° S, 149° W to envelope the cruise track as in Fig. 2, were extracted. March was chosen as the month of study because it was the central month of the cruise. Plots of these four datasets can be found on the OUTPACE dataset website, section "[http://www.obs-vlfr.fr/proof/php/outpace/outpace\\_figures.php](http://www.obs-vlfr.fr/proof/php/outpace/outpace_figures.php)". Probability density distributions were generated for each dataset in its entirety. Additional probability distributions were also calculated on data subsets, for years 2003 and 2011 as chosen by SOI to represent opposite ENSO phases, along with 2015, the year of the cruise. In order to gauge significance between probability distributions of different years, for each of the four datasets the temporal standard deviation of each pixel was calculated. This resulted in a distribution of standard deviations, the median of which was taken to represent inherent inter-annual variability.

The time series of SOI is presented in Fig. 4, with El Niño (La Niña) values shaded red (blue). During OUTPACE cruise sampling in austral summer 2015, a strong El Niño was observed. The other El Niño year considered here was 2003, chosen because of its relative strength and duration similar to 2015; for similar reasons of intensity and duration, 2011 was designated a representative La Niña year.

The probability density distributions for the annual and March means of both SST and chl *a* are presented in Fig. 5. In SST, the March mean showed a larger proportion of warmer temperatures in relation to the annual mean (white lines in Fig. 5a,c), reflecting the austral summer season. The 2011 La Niña distributions showed a greater proportion of warm temperatures in both annual and March distributions (blue lines in Fig. 5a,c), which is consistent with the idea of La Niña accentuating the warm pool present in the WTSP. The probability peak of March 2011 SST was much more localized, between 26 and 30° C, than 2003, 2015, and the mean (Fig. 5c). The 2003 March SST (red line in Fig. 5c) was the widest distribution, with a slight rightward skew. By contrast, both the mean and 2015 March probabilities (white and green lines, respectively) had a left skew. Considering the median 95% confidence interval for the March SST time series, the central peaks for these distributions could not be considered distinct.

Satellite chl *a* showed distributions completely different to SST. For all quantities considered, the annual and March mean (Fig. 5b,d), as well as the years 2003, 2011, and 2015, showed a bi-modal distribution, where the two peaks were distinct enough from each other to be significant from the median pixel variability. Interestingly, 2003 and 2011 (red and blue lines, Fig. 5b) annual chl *a* distributions overlapped considerably more than 2015 (green line), which had its entire probability distribution shifted to the right, though this shift may not have been significant. The March mean for 2003 and 2015 chl *a* (red and green lines, respectively, Fig. 5d), however, almost entirely overlapped, possibly signifying that El Niño chl *a* distributions were more alike than La Niña years. The annual 2015 mean of chl *a* being slightly different from other years, and yet the March 2015 mean resembling 2003, might indicate that 2015 was indeed a slightly different year from a surface chlorophyll perspective, but this slight difference was concentrated in other parts of the year than late austral summer when OUTPACE took place.

In summary, the SOI metric of ENSO showed that 2015 was an El Niño event, and both the SST and chl *a* satellite data in the WTSP partially reflected this. The March 2003 and 2015 SST distributions resembled each other, but they also resembled the entire dataset more than the 2011 La Niña distribution. From the SST point of view, perhaps La Niña events impact the region more than El Niño. Chl *a* distributions for the El Niño years also overlapped more than with La Niña, but the variability inherent the time series precluded declaring significant differences. Overall, in the WTSP both SST and chl *a* were not atypical from what one would expect, and so we determined that climatological effects upon the results of OUTPACE were minimized.

## 7 Special issue presentation

The goal of this special issue is to present the knowledge obtained concerning the functioning of WTSP ecosystems and associated biogeochemical cycles based on the datasets acquired during the OUTPACE experiment. The cruise strategy was organized to promote collaboration between physicists, biologists and biogeochemists with expertise including marine physics, chemistry, optics, biogeochemistry, microbiology, molecular ecology, genetics, and modelling. Most of the contributions to this volume have benefited from this collective effort and are presented according to the three main

objectives of the OUTPACE experiment, namely the zonal characterization of the biogeochemistry and biological diversity of the WTSP during the strongest stratified period (austral summer), the production and fate of organic matter (including C export) of three contrasting oligotrophic environments with particular emphasis on nitrogen fixation, and the representation of the main biogeochemical fluxes (C, N, P, Si, Fe) and dynamics of the planktonic trophic network.

- 5 The physical variability and the hydrodynamic context of biogeochemical sampling are described, as well as the impacts of mesoscale circulation and forcing on biogeographic gradients, along with the longitudinal contrast in small scale turbulence along ~20°S. An optimum multi-parameter analysis of the water mass structure is also provided.

