Abstract

Natural methane emissions from wetlands and fire, and soil uptake of methane, simulated using the Canadian Land Surface Scheme and Canadian Terrestrial Ecosystem (CLASS-CTEM) modelling framework, over the historical 1850-2008 period, are assessed by using a one box model of atmospheric methane burden. This one box model also requires anthropogenic emissions and the methane sink in the atmosphere to simulate the historical evolution of global methane burden. For this purpose, global anthropogenic methane emissions for the period 1850-2008 were reconstructed based on the harmonized representative concentration pathway (RCP) and Emission Database for Global Atmospheric Research (EDGAR) data sets. The methane sink in the atmosphere is represented using bias-corrected methane lifetimes from the Canadian Middle Atmosphere Model (CMAM). The resulting evolution of atmospheric methane concentration over the historical period compares reasonably well with observation-based estimates (correlation=0.99, root mean square error = 35 ppb). The modelled natural emissions are also assessed using an inverse procedure where the methane lifetimes required to reproduce the observed year-to-year increase in atmospheric methane burden are calculated based upon the global anthropogenic and modelled natural emissions that we have used here. These calculated methane lifetimes over the historical period fall within the uncertainty range of observation-based estimates. The present-day (2000-2008) values of modelled methane emissions from wetlands (169 Tg CH₄/yr) and fire (27 Tg CH₄/yr), methane uptake by soil (29 Tg CH₄/yr), and the budget terms associated with overall anthropogenic and natural emissions are consistent with estimates reported in a recent global methane budget that is based on top-down approaches constrained by observed atmospheric methane burden. The modelled wetland emissions increase over the historical period in response to both increase in precipitation and increase in atmospheric CO₂ concentration. This increase in wetland emissions over the historical period yields evolution of the atmospheric methane concentration that compares better with observation-based values than the case when wetland emissions are held constant over the historical period.

60 **1. Introduction**

61

62 Earth system models (ESMs) represent physical climate system processes and their
63 interactions with biogeochemical processes focusing primarily on the carbon cycle in the
64 context of carbon dioxide (CO₂). These models are able to project how the atmospheric
65 concentration of carbon dioxide ([CO₂]) will change in response to changes in anthropogenic
66 CO₂ emissions or alternatively diagnose anthropogenic CO₂ emissions required to achieve a
67 specific CO₂ concentration pathway (Jones et al., 2013). This capability is achieved by
68 modelling [CO₂] as a prognostic variable which itself requires modelling of the surface-
69 atmosphere exchange of CO₂ and hence the need for land and oceanic carbon cycle
70 components in ESMs (Arora et al. 2013; Friedlingstein et al. 2006; Friedlingstein et al. 2014).
71 While most ESMs include the capability of modelling [CO₂] as a prognostic variable there
72 are only a handful of ESMs which are beginning to treat the atmospheric concentration of
73 methane, ([CH₄]), as a fully prognostic variable (Collins et al., 2011; Shindell et al., 2013).

74

75 The [CH₄] has increased from 700 ± 25 ppb in 1750 to 1795 ± 18 ppb in 2010 (Prather et al.,
76 2012). The [CO₂] has increased globally from 278 (276–280) ppm in 1750 to 390.5 (390.3–
77 390.7) ppm in 2011. The greater global warming potential of CH₄ compared to CO₂ (84 and
78 28 for 20-years and 100-year time scales, respectively), has made methane the second most
79 radiatively important greenhouse gas (GHG) after carbon dioxide CO₂ (Myhre et al., 2013).
80 The CO₂ radiative forcing for the period 1750-2011 is 1.82 W/m² (associated with ~112 ppm
81 increase), while the radiative forcing for CH₄ over the same period is 0.48 W/m² (associated
82 with ~1081 ppb = 1.08 ppm increase) (Myhre et al., 2013). Since methane is a short-lived
83 GHG with an atmospheric lifetime of around 9 years (compared to CO₂ which has an
84 atmospheric lifetime of around 100-200 years), mitigation of anthropogenic CH₄ emissions

85 can lead to a decrease in its atmospheric concentration within a timeframe of 10-20 years. As
86 a result methane is considered a short-lived climate forcer (SLCF) and therefore reduction in
87 its anthropogenic emissions offers an attractive and potentially viable target for short-term
88 climate change mitigation policies (Shindell et al., 2012). To be able to address climate
89 benefits of reduction in anthropogenic CH₄ emissions within the framework of
90 comprehensive ESMs, however, it is necessary to model [CH₄] as a prognostic variable in
91 these models.

92

93 Treatment of [CH₄] as a fully prognostic variable in ESMs is hindered by at least two factors.
94 First, the global CH₄ budget is not as well understood as for CO₂. Our lack of ability to close
95 the present-day global CH₄ budget is illustrated in Saunio et al. (2016) who present a recent
96 synthesis of several studies and summarize the present-day global CH₄ budget. Saunio et al.
97 (2016) show a large discrepancy between total CH₄ emissions, from both anthropogenic and
98 natural sources, for the 2003-2012 period as inferred from the top-down atmospheric
99 inversion-based approaches (558 Tg CH₄/yr) and those based on bottom-up modelling and
100 other approaches (736 Tg CH₄/yr). The primary reason for this discrepancy is that there are
101 multiple sources of both natural and anthropogenic CH₄ emissions so the bottom-up
102 approaches that add up all the individual sources inevitably give larger total emissions than
103 top-down approaches that are constrained by the atmospheric CH₄ burden and its loss in the
104 atmosphere. Second, unlike CO₂, CH₄ has a sink in the atmosphere which requires
105 representation of atmospheric chemistry in ESMs to properly account for the removal of CH₄
106 and feedbacks of methane on chemistry. CH₄ is destroyed in the troposphere and stratosphere
107 due to its reaction with OH radicals and chlorine. This is typically very computationally
108 expensive to represent. As an example, the model years per wall clock day simulated by the
109 atmospheric component of the second generation Canadian Earth System Model (CanESM2;

110 Arora et al., 2011) are reduced by a factor of around six when atmospheric chemistry is
111 turned on.

112

113 Despite these two challenges there are ways forward to model [CH₄] as a fully prognostic
114 variable and be able to use comprehensive ESMs to ask questions that the climate modelling
115 community has asked so far in the context of CO₂. For example, how would future [CH₄]
116 change in response to changes in anthropogenic and natural CH₄ emissions, or alternatively
117 what should anthropogenic CH₄ emissions be to achieve a given CH₄ concentration pathway,
118 all while as anthropogenic CO₂ emissions continue to increase? In terms of emissions, since
119 the top-down estimates of CH₄ emissions from natural and anthropogenic sources are better
120 constrained than the bottom-up estimates they are likely to provide more robust estimates for
121 evaluating ESMs and their CH₄ related components. The expensive atmospheric chemistry
122 modules can be replaced with simple first-order representations of chemical losses or,
123 ignoring the spatial variations in CH₄ concentration, the global average concentration of
124 methane can be simulated with a box model using specified methane life times which are
125 calculated a priori using full 3D chemistry-climate models. Although, of course, using
126 specified CH₄ losses implies that feedbacks of methane on methane loss rates and interactions
127 between atmospheric chemistry and climate can be neglected.

128

129 The CLASS-CTEM modelling framework serves as the land surface component in the family
130 of Canadian ESMs (CanESMs) (Arora et al., 2009, 2011; Arora and Scinocca, 2016)
131 developed by the Department of Environment and Climate Change, Government of Canada,
132 and models the land-atmosphere fluxes of water, energy and CO₂. It consists of the Canadian
133 Land Surface Scheme (CLASS) and the Canadian Terrestrial Ecosystem Model (CTEM). In
134 preparation for modelling [CH₄] as a prognostic variable in future versions of CanESMs we

135 have included several CH₄ related processes in the CLASS-CTEM modelling framework.
136 These include representations of dynamic natural wetlands and their CH₄ emissions, CH₄
137 emissions from fires, and uptake of CH₄ by soils. This paper evaluates the simulated spatial
138 distribution of wetlands as well as the magnitude of CH₄ emissions from wetlands and fires,
139 and CH₄ uptake by soils against their respective present-day observation-based estimates. We
140 also evaluate the simulated time evolution of the global sums of these fluxes for the 1850-
141 2008 period by using a one-box model of atmospheric CH₄ burden. This one-box model
142 requires anthropogenic CH₄ emissions, emissions from other natural sources that aren't
143 modelled in the CLASS-CTEM framework, and a representation of atmospheric sinks. The
144 anthropogenic CH₄ emissions for the period 1850-2008 are obtained by harmonizing the RCP
145 and EDGAR data sets, and natural emissions from sources that aren't modelled are specified.
146 Finally, the atmospheric sink of CH₄ is based on bias-corrected global atmospheric lifetime of
147 CH₄ as computed by the Canadian Middle Atmosphere Model (CMAM). The one-box model
148 of atmospheric CH₄ burden is used to evaluate CLASS-CTEM simulated natural CH₄ fluxes
149 by comparing simulated evolution of global [CH₄] with their observation-based estimates as
150 well as by comparing the CH₄ lifetime required to reproduce the observed evolution of global
151 [CH₄] over the historical period with their observation-based estimates.

152

153 The rest of this paper is organized as follows. A brief description of the CLASS-CTEM
154 modelling framework is presented in Section 2 along with the details of methane related
155 processes that are implemented, the data sets used and the experimental protocol. Results are
156 presented in Section 3 and finally discussion and conclusions are presented in Section 4.

157 **2. Model, data and experimental set up**

158 **2.1 The CLASS-CTEM model and its forcing and evaluation data sets**

159 **2.1.1 The CLASS-CTEM model**

160

161 The CLASS-CTEM modelling framework consists of the Canadian Land Surface Scheme
162 (CLASS) and the Canadian Terrestrial Ecosystem Model (CTEM) which are coupled to each
163 other and which together simulate fluxes of energy, water, CO₂ and now CH₄ at the land-
164 atmosphere boundary. Together, CLASS and CTEM form the land surface component in
165 Canadian Earth System Models - CanESM1 (Arora et al., 2009), CanESM2 (Arora et al.,
166 2011), and CanESM4.2 (Arora and Scinocca, 2016).

167

168 CLASS simulates atmosphere-land fluxes of energy and water and it prognostically
169 calculates the liquid and frozen soil moisture contents, and soil temperature for its soil layers,
170 the liquid and frozen moisture contents and temperature of the single vegetation canopy layer
171 (if present) and the snow water equivalent and temperature of a single snow layer (if present).

172 CLASS is described in detail in Verseghy (1991), Verseghy et al. (1993) and Verseghy
173 (2000). In the version 3.6 of CLASS used here, the thicknesses of the three permeable soil
174 layers are specified as 0.1, 0.25 and 3.75 m, although the model can be configured to use any
175 number of layers with specified thicknesses. The thicknesses of the permeable layers also
176 depend on the depth to the bedrock which is specified on the basis of the global data set of
177 (Zobler, 1986). For example, if the depth to bedrock is only 2 m, then the thicknesses of the
178 permeable soil layers are taken to be 0.1, 0.25 and 1.65 m. The energy and water balance
179 calculations are performed for four plant functional types (PFTs) (needleleaf trees, broadleaf
180 trees, crops and grasses). CLASS operates at a sub-daily time step and a time step of 30
181 minutes is used here.

182

183 CTEM simulates the fluxes of CO₂ at the land-atmosphere boundary and in doing so models
184 vegetation as a dynamic component of the climate system. It models photosynthesis,
185 autotrophic respiratory fluxes from its three living vegetation components (leaves, stem and
186 roots, denoted respectively by L, S and R) and heterotrophic respiratory fluxes from its two
187 dead carbon components (litter and soil carbon, denoted respectively by D and H). The flow
188 of carbon through these five carbon pools is explicitly tracked which allows to calculate the
189 amount of carbon in these pools as prognostic variables. Disturbance through fire and land
190 use change are also modelled. CTEM cannot operate without coupling to CLASS. Its
191 photosynthesis module operates at the same time step as CLASS and requires estimates of net
192 radiation and soil moisture from CLASS. In return, CTEM provides CLASS with
193 dynamically simulated structural attributes of vegetation which are functions of the driving
194 meteorological data. The amount of carbon in the leaves, stem and root components is used to
195 estimate structural attributes of vegetation. The leaf area index (LAI) is calculated from leaf
196 biomass using PFT-dependent specific leaf area (SLA, m²/Kg C) which determines the area
197 of leaves that can be constructed per unit leaf carbon biomass (Arora and Boer, 2005a);
198 vegetation height is calculated based on stem biomass for tree PFTs and LAI for grass PFTs
199 (Arora and Boer, 2005a); and rooting depth is calculated based on root biomass (Arora and
200 Boer, 2003). Other than photosynthesis, all terrestrial ecosystem processes in CTEM are
201 modelled at a daily time step. CTEM models its terrestrial ecosystem processes for nine PFTs
202 that map directly to the PFTs used by CLASS. Needleleaf trees in CTEM are divided into
203 deciduous and evergreen for which terrestrial ecosystem processes are modelled separately,
204 broadleaf trees are divided into cold and drought deciduous and evergreen types, and crops
205 and grasses are divided into C₃ and C₄ versions based on their photosynthetic pathways. The
206 version 2.0 of the model is explained in detail in Melton and Arora (2016), while version 2.1

207 is used here which amongst other minor changes includes all methane related processes
208 discussed below.

209

210 The methane related processes implemented in CLASS-CTEM build on the model's existing
211 capabilities. Processes are implemented to be able to dynamically model the geographical
212 distribution of wetlands and their methane emissions, methane emissions from fire and
213 methane uptake by upland soils. The fractional coverage of wetlands in a grid cell is based on
214 flat fraction within a grid cell with slope less than 0.2% and grid-averaged soil moisture. The
215 methodology is explained in Appendix A.

216 **2.1.1.1 Wetland methane emissions**

217

218 The dominant controls on methane emissions in nature are considered to be 1) the position of
219 the water table below which methane is produced due to anoxic decomposition of available
220 organic matter and above which methane is oxidized, 2) the soil temperature which
221 determines the rate of decomposition of organic matter, 3) the availability of organic matter
222 itself, and 4) the pathway through which methane is transferred to the atmosphere (through
223 soil via molecular diffusion, through stems of the vascular plants and through ebullition if the
224 water table is above the soil surface). These factors are not completely independent and their
225 relative importance changes as environmental conditions change (Walter and Heimann,
226 2000). The explicit consideration of these factors becomes more important as the spatial
227 scale at which CH₄ emissions are being modelled reduces. For example, Zhu et al. (2014b)
228 show that as the modelling spatial scale reduces from 100 to 5 km, the dominant control on
229 simulated wetland CH₄ emissions switches from soil temperature to water table depth.

230

231 At the current operational resolution of around 2.81° of CanESM (equal to about 310 km at
 232 the equator) we expect dominant controls on methane emissions to be soil moisture, soil
 233 temperature and the availability of organic matter and this allows us to use the simple
 234 approach that we have used here. This approach also allows us to estimate CH₄ emissions
 235 from wetlands without the use of wetland specific PFTs since at large spatial scales net
 236 primary productivity (NPP) and heterotrophic respiration are governed by climate (Chengjin
 237 et al., 2016) . CH₄ emissions are simulated to occur over the wetland fraction of the grid cell.
 238 The simulated CH₄ emissions from wetlands are calculated by scaling the heterotrophic
 239 respiratory flux (R_h) from model's litter (D) and soil (H) carbon pools which itself depends
 240 on soil temperature, soil moisture, and the available organic matter. Heterotrophic respiration
 241 from the litter and soil carbon pools takes the following basic form, with the formulation
 242 explained in detail in Melton and Arora (2016)

$$R_{h,i} = 2.64 \times 10^{-6} \zeta_i C_i f_i(Q_{10}) f_i(\Psi), i = D, H$$

$$R_h = R_{h,D} + R_{h,H} \quad (1)$$

246 where ζ_i represents the base respiration rate (kg C (kg C)⁻¹ year⁻¹) at 15°C, C_i is the amount
 247 of carbon in model's litter or soil carbon pool (kg C m⁻²), $f_i(Q_{10}) = Q_{10}^{0.1(T_i-15)}$ is a Q₁₀
 248 function that models the effect of temperature, T_i is the temperature of litter or soil carbon
 249 pool (°C) and $f_i(\Psi)$ is the function that reduces heterotrophic respiration when soils are too
 250 dry and too wet using the soil matric potential (Ψ) (Melton et al., 2015). The constant 2.64
 251 $\times 10^{-6}$ converts units from kg C m⁻² yr⁻¹ to mol CO₂ m⁻² s⁻¹.

253 Modelled CH₄ emissions from wetlands, per unit area of a grid cell (mol CH₄ m⁻² s⁻¹), are
 254 calculated as

255

$$E_w = R_h f_w \alpha_w \delta_s \quad (2)$$

257

258 where f_w is the wetland fraction in a grid cell mentioned above, α_w is the ratio of wetland to
259 upland heterotrophic respiratory flux, and δ_s converts flux from CO₂ to CH₄ units but also
260 takes into account that some of the CH₄ flux is oxidized in the soil column before reaching
261 the atmosphere. A value of 0.45 is used for α_w since heterotrophic CO₂ respiratory flux over
262 lowlands is typically lower than over uplands due to limitation by increased soil moisture
263 including a high water table level. While the $f_i(\Psi)$ function in equation (1) does reduce
264 heterotrophic respiration when soils are wet it does so using only the grid averaged soil
265 moisture content. Wania et al. (2010) use a preferred value of δ_s equal to 0.1 and Zhu et al.
266 (2014a) found δ_s varies between 0.1 and 0.7 with a mean value of 0.23 when calibrating
267 their model against data from 19 sites. A value of 0.135 is used for δ_s in this study. The
268 product $\alpha_w \delta_s$ thus equals 0.061 which implies that for each mol CO₂ m⁻² s⁻¹ of heterotrophic
269 respiratory flux 0.061 mol CH₄ m⁻² s⁻¹ is generated over unit area that is deemed wetland. At
270 large spatial scales CH₄ and CO₂ heterotrophic respiratory fluxes are expected to be highly
271 correlated since to the first order they are both governed by temperature and the amount of
272 organic matter available for decomposition (Dalva et al., 2001; Zhu et al., 2014a). In addition,
273 as the spatial scale increases it is possible to ignore the effect of water table depth as Zhu et
274 al. (2014b) illustrate.

275 **2.1.1.2 Fire methane emissions**

276

277 Fire in CLASS-CTEM is modelled using an intermediate complexity scheme, which
278 represents both natural and human-caused fires, and accounts for all elements of the fire

279 triangle: fuel load, combustibility of fuel, and availability of ignition sources. The fire module
280 accounts for both natural fires caused by lightning and anthropogenic fires which are the
281 result of ignitions caused by humans expressed as a function of population density. Increasing
282 population density increases human-caused fire ignitions but also increases suppression of
283 fire. The suppression of fire represents fire-fighting efforts, landscape fragmentation and
284 other processes which leads to a reduction in area burned and is also modelled as a function
285 of population density. The original fire parametrization is described in Arora and Boer
286 (2005b) which has since been adapted and used in several other DGVMs (Kloster et al.,
287 2010; Li et al., 2012; Migliavacca et al., 2013). The fire module in CTEM v. 2.1 incorporates
288 changes suggested in these studies as well as several new improvements which are
289 summarized in detail in Melton and Arora (2016). The approach has been evaluated at the
290 global scale in Arora and Melton (2018) who assess how reduction in global wildfire
291 emissions since 1930s leads to an enhanced land carbon sink. The two primary outputs from
292 the fire module are fraction of area burned per grid cell and dry organic biomass burned per
293 unit area (gC m^{-2}). The dry organic matter burned is then multiplied by corresponding
294 emissions factors to obtained emissions (g species m^{-2}) for several species of trace gases and
295 aerosols including methane (CO_2 , CO , CH_4 , H_2 , NH_3 , NO_x , N_2O , total particulate matter,
296 particulate matter less than $2.5 \mu\text{m}$ in diameter, and black and organic carbon). These
297 emissions factors are based on an updated set by Andreae and Merlet (2001) listed in Tables
298 3 and 4 of Li et al. (2012).

299 **2.1.1.3 Soil uptake of methane**

300

301 The methane uptake over soil occurs over the unsaturated (upland) fraction of a grid cell that
302 is not deemed wetland. The parameterization is based on an exact solution of the one-
303 dimensional diffusion-reaction equation in the near-surface (top) soil layer and described in

304 detail in Curry (2007). Briefly, the methane uptake by soil is a function of diffusion of
305 methane into soil (which depends on atmospheric methane concentration) and its subsequent
306 oxidation by microbes. The diffusion of methane into the soil depends primarily on air filled
307 porosity of the soil and increases as the pore volume filled by liquid and frozen moisture
308 decreases. The oxidation of methane by microbes is a function of both soil moisture and
309 temperature. Oxidation preferably occurs when soils are neither too dry (when microbial
310 activity is limited by low soil moisture) and nor too wet (when microbes are deprived of
311 oxygen). Warmer temperatures favour oxidation of methane in soil and oxidation increases
312 by about 4 times as soil temperature increases from 0 °C to 27.5 °C. Finally, the inhibition of
313 methane uptake in cultivated soils is accounted for by a linear factor that reduces oxidation as
314 crop fraction in a grid cell increases.