The focus on diazotrophs and dinitrogen fixation concerns the distribution and drivers of symbiotic and free-living diazotrophic cyanobacteria, the contribution of particulate and dissolved (N release) fractions to the hot spot of N<sub>2</sub> fixation found during the cruise, zonal gradient in N<sub>2</sub> fixation rates, the partition of N<sub>2</sub> fixation rates between the particulate and dissolved fractions, the diazotroph-derived N transfer to the planktonic food web, the N<sub>2</sub> fixation contribution to export production, and finally the N budget at the LD stations studied using a lagrangian adaptative strategy. Aphotic N<sub>2</sub> fixation, heterotrophic diazotrophs and their relationship with labile organic matter, as well as programmed cell death in diazotrophs, are also investigated.

- 15 The dynamics of phytoplankton, heterotrophic bacterioplankton, and zooplankton along the gradient of diazotroph diversity and activity are described together with the composition and distribution of dissolved organic carbon and the changes in inorganic carbon content along the longitudinal transect. Net community production, the assimilation of organic carbon and nutrient substrates by unicellular cyanobacteria, microbial response to the N and P compounds excreted by copepods are quantified. A specific focus on siliceous plankton and Si biogeochemical cycling is also presented.
- 20 Optical properties of the WTSP waters are presented, with a focus on the cyanobacterial (diazotroph) impact on bio-optical properties, UV-VIS light attenuation and chl *a* algorithms for WTSP oligotrophic waters.

Finally the main processes controlling the biological carbon pump in the WTSP are investigated using a 1DV biogeochemical-physical coupled model and a regional model, and the new knowledge gained on the interactions between planktonic organisms and the cycle of biogenic elements used to propose a new scheme for its functioning and role, at the

- 25 present time and in the near future, in the oligotrophic Pacific Ocean.

## Acknowledgements

This is a contribution of the OUTPACE (Oligotrophy from Ultra-oligoTrophy PACific Experiment) project (<https://outpace.mio.univ-amu.fr/>) funded by the French research national agency (ANR-14-CE01-0007-01), the LEFE-CyBER program (CNRS-INSU), the GOPS program (IRD) and the CNES (BC T23, ZBC 4500048836). The OUTPACE  
30 cruise (<http://dx.doi.org/10.17600/15000900>) was managed by MIO (OSU Institut Pytheas, AMU) from Marseilles (France). The authors thank the crew of the RV *L'Atalante* for outstanding shipboard operations. G. Rougier and M. Picheral are warmly thanked for their efficient help in CTD rosette management and data processing, as well as C. Schmechtig for the LEFE-CyBER database management. The satellite-derived data of Sea Surface Temperature, chl *a* concentrations and

currents have been provided by CLS in the framework of the CNES funding; we warmly thank I. Pujol and G. Taburet for their support in providing these data. We acknowledge NOAA, and in particular R. Lumpkin, for providing the SVP drifters. All data and metadata are available at the following web address: <http://www.obs-vlfr.fr/proof/php/outpace/outpace.php>

## Figures caption

Fig. 1. Major C fluxes for a biological pump budget. Biological pump: C transfer by biological processes into the ocean interior. DIC: Dissolved Inorganic C, POC: Particulate Organic C, DOC: Dissolved Inorganic C. See Moutin et al., (2012) for a detailed description.

Fig. 2. Transect of the OUTPACE cruise superimposed on (a) arithmetic mean surface chl  $a$  and (b) quasi-Lagrangian weighted mean chl  $a$  of the WTSP during OUTPACE. The two types of station, short duration (X) and long (+) duration investigated for a period longer than seven days, are indicated. The satellite data are weighted in time by each pixel's distance from the ship's average daily position for the entire cruise. The white line shows the vessel route (data from the hull-mounted ADCP positioning system). Coral reefs and coastlines are shown in black, land is grey, and areas of no data are left white. The ocean color satellite products are produced by CLS with support from CNES.

Fig. 3. Zonal sections of (a) conservative temperature  $\Theta$ , (b) absolute salinity SA, (c) density anomaly, and (d) fluorescence in the upper 700 m from the classic CTD rosette during SD and LD stations along the OUTPACE transect. The three LD stations are highlighted by their color-coded letter and corresponding arrow.

Fig. 4. Time series of monthly Southern Oscillation Index (SOI) from January 2000 to October 2016. Negative and positive values are shaded red and blue to signify El Niño and La Niña, respectively. SOI smoothed by 'lowess' filter with a five point window is shown as a solid black line. Black arrows indicate March for the years where satellite data are available. Dashed vertical lines indicate March 2003, 2011, and 2015.

Fig. 5. Probability density estimates for MODIS Aqua data in the OUTPACE region, using mean (a) Annual SST, (b) Annual chl  $a$ , (c) March SST, and (d) March chl  $a$ . Probability densities for the ensemble of all years is shown in white, while densities for 2003, 2011, and 2015 are in red, blue, and green, respectively. Also plotted are 95% confidence intervals (two standard deviations) for each subset estimated using the median variance of pixel inter-annual variability. Note the logarithmic scale for chl  $a$ .