315 **2.1.2 Forcing data for the CLASS-CTEM model**

316

317 The CLASS-CTEM model is driven with meteorological data and atmospheric CO₂ and CH₄
318 concentrations. The model also requires geophysical fields for the fractional coverage of nine
319 CTEM PFTs, soil texture and depth to bedrock. The meteorological data are based on version
320 7 of the Climate Research Unit – National Centre for Environmental Prediction (CRU-NCEP)
321 reanalysis dataset (Viovy, 2012). The meteorological variables (surface temperature,
322 pressure, precipitation, wind, specific humidity, and incident short-wave and long-wave
323 radiation fluxes) are available at a spatial resolution of 0.5° × 0.5° and at a six hourly time
324 interval for the period 1901-2015. These data are regridded to a spatial resolution of 2.81°
325 and temporally to a half-hour time step to drive the CLASS-CTEM model. Temperature,
326 pressure, wind, specific humidity, and long-wave radiation are linearly interpolated in time
327 while short-wave radiation is assumed to change with the solar zenith angle with maximum
328 radiation occurring at solar noon. Following Arora (1997) the six-hourly precipitation amount

329 (P , mm/6-hour) is used to estimate the number of wet half-hours in a given six-hour period
330 and the six- hourly precipitation amount is randomly distributed over these wet half hours.
331 Figure B1 in Appendix B shows the annual land-averaged temperature and precipitation
332 (excluding Antarctica) as derived from the CRU-NCEP data. Both temperature and
333 precipitation show an overall increase over the 20th century that continues into the 21st
334 century, associated with the changing climate.

335

336 The land cover data are used by the model to specify the fractional coverage of CTEM's nine
337 PFTs in each grid cell. These data are based on a geographical reconstruction of the historical
338 land cover driven by the increase in crop area (Arora and Boer, 2010) but using the crop area
339 data based on the LUH2 v1h version of the Hurtt et al (2006) land cover product. The final
340 data set consists of the fractional coverage of CTEM's nine PFTs for the period 1850-2015 at
341 the global scale and at 2.81° spatial resolution. The increase in crop area over the historical
342 period leads to decrease in area of natural vegetation thus leading to deforestation. A fraction
343 of deforested vegetation is burned but deforested biomass is also converted to paper and
344 wood products which decompose over time leading to land use change emissions. These
345 processes are described in detail in Arora and Boer (2010). In context of terrestrial methane
346 budget, an increase in crop area leads to lower methane uptake by soil over the cultivated
347 fraction of a grid cell.

348

349 The globally averaged atmospheric CO₂ and CH₄ concentrations used to drive the model are
350 obtained from the data sets put together for the sixth phase of the Coupled Model
351 Intercomparison Project (CMIP6) and available from input4MIPs web site ([https://esgf-
352 node.llnl.gov/projects/input4mips/](https://esgf-node.llnl.gov/projects/input4mips/)). These data are shown in Figure B2.

353 **2.1.3 Observation and model-based data for CLASS-CTEM evaluation**

354

355 In addition to evaluating the CLASS-CTEM simulated methane emissions from wetlands, fire
356 and methane uptake by soils in the context of the one-box atmospheric CH₄ model as
357 mentioned in section 2.2 below, we also evaluate simulated present-day wetland extent and
358 all modelled methane fluxes directly against other model and observation-based estimates.

359

360 The CLASS-CTEM simulated wetland extent is compared against two data sets: the wetland
361 data from the Global Lakes and Wetlands Database (GLWD; Lehner and Döll, 2004) and a
362 new product that is formed by merging remote sensing based observations of daily surface
363 inundation from the Surface Water Microwave Product Series (SWAMPS; Schroeder et al.,
364 2015) with the static inventory of wetland area from the GLWD. The derivation of the second
365 product is explained in detail in Poulter et al. (2017). SWAMPS provides estimates of
366 fractional surface water based on data from multiple passive and active microwave satellite
367 missions. While open water (e.g. rivers, lakes and ocean) and inundated wetlands comprising
368 of open plant canopies are mapped by satellites, inundation beneath closed forest canopies,
369 and exposed wetlands with water table below the surface cannot be mapped. However,
370 satellite data are able to provide the seasonal cycle which static data sets like GLWD cannot.
371 The merged SWAMPS-GLWD product attempts to overcome limitations of both individual
372 data sets.

373

374 The simulated present-day methane emissions from wetlands and fire, and methane uptake by
375 soil, are compared to top-down estimates compiled by Saunio et al. (2016). We also
376 compare the anthropogenic emissions we have used within the framework of one-box
377 atmospheric methane model (Section 2.2) with estimates from Saunio et al. (2016).

378

379 Finally, we also evaluate the model regionally over the West Siberian Lowlands (WSL). This
380 region is chosen because inversion-based methane fluxes are readily accessible over the
381 region which were compiled and documented for the WETCHIMP-WSL Intercomparison
382 project (Bohn et al., 2015). We compare simulated wetland extent and wetland methane
383 emissions with observation- and inversion-based results from Bousquet et al. (2011), Kim et
384 al. (2011), and Winderlich (2012) and participating models in the Wetland and Wetland CH₄
385 Intercomparison of Models Project (WETCHIMP, Melton et al. (2013)) focused on the West
386 Siberian Lowlands region (WETCHIMP-WSL) (Bohn et al., 2015). Of these the Kim et al.
387 (2011) and Winderlich (2012) are regional inversions. Kim et al. (2011) used wetland
388 methane emissions from Glagolev et al. (2010) at 1° spatial resolution as their prior and used
389 the NIES-TM atmospheric transport model for the period 2002–2007. They derived
390 climatological monthly wetland emissions optimized to match atmospheric methane
391 concentrations obtained by aircraft sampling. Winderlich (2012) used the Kaplan (2002)
392 wetland inventory for prior wetland emissions with the TM3-STILT global inversion system
393 for year 2009. Their posterior monthly wetland emissions were uniquely determined for each
394 grid cell within their domain at 1° spatial resolution and optimized to match atmospheric
395 methane concentrations measured at four tower observation sites located between 58°N and
396 63 °N. The Bousquet et al. (2011) is a global inversion but uses two priors – the first one
397 based on the Matthews and Fung (1987) emissions inventory and the second based on Kaplan
398 (2002). Bousquet et al. (2011) inversion used the Laboratoire de Météorologie Dynamique
399 general circulation model (LMDZ) atmospheric transport model at a 3.75° × 2.5° grid and
400 estimated monthly methane emissions at a 1° spatial resolution for the period 1993–2009.
401 Being a global inversion they optimized atmospheric concentrations relative to global surface
402 observations at several flask stations for methane but also other trace gases. For wetland
403 extent, we compare the CLASS-CTEM simulated wetland extent over the WSL region with

404 models participating in the WETCHIMP-WSL intercomparison, and GLWD and
405 SWAMPS+GLWD products mentioned above but also the Global Inundation Extent from
406 Multi-Satellites (GIEMS; Papa et al., 2010; Prigent et al., 2007) derived from visible and
407 near-infrared and active and passive microwave sensors for the period 1993–2004. In
408 addition, we also use the estimate from Peregon et al., (2009) who used a regional wetland
409 typology map further refined by satellite image classifications to calculate the wetland extent
410 in the WSL region.

411 **2.2 Atmospheric methane – one box model, anthropogenic emissions and lifetime**

412 **2.2.1 One-box model of atmospheric methane**

413

414 A one-box model of atmospheric CH₄ is used to evaluate the time evolution of simulated
415 methane emissions from wetlands (E_w), methane emissions from fire (E_f) and the soil uptake
416 of methane (S_{soil}) over the period 1850-2008. The model describes the changes in burden of
417 atmospheric CH₄ (B) as a balance of surface emissions (consisting of natural, E_N , and
418 anthropogenic emissions, E_A) and the atmospheric (S_{atmos}) and surface soil sinks (S_{soil}).

$$419 \quad \frac{dB}{dt} = E_N(t) + E_A(t) - S_{atmos}(t) - S_{soil}(t) \quad (3)$$

420 where t is the time and equation (3) is applied at an annual time step. The atmospheric CH₄
421 burden (B , Tg CH₄) equals 2.78 times [CH₄] (represented in units of parts per billion, ppb)
422 (Denman et al., 2007). The distinction between natural and anthropogenic emissions is not
423 straight-forward for fire which contains emissions due to both natural and human-caused
424 fires. For comparison with Saunio et al. (2016) global CH₄ budget (as shown later in Section
425 3) we consider all emissions from fire as anthropogenic, although the CLASS-CTEM model
426 calculates fire emissions due both to lightning and human-caused ignitions. Natural emissions
427 ($E_N = E_w + E_o$) consist of modelled wetlands emissions (E_w) and emissions from other

428 natural sources (E_o) (including termites, geological sources, wild animals and freshwater)
 429 which we specify at 25 Tg CH₄/yr (consistent with but towards the lower end of the range
 430 natural emissions, 21-130 Tg CH₄/yr, as deduced by top-down approaches summarized in
 431 Saunois et al. (2016)). The reason for specifying E_o at 25 Tg CH₄/yr is discussed later in
 432 section 4. Anthropogenic emissions ($E_A = E_{A \text{ excl fire}} + E_f$) consist of specified emissions
 433 from all anthropogenic sources excluding fire ($E_{A \text{ excl fire}}$) and fire emissions which we
 434 explicitly model (E_f). Estimation of anthropogenic emissions excluding those from fire and
 435 biomass burning ($E_{A \text{ excl fire}}$) data are explained in section 2.2.2.

436

437 The atmospheric sink S is calculated as a first-order loss process from methane's lifetime
 438 τ_{chem} in the atmosphere as $S_{atmos}(t) = B(t)[1 - \exp(-1/\tau_{chem}(t))]$. An estimate of τ_{chem}
 439 is obtained from the Canadian Middle Atmosphere Model (CMAM) with chemistry and
 440 compared to an observation-based estimate from Prather et al. (2012) as later shown in
 441 Section 2.2.3. With S_{atmos} represented in terms of τ_{chem} equation (4) can be rewritten as

442

$$\begin{aligned}
 443 \quad B(t + \Delta t) &= B(t) - B(t)[1 - \exp(-1/\tau_{chem}(t))] + (E_N(t) + E_A(t) - S_{soil}(t))\Delta t \\
 &= B(t)[\exp(-1/\tau_{chem}(t))] + (E_N(t) + E_A(t) - S_{soil}(t))\Delta t \quad (4)
 \end{aligned}$$

444

445 where $\Delta t = 1$ year. Equation (4) can be used to evaluate simulated natural methane emissions
 446 E_N in two ways. First, when all the terms on the right hand side of equation (4), including an
 447 initial value of $B(t)$, are known then the time evolution of B can be calculated and compared
 448 to its observation-based estimate. Second, if the time evolution of B is specified based on
 449 observations of methane concentration in the atmosphere then the value of τ_{chem} required to

450 satisfy equation (4) can be calculated (see equation 5) and compared its observation-based
 451 estimate e.g. from Prather et al. (2012).

$$452 \quad \tau_{chem}(t) = - \frac{1}{\log\left(\frac{B(t+\Delta t) - (E_N(t) + E_A(t) - S_{soil}(t))\Delta t}{B(t)}\right)} \quad (5)$$

453

454 In section 3, we have used both these methodologies to assess CLASS-CTEM simulated
 455 methane emissions from wetlands (E_w), methane emissions from fire (E_f) and the soil uptake
 456 of methane (S_{soil}). Note that equation (4) does not include any term for oceanic methane
 457 emissions. Saunois et al. (2016) report a range of 0–5 Tg CH₄/yr, with a mean value of 2 Tg
 458 CH₄/yr for oceanic methane emissions. Given the large uncertainty in other components of
 459 the global methane budget, and the small magnitude of oceanic methane emissions, we have
 460 ignored this term.

461

462 Equation (3) may also be used to calculate pre-industrial methane concentration assuming
 463 atmospheric methane concentration was in equilibrium with pre-industrial emissions and
 464 sinks, i.e. by setting $\frac{dB}{dt} = 0$, which yields

$$465 \quad E_N(t) + E_A(t) = S_{atmos}(t) + S_{soil}(t). \quad (6)$$

466 Substituting $S_{atmos}(t) = B(t)[1 - \exp(-1/\tau_{chem}(t))]$ similar to as was done in equation
 467 (4) and solving for $B(t)$ gives

$$468 \quad B(t) = \frac{E_N(t) + E_A(t) - S_{soil}(t)}{1 - \exp(-1/\tau_{chem}(t))}. \quad (7)$$

469 Using values of sources and sinks and τ_{chem} corresponding to year 1850, for example, yields
 470 $B(t)$ (Tg CH₄) which when divided by 2.78 yields [CH₄] in ppb for year 1850.

471 **2.2.2 Anthropogenic methane emissions**

472

473 The time evolution of global E_A (used in equation 4) for the 1850-2008 period is based on
474 two data sets. The first data set is the decadal representative concentration pathway (RCP)
475 anthropogenic methane emissions data set (version 2.0.5) available at 0.5° spatial resolution
476 for the period 1850-2000 and provided for the fifth phase of the coupled model
477 Intercomparison project (CMIP5) by the International Institute for Applied Systems Analysis
478 (IIASA) (<http://www.iiasa.ac.at/web-apps/tnt/RcpDb>). The value for the first year of each
479 decade is assumed to correspond to the rest of the decade. So the 1850 value corresponds to
480 the 1850-1859 decade, the 1860 value corresponds to the 1860-69 decade and so on. The
481 second anthropogenic methane emissions data set is part of version 4.2 of the Emission
482 Database for Global Atmospheric Research (EDGAR,
483 <http://edgar.jrc.ec.europa.eu/overview.php?v=42>) available at 0.1° spatial resolution and
484 available for the period 1970-2008. These data sets were selected because the RCP data set
485 provides the anthropogenic methane emissions going back to 1850 and the EDGAR data set
486 provides the anthropogenic methane emissions for more recent years since 1970. The
487 EDGAR data set was also chosen because amongst the recent anthropogenic data sets this is
488 the only data set which provides gridded anthropogenic methane emissions at an annual time
489 scale (see Table 1 of Saunio et al (2016)).

490

491 These two data sets are blended (or harmonized) to obtain a consistent time series of annual
492 global anthropogenic methane emissions for the period 1850-2008. First the RCP and
493 EDGAR data are regridded from their 0.5° and 0.1° spatial resolutions, respectively, to the
494 2.81° resolution at which the model is applied. Next all non-biomass burning emission
495 categories are added separately in both data sets to obtain total anthropogenic emissions for
496 each data set. The emissions categories in both data sets are somewhat different as shown in

497 Table 2. Emissions from fire and biomass burning are excluded because CLASS-CTEM
 498 simulates CH₄ emissions from fire explicitly. Since our framework requires only total
 499 anthropogenic methane emissions (excluding biomass burning) the different emissions
 500 categories in the two data sets do not matter. The wetland emissions from rice paddies, which
 501 we do not explicitly model, are included in the specified anthropogenic emissions (in
 502 category 11 of the EDGAR data set and category 1 of the RCP data set as shown in Table 2).
 503 Equation (8) summarizes this harmonization methodology for a given grid cell.

504

$$505 \quad E_{A,RCP \text{ adjusted}}(t) = E_{A,RCP}(t) + \frac{t-1850}{1970-1850} (E_{A,EDGAR}(1970) - E_{A,RCP}(1970)) \quad (8)$$

506

507 where $E_{A,RCP}$ and $E_{A,EDGAR}$ represent annual anthropogenic methane emissions (excluding
 508 biomass burning) in the RCP and EDGAR data sets, respectively, $E_{A,RCP \text{ adjusted}}$ represent the
 509 adjusted RCP emissions and t is the time in years from 1850 to 1970. The harmonization
 510 algorithm adjusts the annual total anthropogenic methane emissions in the RCP data, for each
 511 2.81° grid cell, from 1850 to 1970 such that by the time RCP emissions reach 1970 they are
 512 the same as the EDGAR's total emissions excluding biomass burning. As a result of this
 513 harmonization, the largest change is made to RCP emissions for year 1970 and the smallest
 514 change is made for year 1851. The RCP emissions for year 1850 are not changed. The final
 515 harmonized time series for E_A is obtained by concatenating $E_{A,RCP \text{ adjusted}}$ for the period 1850
 516 to 1970 and $E_{A,EDGAR}$ for the period from 1971 to 2008.

517

518 Figure 1a shows the harmonized time series of global anthropogenic methane emissions
 519 along with the decadal RCP and annual EDGAR emissions (excluding biomass burning). The
 520 RCP and EDGAR emissions are fairly similar for the period 1970-1990 but are different after
 521 1990. Figures 1b and 1c illustrate how the harmonization works for two selected grid cells

522 based on equation (8). In Figure 1b anthropogenic methane emissions are shown for a land
523 grid cell where emissions first increase and then decrease. In Figure 1c anthropogenic
524 methane emissions are shown for an ocean grid cell, with six orders of magnitude lower
525 emissions than the land grid cell, where emissions more or less continuously increase. In both
526 case, the harmonization ensures that by 1970 the adjusted RCP emissions are same as the
527 EDGAR emissions. Although for the purpose of using E_A in equation (4) only its global
528 values are required, the methodology described here yields a continuous consistent gridded
529 data set of anthropogenic methane emissions for the period of our analysis with no abrupt
530 jumps.

531

532 **2.2.3 Lifetime of atmospheric methane**

533

534 To use equation (4), for evaluation of CLASS-CTEM simulated annual values of E_w , E_f and
535 S_{soil} over the historical period, time-evolving annual values of τ_{chem} are required. We obtain
536 values of τ_{chem} simulated by the Canadian Middle Atmosphere Model (CMAM). The
537 CMAM is a fully interactive chemistry-climate model (CCM) that is based on a vertically
538 extended version of the third generation Canadian Atmospheric General Circulation Model
539 with a model lid at 95 km (Scinocca et al., 2008). The model contains a description of the
540 important physical and chemical processes of the stratosphere/mesosphere and has been
541 extensively assessed against observations through participation in two phases of the
542 Chemistry-Climate Model Validation (CCMVal) activity (Eyring et al., 2006; SPARC
543 CCMVal, 2010). Of more importance for methane, the chemistry has been extended
544 throughout the troposphere by including cloud corrections on clear-sky photolysis rates,
545 emissions of ozone precursors CO and NO_x (NO + NO₂) including emissions of NO_x from
546 lightning, hydrolysis on specified tropospheric sulphate aerosols and interactive wet and dry

547 deposition. Note that the chemical mechanism currently used in CMAM has not yet been
548 extended to include the chemistry of non-methane hydrocarbons important in the
549 troposphere; only methane chemistry is considered.

550

551 Results from CMAM with tropospheric chemistry have been submitted to the Atmospheric
552 Chemistry and Climate Model Intercomparison Project (ACCMIP) (Lamarque et al., 2013).

553 The experimental design for ACCMIP involved timeslice simulations at various points in
554 time between 1850 and 2100, with simulations for year 2000 conditions used for assessing
555 the model chemical climate against available present-day observations. The ACCMIP
556 intercomparison found that the CMAM produced estimates of tropospheric chemical
557 quantities that fell well within the range of current generation CCMs. For example, the
558 present-day tropospheric ozone burden from CMAM was 323 Tg, versus a multi-model mean
559 of 337 ± 23 Tg, where the range is given as one standard deviation across the 15 participating
560 models (Young et al., 2013). The present-day methane lifetime to reaction with OH in the
561 troposphere was found to be 9.4 years, again well within the range of ACCMIP models of 9.7
562 ± 1.5 years (Naik et al., 2013). However, like the majority of ACCMIP models, the CMAM
563 predicts a too fast removal of CH₄ by OH as compared with our best-estimate from methyl-
564 chloroform decay of 11.2 ± 1.3 years (Prather et al., 2012). As described further below, the
565 calculated CH₄ lifetime to chemical loss from CMAM is therefore scaled to agree with
566 observationally-based estimates before being used in the one box atmospheric model of CH₄.

567

568 Time-dependent values of τ_{chem} are derived from a simulation over the 1850-2014 period
569 that uses specified sea-surface temperatures and sea-ice from one member of the five-member
570 historical ensemble performed by CanESM2 for the CMIP5. Data for 2006-2014 was taken
571 from a continuation of that simulation for the RCP 6.0 scenario. Specified anthropogenic and

572 biomass burning emissions of CO and NO_x were taken from the CMIP5 historical database
 573 (Lamarque et al., 2010) up to 2000 and for the RCP 6.0 scenario to 2014. Specified
 574 concentrations of long-lived greenhouse gases were from Meinshausen et al. (2011),
 575 following RCP 6.0 from 2006-2014. Specified stratospheric aerosol surface area density
 576 fields, used to account for the effects of large volcanic eruptions, was based on the 1960-2010
 577 database created for the Chemistry Climate Model Initiative (CCMI) extended back to 1850
 578 following the approach described in Neely III et al. (2016). Solar variability was included by
 579 calculating the wavelength-resolved daily variability relative to the long-term average (June
 580 1976 – January 2007) from the recommended CMIP6 database (Matthes et al., 2017).

581

582 The observation-based estimate of τ_{chem} is obtained from Prather et al. (2012) who calculate
 583 τ_{CH_4} based on equation (9) as

$$584 \quad \frac{1}{\tau_{CH_4}} = \frac{1}{\tau_{OH}} + \frac{1}{\tau_{strat}} + \frac{1}{\tau_{trop-Cl}} + \frac{1}{\tau_{soil}} = \frac{1}{\tau_{chem}} + \frac{1}{\tau_{soil}} \quad (9)$$

585 where τ_{OH} (present day value of 11.2 years), τ_{strat} (120 years), $\tau_{trop-Cl}$ (200 years) and τ_{soil}
 586 (150 years) are the lifetimes associated with the destruction of CH₄ by tropospheric OH
 587 radicals, loss in the stratosphere, reaction with tropospheric chlorine and uptake by soils,
 588 respectively, which yields a present day (corresponding to year 2010) value of τ_{CH_4} as
 589 9.1 ± 0.9 years. τ_{chem} is the methane life time associated with chemical processes in the
 590 atmosphere. For the pre-industrial period (corresponding to year 1750), Prather et al. (2012)
 591 estimate τ_{CH_4} as 9.5 ± 1.3 years assuming τ_{OH} to be equal to 11.76 years (based on
 592 Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) results
 593 (Voulgarakis et al., 2013)) and lifetimes associated with other processes are assumed to stay
 594 the same. In our study, the methane soil sink is explicitly simulated in the CLASS-CTEM

595 framework and this corresponds to the term $\frac{1}{\tau_{soil}}$ in equation (9). The remaining terms in
596 equation (9) all correspond to atmospheric processes. Removing the $\frac{1}{\tau_{soil}}$ term in equation (9)
597 gives us an observation-based estimate of τ_{chem} making it consistent with CMAM's methane
598 lifetime corresponding only to atmospheric processes and increases the observation-based
599 estimates of pre-industrial and present-day atmospheric CH₄ lifetimes to 10.15±1.45 years
600 and 9.7±1.0 years, respectively.

601

602 Figure 2 compares the τ_{chem} values from CMAM with its observation-based estimate from
603 Prather et al. (2012) and shows that CMAM based estimates are biased low and outside the
604 uncertainty range of observation-based estimates, as mentioned earlier. When used in the
605 one-box model of atmospheric methane, the lower than observed τ_{chem} values will
606 inevitably lead to a higher than observed atmospheric sink (S_{atmos}) and thus lower than
607 observed atmospheric methane concentration even if all the other flux terms (E_N , E_A , and
608 S_{soil}) in equation (5) are realistic. We therefore adjust the CMAM derived values of τ_{chem}
609 upwards by 15% so that they lie within the uncertainty range of observation-based estimates
610 of the τ_{chem} as derived by Prather et al. (2012). These adjusted values of τ_{chem} are also
611 shown in Figure 2.

612

613 **2.3 The experimental setup**

614

615 **2.3.1 Equilibrium pre-industrial simulation**

616

617 The equilibrium pre-industrial simulation was initialized from zero biomass for all PFTs. The
618 fractional coverages of CTEM's nine PFTs for the pre-industrial simulation are based on the

619 land cover product described in section 2.1.2 for year 1850. The model was then driven with
620 1901-1925 CRU-NCEP climate data cycled repeatedly until the model pools reach
621 equilibrium. The early part of the 20th century does not show any significant trends compared
622 to the later part of the 20th century, as seen in Figure B1 (Appendix B), so using the 1901-
623 1925 data to spin up the model to equilibrium for 1850 conditions is reasonable. Atmospheric
624 CO₂ and CH₄ concentration levels were set to 285 ppm and 791 ppb, respectively,
625 corresponding to their pre-industrial 1850 levels. This pre-industrial equilibrium simulation
626 yields initial conditions for all CLASS-CTEM prognostic variables for the transient 1851-
627 2015 simulation.

628

629 **2.3.2 Transient historical simulation**

630

631 The transient historical simulation is performed for the period 1851-2015 and its prognostic
632 variables are initialized from the equilibrium pre-industrial simulation as mentioned above.
633 For the period 1851 to 1900 of this simulation the model is driven with meteorological data
634 from 1901-1925 twice similar to what was done for spinning up the model for the pre-
635 industrial simulation. For the period 1901-2015 the meteorological data corresponding to
636 each year are used. Time varying concentrations of atmospheric CO₂ and CH₄ are specified
637 for the period 1851-2015. The annual time-varying fractional coverages of C₃ and C₄ crop
638 PFTs in each grid cell are based on LUH2 v1h version of the Hurtt et al (2006) land cover
639 product.

640

641 In this transient simulation, 1) wetland extent and its methane emissions respond to changes
642 in climate but also increases in atmospheric CO₂ concentration (which increases net primary
643 productivity and thus heterotrophic respiration), 2) methane emissions from fire respond to

644 changes in climate, atmospheric CO₂ concentration, population density and land use change,
645 and 3) methane uptake by soil responds to climate, changes in atmospheric CH₄ concentration
646 and changes in crop fraction.

647

648 **3. Results**

649

650 We first show the results from the transient 1851-2015 simulation and evaluate the time-
651 evolution of CLASS-CTEM simulated global natural methane fluxes over the historical
652 period using the one-box model of atmospheric methane described in section 2.2. This is
653 followed by evaluation of model fluxes for the present day against observation-based
654 estimates and for the WSL region using observation-based estimates and results from other
655 models.

656

657 **3.1 Time evolution of simulated global natural methane fluxes**

658

659 Figure 3 shows the time evolution of simulated annual maximum wetland extent, methane
660 emissions from wetlands and fire, and soil uptake by methane from the 1851-2015 transient
661 historical simulation. In Figure 3: 1) the simulated wetland methane emissions increase by
662 30% over the historical period from about 130 to 169 Tg CH₄/yr from 1850s to the present
663 day (2000-2008) partly due to increase in wetland extent which increases by 8% from 7.5 to
664 8.1 million km² from 1850s to the present day, 2) the simulated fire methane emissions
665 decrease from their 1850s value by 20% from about 34 to 27 Tg CH₄/yr for the present day
666 and 3) the soil methane uptake more than doubles from its 1850s value of about 14 to 29 Tg
667 CH₄/yr for the present day.

668

669 The increase in wetland methane emissions over the historical period is due to an increase in
670 the wetland area, driven by increase in precipitation seen in Figure B1 (Appendix B), but also
671 higher methane fluxes per unit area. The higher methane fluxes per unit area are caused by
672 increase in atmospheric CO₂ concentration which increases both net primary productivity and
673 heterotrophic respiration over the historical period as shown in Figure C1 in Appendix C.
674 Since wetland methane emissions are proportional to heterotrophic respiration (R_h) in
675 equation (2) an increase in R_h also increases methane emissions from wetlands.

676

677 The decrease in methane emissions from wildfires is driven by a decrease in area burned
678 which itself is driven by an increase in crop area and population density over the historical
679 period (Arora and Melton, 2018). The increase in cropland area decreases area burned by
680 wildfires in the model since croplands are not allowed to burn. In the real world cropland area
681 also fragments the landscape which affects the spread of fire. Direct anthropogenic influences
682 on wildfires are more complex since accidental, as well as intentional, human-caused
683 ignitions enhance wildfires while anthropogenic suppression of wildfires decreases area
684 burned and fire related emissions. Figure C2 (Appendix C) shows that the overall effect of
685 increase in crop area and population density in the model is that area burned increases
686 slightly up to about 1930, and then starts decreasing thereafter and this area burned pattern
687 compares reasonably with the decadal charcoal index from the Global Charcoal Database
688 version 3 (Marlon et al., 2008) for the full length of the historical simulation. Winds and
689 smoke carry charcoal from fires and deposit it onto aquatic sediments and this forms the basis
690 of sediment charcoal indices. The caveat with the comparison with sediment charcoal records
691 is that they provide only a proxy for fire activity and indicate if fire activity is higher or lower
692 relative to a point in time. Figure C2 also compares area burned with estimates from version

693 4.1s of the Global Fire Emissions Database (Giglio et al., 2013; Randerson et al., 2012) that
694 are based on the satellite record and available only for the short 1997-2014 period. Model and
695 observation-based average burned area over this 1997-2014 period are 483.4 and 485.5
696 million hectares year⁻¹ and their trends are -5.57 ± 1.25 and -3.43 ± 1.05 million hectares year⁻
697 ², respectively. The negative trends indicate burned area has been decreasing.

698

699 Finally, the increase in methane uptake by soils is primarily the response to an increase in the
700 atmospheric concentration of methane. Diffusion of methane into the soil is directly
701 proportional to its atmospheric concentration (Curry, 2007) which more than doubles from
702 around 790 ppb in 1850 to around 1830 ppb in 2015 (Figure B2, panel b).

703

704 **3.2 Evaluation of simulated global natural methane fluxes**

705

706 We first evaluate the CLASS-CTEM simulated global natural methane fluxes in a forward
707 simulation where all the right hand side terms of equations (3) and (4) are specified at an
708 annual time step and the change in atmospheric methane burden $\frac{dB}{dt}$ is calculated every year.

709 Although the CRU-NCEP meteorological data are available to 2015 allowing us to perform
710 offline CLASS-CTEM simulations up until 2015, the last year for which harmonized RCP-
711 EDGAR emissions are available is 2008. We therefore simulate the time evolution of
712 atmospheric methane concentration for the period 1851-2008. In this forward calculation of
713 atmospheric methane burden the one box model may be initialized using the observed 1850
714 methane concentration or using the 1850 concentration that is in equilibrium with 1850 sinks
715 and sources. The latter is calculated by assuming $\frac{dB}{dt} = 0$ as illustrated in equations (6) and
716 (7). The numerator term in equation (7) ($E_N(t) + E_A(t) - S_{soil}(t)$) for year 1850 is 214.2 Tg

717 CH₄/year (wetland emissions are 130.1, other natural emissions are specified at 25,
718 anthropogenic emissions are 39.5, fire emissions are 33.2, and soil uptake is 13.6). In
719 equation (7) using adjusted CMAM τ_{chem} value of 8.82 years (for year 1850, red line in
720 Figure 2) yields an 1850 equilibrium [CH₄] for 1850 of 719 ppb compared to its observation-
721 based value of 791 ppb. In contrast, using the midrange value of τ_{chem} of 9.97 years based on
722 Prather et al. (2012) yields equilibrium [CH₄] for 1850 of 808 ppm which compares much
723 better with its observation-based estimate of 791 ppm. An equilibrium methane concentration
724 in 1850 that is lower than observed, when using adjusted CMAM τ_{chem} , implies that the
725 atmospheric methane sink is higher and associated with lower than observed atmospheric
726 methane lifetime in 1850. Indeed, the adjusted CMAM τ_{chem} for 1850 of 8.82 years is less
727 than Prather et al. (2012) midrange estimate of 9.97 years but still within their uncertainty
728 range as seen in Figure 2. Regardless, since the lifetime of methane in the atmosphere is only
729 around 10 years the effect of initial conditions disappears by around 1870. This is shown in
730 Figure 4a which compares the simulated evolution of atmospheric methane burden with its
731 observations using the adjusted CMAM τ_{chem} . Figure 4a shows that overall the simulated
732 increase in methane concentration over the historical period is reasonable compared to
733 observation-based estimates despite the various specified and modelled sources and sinks that
734 contribute to the time evolution of atmospheric methane burden. In Figure 9a, the coefficient
735 of correlation between observation-based (black line) and simulated (green and blue lines)
736 [CH₄] is 0.99 and root mean square error (RMSE) is 35 ppb (green line) and 41 ppb (blue
737 dashed line). The simulated values are somewhat overestimated from 1885 to 1980 and
738 underestimated from 1980 to 2005. The increase in observed methane concentration over the
739 1850 to 2008 period is 998 ppb, while the one box model yields an increase of 1006 ppb
740 when initialized from observed 1850 methane concentration. The year 2008 concentration is
741 calculated to be 1797 ppb compared to the observation-based value of 1790 ppb.

742

743 An alternative approach to evaluate the modelled natural sinks and sources is to specify the
744 rate of increase of atmospheric methane burden according to its observations and calculate
745 the required atmospheric lifetime of methane (excluding the soil sink), given modelled
746 natural sinks and sources, following equation (5) as discussed in section 2.2. These results are
747 shown in Figure 4b, which compares the methane lifetimes required to achieve the observed
748 increase in methane concentration over the historical period (black line) to within ± 3 ppb
749 (shaded area between grey lines) with observation-based estimate of atmospheric methane
750 lifetime based on Prather et al. (2012) and the adjusted atmospheric methane lifetime from
751 CMAM (both of which were shown earlier in Figure 2). Figure 4b shows that for the most
752 part, the calculated atmospheric methane lifetime stays within the uncertainty of observation-
753 based estimates. More over the temporal trend after 1900 in calculated atmospheric methane
754 lifetime compares well to the trend in the atmospheric methane lifetime from the CMAM
755 model. Both anthropogenic emissions and methane concentration during the early part of the
756 1850-2008 historical period are more uncertain than during the later part and therefore the
757 differences between simulated and observation-based estimates of atmospheric methane
758 concentration (in Figure 4a) and methane lifetimes (in Figure 4b) for the period 1850-1900
759 are not unexpected.

760

761 While the results in Figures 4a and 4b provide some confidence that the magnitude and
762 temporal evolution of simulated global natural methane sources and sinks over the historical
763 period are reasonable they, of course, do not allow the evaluation of all of the simulated
764 natural fluxes individually.

765

766 We also evaluate the role of increase in wetland methane emissions over the historical period
767 (as seen in Figure 3) on the historical methane budget. Instead of using wetland methane
768 emissions from the transient historical simulation in the one box model of atmospheric
769 methane we use wetland methane emissions from the equilibrium pre-industrial simulation in
770 which 1901-1925 CRU-NCEP meteorological data are used repeatedly and CO₂ is held
771 constant at its pre-industrial level of 285 ppm. As a result wetland extent and methane
772 emissions do not respond to changes in climate and increasing CO₂, and do not increase over
773 the historical period (as seen in Figure 5a). Methane emissions from fire and soil uptake of
774 methane still respond to changes in climate and increasing CO₂. The result of using these
775 wetland methane emissions (shown in Figure 5a) in the framework of the one box model of
776 atmospheric methane is shown in Figure 5b. In Figure 5b, although [CH₄] overall increases
777 over the historical period in response to increase in anthropogenic emissions, the result of
778 wetland methane emissions not increasing over the historical period is that the simulated
779 atmospheric methane concentration in year 2008 is calculated to be 1667 ppm, which is 130
780 ppb lower than the 1797 ppb seen in Figure 4a.

781

782 **3.3 Geographical distribution of wetland extent**

783

784 Figure 6 compares the zonally-averaged maximum wetland fraction over land with
785 observation-based estimates based on the Global Lakes and Wetland (GLWD; Lehner and
786 Döll, 2004) and the new product formed by merging remote sensing based observations of
787 daily surface inundation from the Surface Water Microwave Product Series (SWAMPS;
788 Schroeder et al., 2015) with the static inventory of wetland area from the GLWD from
789 Poulter et al. (2017), as mentioned earlier in section 2.1.3. Maximum wetland fraction from
790 the model and SWAMPS+GLWD product is calculated as the maximum of 12 mean monthly

791 values from the 13 years spanning the 2000-2012 period. Figure 6 shows that overall the
792 model is able to capture the broad latitudinal distribution of wetlands with higher wetland
793 fraction at northern high-latitudes and in the tropics. The model yields higher wetland
794 fraction in the tropics than both observation-based estimates and this is due to higher wetland
795 fraction simulated in the Amazonian region. The Amazonian region is densely forested and
796 the SWAMPS product is unable to map wetlands beneath closed forest canopies. Biases also
797 likely exist in the GLWD data set since parts of the Amazonian region are fairly remote. This
798 is shown in Figure 7 which compares the geographical distribution of simulated maximum
799 wetland fraction with that from the GLWD and SWAMPS+GLWD products. The model
800 successfully captures wetlands in the Hudson Bay lowlands, the West Siberian lowlands, the
801 Pantanal and the region bordering Argentina, Paraguay and Uruguay in South America,
802 Indonesia and the low lying region around Bangladesh. In terms of differences from these
803 observation-based data sets the model most notably overestimates wetland extent in Europe.
804 One possible reason for this is that wetlands in Europe have been drained for agriculture and
805 our wetland parameterization does not take this into account. About two-thirds of the
806 European wetlands that existed 100 years ago have been lost (European Commission, 1995)
807 leading to a substantial decrease in the number and size of large bogs and marshes, and small
808 or shallow lakes.

809

810 **3.4 Geographical distribution of simulated natural fluxes**

811

812 Figure 8 shows the geographical distribution of methane emissions from dynamic wetlands
813 (panel a) and fire (panel b) and the soil uptake of methane (panel c) simulated by the CLASS-
814 CTEM model. The figures also show the global total of these fluxes averaged over the 2000-
815 2008 period for later comparison with estimates from Saunois et al. (2016). Methane

816 emissions from wetlands (168.9 Tg CH₄/yr) are the largest of natural fluxes, as is well
817 known, while emissions from fire (26.8 Tg CH₄/yr) and methane uptake by soil (28.7 Tg
818 CH₄/yr) are an order of magnitude lower. As expected, the geographical distribution of
819 methane emissions from wetlands (Figure 8a) corresponds well to the geographical
820 distribution of wetlands themselves (Figure 8a) although per unit wetland area methane
821 emissions are higher in tropics and milder temperate regions than in high-latitude regions.
822 This is because warmer temperatures and longer growing season in the tropical and milder
823 temperate regions imply that wetlands can emit more methane per unit wetland area and for a
824 longer period of time than the colder high-latitude regions with a shorter growing season. In
825 Figure 8b the geographical distribution of methane fire emissions shows higher values in
826 seasonally-dry tropical regions and order of magnitudes lower values in mid-high latitude
827 regions. These results are consistent with area burned (not shown) which shows a similar
828 pattern (Arora and Melton, 2018). Finally, the geographical distribution of methane uptake by
829 soils in Figure 8c shows higher methane uptake by soils in parts of arid regions (including the
830 Sahara and the Australian outback) where soil moisture doesn't get too dry (so as to not
831 excessively limit soil microbial activity) but otherwise fairly uniform uptake in the tropics
832 and lower values in mid-high latitude regions where lower temperatures and higher soil
833 moisture limit methane uptake by soils.

834

835 **3.5 Regional evaluation over West Siberia lowlands**

836

837 While evaluation of simulated global wetland extent and wetland methane emissions, and
838 their geographical distribution, provides confidence in model results, we further evaluate the
839 model at a regional scale over the West Siberia lowlands. The model results are sampled for
840 the region lying between 50 to 75 °N and 60 to 95°E for comparison with observation- and
841 inversion-based estimates (mentioned earlier in section 2.1.3). Figure 9a compares CLASS-

842 CTEM simulated wetland extent with those from models participating in the WETCHIMP-
843 WSL intercomparison, and the GIEMS, SWAMPS and merged SWAMPS and GLWD
844 products mentioned in section 2.1.3. Table 2 compares the simulated annual maximum
845 wetland extent with models participating in the WETCHIMP-WSL intercomparison and these
846 observation-based products. All values are reported as average for the period 1993-2004
847 except for the merged SWAMPS and GLWD product whose average is for the 2002-2012
848 period, and the Pregon et al. (2009) estimate that is based on wetland typology map from a
849 1977 publication and a more recent satellite land cover product. CLASS-CTEM simulated
850 monthly wetland extent in Figure 9a compares best with the merged SWAMPS and GLWD
851 product, while both the satellite-based inundation products by themselves (SWAMPS and
852 GIEMS) show much lower values. Satellite-based products that remotely sense inundated
853 areas can only do so when water table is above the ground and therefore wetland areas
854 inferred from these products are expected to be lower in magnitude than products which also
855 take into account land cover as is the case for the merged SWAMPS and GLWD product.

856

857 In Table 2, the annual maximum wetland extent is quite similar for the merged SWAMPS
858 and GLWD product (0.55 million km²) and CLASS-CTEM simulated values (0.53 million
859 km²) but the maximum occurs in different months. In Figure 9b, for the merged SWAMPS
860 and GLWD product the maximum wetland extent occurs in June while CLASS-CTEM
861 simulated values show peak both in June and September. The participating models from the
862 WETCHIMP-WSL intercomparison show a range of values for the monthly wetland extent in
863 the WSL region (Figure 9a). Models range from those which specify constant values with no
864 seasonality for the wetland extent to models which dynamically model wetland extent two of
865 which show maximum wetland extent of greater than 1 million km². The average annual
866 maximum wetland extent across the participating models in the WETCHIMP-WSL is

867 0.70±0.15 million km² (mean ± standard error). Finally, the Peregon et al. (2009) estimate is
868 0.68 million km² which is somewhat higher than the CLASS-CTEM simulated value (0.53
869 million km²) and the merged SWAMPS and GLWD product (0.55 million km²).

870

871 Figure 9b compares CLASS-CTEM simulated monthly wetland methane emissions with
872 those from models participating in the WETCHIMP-WSL intercomparison and four
873 inversion-based estimates mentioned in section 2.1.3. The two Bousquet et al. (2011)
874 inversions shown in Figure 9b correspond to ones using the reference Matthews and Fung
875 (1987) emissions inventory (Bousquet 2001 R) and the emissions inventory based on Kaplan
876 (2002) (Bousquet 2001 K). All values are reported as average for the period 1993-2004
877 except for the Kim et al. (2011) inversion which reports fluxes for year 2005 and the
878 Winderlich (2012) inversion which corresponds to year 2009.

879

880 Table 2 compares the simulated annual wetland methane emissions from CLASS-CTEM with
881 those from models participating in the WETCHIMP-WSL intercomparison and the four
882 inversion-based estimates. In Table 2, the inversion-based annual wetland methane emissions
883 vary from 3.08 to 9.80 Tg CH₄/yr. The highest annual emissions in the Winderlich (2012)
884 inversion are due to higher emissions in the shoulder months of spring and fall compared to
885 other inversions but also non-zero emissions during winter months (December to February)
886 as seen in Figure 9b. The CLASS-CTEM model calculates annual wetland methane
887 emissions of 7.76 Tg CH₄/yr and the average for models participating in the WETCHIMP-
888 WSL intercomparison is 5.34±0.54 Tg CH₄/yr (mean ± standard error). Of all the models and
889 inversions only the Winderlich (2012) inversion shows substantial methane emissions for the
890 November to April period. In CLASS-CTEM as the liquid soil moisture in the top soil layer
891 freezes wetland extent contracts to zero (Figure 9a) and methane emissions are shut off

892 during the winter months. Bohn et al. (2015) note that Winderlich (2012) inversion-based
893 estimates may have been influenced by emissions from fossil fuel extraction and biomass
894 burning, although the seasonality of Winderlich (2012) fluxes, with non-zero emissions even
895 in winter, is plausible. Based on year-round eddy flux measurements of methane emissions
896 from an Alaskan Arctic tundra sites Zona et al. (2016) find that cold season (September to
897 May) emissions account for $\geq 50\%$ of the annual methane flux, with the highest emissions
898 from non-inundated upland tundra. They find a major fraction of cold season emissions occur
899 during the “zero curtain” period, when subsurface soil temperatures are near 0 °C. Langer et
900 al., (2015) report winter emissions from tundra ponds in Siberia as they are freezing during
901 early winter. They analyzed concentrations of methane in bubbles (trapped in the lake ice)
902 which were higher at depths than at the ice surface. So it is entirely plausible that methane
903 emissions occur during transition to winter months which models fail to simulate and most
904 inversions fail to capture.

905

906 **3.6 Evaluation of present-day global methane budget**

907

908 Our final evaluation of simulated global methane budget is against estimates compiled by
909 Saunois et al. (2016) who synthesize several recent studies to summarize the present-day
910 global methane budget. Our global methane budget is based on simulated and specified fluxes
911 and the use of one box model of atmospheric methane. We exclusively evaluate our
912 simulated global methane budget against the top-down approaches presented in Saunois et al.
913 (2016) since estimates from bottom-up approaches are known to yield higher total emissions
914 than those based on top-down approaches as mentioned earlier in the Introduction. The global
915 methane budget based on top-down approaches which are constrained by the atmospheric
916 CH₄ burden and its loss in the atmosphere is considered more reliable than that based on the

917 bottom-up approaches. These comparisons are shown in Table 3. The natural and
918 anthropogenic sources are divided into their broad categories and so are the sinks which are
919 divided into atmospheric and soil sinks. The Sauniois et al. (2016) estimates are reported for
920 the period 2000-2009 while the CLASS-CTEM values correspond to the 2000-2008 period
921 since the EDGAR anthropogenic emissions were available only until 2008 at the time of this
922 study and therefore the one box model of atmospheric methane is also run up until 2008. For
923 clarity, Table 3 also identifies which fluxes are modelled by CLASS-CTEM, which are
924 specified and which are based on atmospheric methane lifetimes.

925

926 In Table 3 the total emissions from natural sources in our framework are 199 Tg CH₄/yr
927 which are in the lower part of the range of 194-292 Tg CH₄/yr compiled by Sauniois et al.
928 (2016). This is due to lower specified emissions from non-wetland sources. While our
929 modelled emissions from wetlands of 169 Tg CH₄/yr compare well with the Sauniois et al.
930 (2016) central estimate of 166 Tg CH₄/yr, our specified emissions from other natural sources
931 (including termites, geological sources and fresh water bodies) of 25 Tg CH₄/yr are near the
932 low end of their range (21-130 Tg CH₄/yr). In contrast, our anthropogenic emissions of 344
933 Tg CH₄/yr (which include emissions from fire for consistency with Sauniois et al. (2016)) are
934 higher than Sauniois et al. (2016) central estimate of 319 Tg CH₄/yr and towards the higher
935 end of their range (255-357 Tg CH₄/yr). This is due to the use of EDGAR emissions which as
936 Sauniois et al. (2016) note are towards the higher end of all data sets of anthropogenic
937 emissions. Our modelled fire emissions of 27 Tg CH₄/yr are lower than Sauniois et al. (2016)
938 central estimate of 35 Tg CH₄/yr. One reason for this is that while we include natural and
939 anthropogenic fires in our framework we do not account for biofuel burning. Overall, our
940 emissions from natural sources are 35 Tg CH₄/yr lower, and emissions from anthropogenic
941 sources are 25 Tg CH₄/yr higher, than the Sauniois et al. (2016) central estimates. As a result,

942 the sum of natural and anthropogenic emissions (543 Tg CH₄/yr) in our framework is 9 Tg
943 CH₄/yr lower than Sauniois et al. (2016) central estimate (552 Tg CH₄/yr).

944

945 The total sink strength is calculated to be 538 Tg CH₄/yr in our framework which compares
946 well with the Sauniois et al. (2016) estimate of 546 Tg CH₄/yr. Sauniois et al. (2016) do not
947 provide uncertainty ranges for the atmospheric and total sink. The modelled atmospheric (509
948 Tg CH₄/yr) and soil (29 Tg CH₄/yr) sinks in Table 3 also compare well with Sauniois et al.
949 (2016) estimates of 514 and 32 Tg CH₄/yr, respectively.

950

951 **4. Discussion and conclusions**

952

953 The offline evaluation of natural methane fluxes simulated by the CLASS-CTEM modelling
954 framework presented here is the first step in making atmospheric methane concentration a
955 prognostic variable in the family of Canadian earth system models. The evaluation is based
956 on comparison of present-day fluxes with existing observation- and model-based estimates
957 compiled by Sauniois et al. (2016) but also the historical evolution of atmospheric methane
958 burden and methane's lifetime simulated using a one box model of atmospheric methane.
959 While our simulated and specified present-day global methane budget components lie within
960 the uncertainty range for top-down estimates from Sauniois et al. (2016) this also implies that
961 methane emissions from individual sectors for the present-day budget can be increased or
962 decreased within their uncertainty ranges as long as the total emissions stay the same. The
963 time evolution of the atmospheric methane burden over the historical period, however,
964 provides additional constraints than the present-day methane budget. For example, our
965 specified methane emissions of 25 Tg CH₄/yr from other nature sources (E_o) (including
966 termites, geological sources, wild animals and freshwater) are lower than Sauniois et al.

967 (2016) central estimate of 68 Tg CH₄/yr, although still within their uncertainty range (21-130
968 Tg CH₄/yr). In the absence of any information about its time evolution we have assumed that
969 E_o remains constant over the historical period. This is a plausible assumption since we do not
970 expect emissions from termites, geological sources, wild animals and freshwater to show a
971 large response to changing environmental conditions over the historical period. Certainly, not
972 as large as we saw for wetland emissions which increased by 40 Tg CH₄/yr over the 1850-
973 2008 period (Figure 3). However, when we use a constant E_o of 68 Tg CH₄/yr in our
974 framework we obtain higher than observed methane concentration throughout the historical
975 period and the year 2008 value is 1953 ppb compared to 1797 ppb that we obtain in Figure 4a
976 (observed methane concentration for 2008 is 1790 ppb). This is shown in Figure 10. Part of
977 the reason for this may be that present-day EDGAR emissions are higher than other estimates
978 as Saunio et al. (2016) note and that's why we had to choose a lower E_o . However, the
979 global harmonized and RCP anthropogenic emissions are fairly similar up until 1990 (see
980 Figure 1a) and therefore had we use RCP based emissions (up until year 2000) we still would
981 have obtained higher than observed atmospheric methane concentrations throughout the
982 historical period when using E_o of 68 Tg CH₄/yr. Our framework cannot accommodate E_o
983 larger than about 25-30 Tg CH₄/yr without overestimating atmospheric methane
984 concentrations throughout the historical period.

985

986 The second constraint provided by the time evolution of the atmospheric methane burden
987 over the historical period is that related to wetland methane emissions. As seen in section 3.2,
988 in the absence of the simulated increase in wetland methane emissions from about 130 to 170
989 Tg CH₄/yr from 1850s to the present day the simulated year 2008 atmospheric methane
990 concentration is about 100 ppb lower than observed (as seen in Figure 5). Assuming our RCP
991 and EDGAR based harmonized anthropogenic emissions and their increase over the historical

992 period is reasonably realistic, this indicates that it is very likely that wetland methane
993 emissions have indeed increased over the historical period in response to changes in climate
994 and increased atmospheric CO₂ concentration. The results in section 3.1 showed that this
995 increase of 30% in wetland methane emissions is driven more by an increase in methane
996 emissions per unit area than the increase in maximum wetland extent, which increased by
997 about 8% over the historical period. The implication of this is that wetland methane
998 emissions will likely keep increasing in the future in response to the increasing atmospheric
999 concentration of CO₂ driven by higher heterotrophic respiration.

1000

1001 The evaluation of simulated wetland extent against the GLWD and the merged SWAMPS
1002 and GLWD product provides confidence that the model is broadly able to reproduce the
1003 geographical distribution of wetlands although, of course, some limitations remain. Over the
1004 WSL region the simulated estimates of wetland extent and wetland methane emissions are
1005 also broadly consistent with observation-based estimates.

1006

1007 The version of the model used here treats its land mask as binary so each grid cell is either
1008 land or ocean/water. While the model is capable of representing inland lakes using a separate
1009 tile (and simulate the resulting impact on energy and water fluxes) this functionality was not
1010 used in this study. In addition, representation of inland lakes requires modelling methane
1011 emissions from their anoxic sediment (Bastviken et al., 2004) and care needs to be taken to
1012 avoid double counting the wetland extent of inland lakes (Thornton Brett et al., 2016).

1013

1014 We have not evaluated the model's wetland methane emissions at the site level against
1015 observations. Wetland methane emissions are known to be spatially highly heterogeneous and
1016 temporally intermittent (e.g. Godwin et al., 2013) and CLASS-CTEM does not represent

1017 physical processes that govern methane emissions at small spatial and temporal scales.
1018 Instead the model is designed for operation at large spatial scales (> 100 km) and
1019 implementation within an Earth system model and as such only temperature, soil moisture
1020 and substrate availability (through heterotrophic respiration) are taken into account. Water
1021 table depth, ebullition, transport through vascular plants, and PFTs specific to wetlands are
1022 not considered in our modelling framework. The corollary of this is that our model cannot be
1023 expected to reproduce wetland methane emissions at a point scale where site specific
1024 processes and conditions including water depth, ebullition, and wetland specific PFTs
1025 become more important. Similar approaches are followed by several large scale models
1026 including a recent attempt by Bloom et al. (2017) who derive wetland methane emissions
1027 using heterotrophic respiration from eight terrestrial ecosystem models.

1028

1029 We have also not evaluated parameter and forcing uncertainties in relation to simulated
1030 methane emissions. However, several aspects of the CLASS-CTEM model have been
1031 evaluated before against observations including photosynthesis, autotrophic and heterotrophic
1032 respiration, allocation of carbon from leaves to stem and root components, dynamic leaf
1033 phenology, fire, and land use change. These aspects of the model have been evaluated at
1034 point (Arora and Boer, 2005a; Melton et al., 2015), regional (Arora et al., 2016; Garnaud et
1035 al., 2015; Peng et al., 2014) and global (Arora and Boer, 2010; Melton and Arora, 2014,
1036 2016) scales. In regards to processes relevant to methane emissions from wetlands (which, of
1037 course, is the largest natural source) heterotrophic respiration and wetland extent are the most
1038 important. Uncertainties in these two quantities will propagate to calculated methane
1039 emissions from wetlands. The majority of increase in wetland methane emissions over the
1040 historical period comes from an increase in heterotrophic respiratory flux due to increase in
1041 gross and net primary productivities in response to increase in atmospheric CO_2

1042 concentration. The rate of increase of simulated gross primary productivity is adjusted in
1043 CLASS-CTEM to obtain realistic land carbon sink from 1960 onwards (Le Quéré et al.,
1044 2018) but also to obtain a realistic amplitude of the annual CO₂ cycle in a fully coupled Earth
1045 system model simulation (Arora and Scinocca, 2016). The response of model's heterotrophic
1046 respiration to soil moisture is expressed as a function of soil matric potential as mentioned
1047 earlier in section 2.1.1.1. This response is based on Griffin (1981) who suggests that the
1048 microbial activity is optimal at an absolute soil matric potential of 0.05 MPa and decreases as
1049 the soil becomes waterlogged near 0.00 MPa or too dry near 1.5 MPa . This parameterization
1050 has been evaluated indirectly at seasonally dry locations in the Amazonia (Melton et al.,
1051 2015).

1052

1053 Our next step to evaluate natural methane fluxes from CLASS-CTEM is to use these fluxes in
1054 an atmospheric transport model to simulate and compare methane concentrations at selected
1055 stations to assess seasonality of simulated wetland methane emissions at large spatial scales
1056 in a somewhat more direct manner. In addition, CLASS-CTEM simulated natural fluxes can
1057 be used as a prior in a methane inversion-based system, together with anthropogenic methane
1058 emissions, to calculate optimized posterior fluxes to which the prior fluxes can be compared.
1059 Although atmospheric inversions-based systems have their own limitations (Houweling et al.,
1060 2017), the objective is to evaluate CLASS-CTEM simulated natural methane fluxes using a
1061 range of available methodologies.

1062

1063 Overall the results presented here suggest that the natural fluxes of methane between the
1064 atmosphere and the land, and the geographical distribution of wetland extent, simulated by
1065 the CLASS-CTEM modelling framework are sufficiently realistic to use the model to study
1066 the changes in natural methane fluxes due to changes in environmental conditions.

1067

1068

1069 **Acknowledgements**

1070

1071 We would like to thank Douglas Chan and Reinel Sospedra-Alfonso for providing comments
1072 on an earlier version of this manuscript. We also thank the two anonymous reviewers for their
1073 comments and our handling editor Alexey V. Eliseev for his time and effort.

Table 1: Emissions categories for EDGAR and RCP anthropogenic methane emissions.

EDGAR	RCP
Non-biomass burning categories	
1. Energy manufacturing transformation 2. Non-road transportation 3. Road transportation 4. Residential 5. Fugitive from solid 6. Oil production and refineries 7. Gas production and distribution 8. Industrial processes and product use 9. Enteric fermentation 10. Manure management 11. Agricultural soils 12. Agricultural waste burning 13. Soil waste disposal 14. Waste waster 15. Fossil fuel fires	1. Agricultural sector 2. Agricultural waste burning 3. Residential and commercial combustion 4. Energy production and distribution 5. Industrial processes and combustion 6. Land transport emissions 7. Waste treatment and disposal 8. Shipping
Biomass burning categories	
16. Large scale biomass burning	9. Biomass burning from forest fires 10. Biomass burning from grass fires

1428
 1429

1430 **Table 2:** Comparison of CLASS-CTEM simulated annual methane emissions and annual
 1431 maximum wetland extent for the West Siberia lowlands (WSL) region with models
 1432 participating in the WETCHIMP-WSL intercomparison and observation- and inversion-based
 1433 estimates as discussed in section 3.5. Numbers shown are mean \pm standard error from Bohn
 1434 et al. (2015) for models participating in the WETCHIMP-WSL intercomparison. Standard
 1435 error is not available for all inversions. All values are reported as average for the period
 1436 1993-2004 unless otherwise noted.
 1437

WSL annual maximum wetland extent (million km²)	
Model mean from participating models in the WETCHIMP-WSL Intercomparison	0.70 \pm 0.15
CLASS-CTEM (this study)	0.53
GIEMS inundation data set	0.21
SWAMPS inundation data set	0.15
SWAMPS and GCP product (for period 2002-2012)	0.55
Peregon et al. (2009)	0.68
WSL annual wetland emissions (Tg CH₄/yr)	
Model mean from participating models in the WETCHIMP-WSL Intercomparison	5.34 \pm 0.54
CLASS-CTEM (this study)	7.76
Bousquet 2011 K	7.06
Bousquet 2011 R	7.13
Kim 2011 (for year 2005)	3.08 \pm 1.40
Winderlich 2012 (for year 2009)	9.80

Table 3: Comparison of the components of the present day methane budget based on this study with those from Saunois et al. (2016) (based on synthesis of published studies). The values used in this study are averaged for the period 2000-2008 (since the last year of the version of EDGAR emissions used is 2008) while Saunois et al. (2016) values correspond to the 2000-2009 period.

	Saunois et al. (2016) estimates based on top-down approaches	Values used in this study and how they were obtained.	
<i>Natural sources</i>	234 [194-292]	199	
Natural wetlands	166 [125-204]	169	CLASS-CTEM simulated
Other natural sources (termites, geological, fresh water etc.)	68 [21-130]	30	Specified as a constant over the historical period
<i>Anthropogenic sources</i>	319 [255-357]	344	
Agriculture and waste	183 [112-241]	200	EDGAR
Fossil fuels	101 [77-126]	117	EDGAR
Biomass and biofuel burning	35 [16-53]	27	CLASS-CTEM simulated
<i>Sum of all sources</i>	552 [535-566]	543	
<i>Sum of all sinks</i>	546	538	
Atmospheric sink	514	509	Based on specified bias-corrected atmospheric CH4 lifetimes from CMAM
Soil sink	32 [27-38]	29	CLASS-CTEM simulated

1482

1484
 1485 Figure 4: Comparison of simulated methane concentration over the historical period with its
 1486 observation-based estimates (panel a). The simulation may be initialized from the 1850
 1487 observed methane concentration (solid green line) or from an 1850 concentration that is in
 1488 equilibrium with 1850 specified methane sources and sinks (dashed blue line) as explained in
 1489 section 3.2. Panel (b) compares the methane lifetimes required to achieve the observed
 1490 increase in methane concentration over the historical period (black line) to within ± 3 ppb
 1491 (shaded area between grey lines) with observation-based estimate of atmospheric methane
 1492 lifetime based on Prather et al. (2012) and the adjusted atmospheric methane lifetime from
 1493 CMAM.
 1494

CLASS-CTEM simulated natural methane sinks and sources and annual maximum wetland extent

Atmospheric methane concentration (ppb)

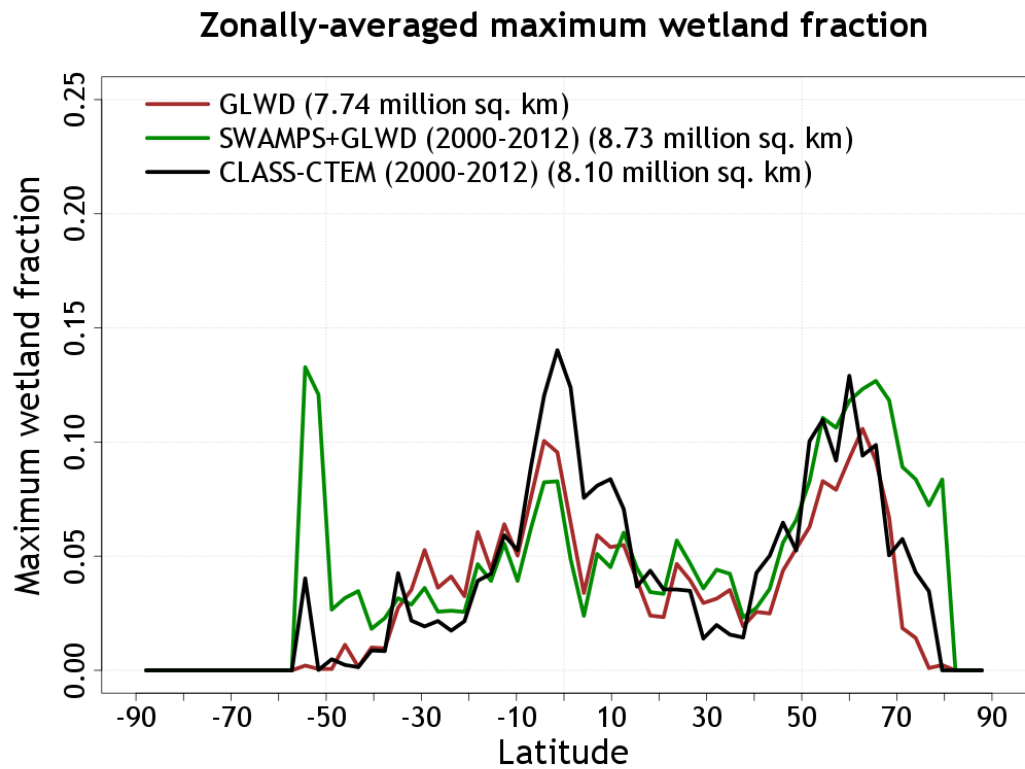

1495

1496 Figure 5: Time evolution of simulated natural methane fluxes (shown on the primary y-axis)
 1497 and annual maximum wetland extent (shown on the secondary y-axis) by CLASS-CTEM for
 1498 the 1851-2008 period for the case when wetland extent and methane emissions are not
 1499 allowed to respond to changing climate and increase atmospheric CO₂ over the historical
 1500 period (panel a). Panel (b) shows the simulated methane concentration over the historical
 1501 period, together with its observation-based values, when the natural fluxes shown in panel (a)
 1502 are used within the framework of the one box model of atmospheric methane.

1564

1565

1566 **Appendix A: Calculation of wetland extent**

1567

1568 The distribution of wetlands is based on a simple formulation which takes into account the
1569 topography in a grid cell and its simulated grid-averaged soil moisture content similar to
1570 Kaplan (2002). The ETOPO1 digital elevation data (Amante and Eakins, 2009) are used to
1571 calculate slopes at 1 arc minute (1/60th degree) resolution. Each 1 arc minute grid cell is
1572 assigned a slope that is the average of eight slopes based on its elevation and the elevation of
1573 its eight surrounding grid cells. The objective is to find what fraction of a grid cell, at some
1574 given resolution, has slopes flatter than a given slope threshold. Figure A1 displays the
1575 fraction of each 0.5 degree grid cell with slopes less than the threshold of 0.002 (i.e. 0.2%
1576 slope) calculated using 1 arc minute slopes, hereafter referred to as the “flat” fraction of a
1577 grid cell (f_s). The flat fraction of grid cell is also shown at the current operational 2.81°
1578 resolution of CanESM4.2, which is the spatial resolution we have used in this study. Figure 1
1579 shows that the approach is able to identify the flat regions of the world including the West
1580 Siberian and Hudson Bay lowlands, parts of northern Africa and in South America the
1581 Pantanal and the region bordering Argentina, Paraguay and Uruguay.

1582

1583 The flat fraction is the maximum fraction of a grid cell that can potentially become a wetland,
1584 if soils are sufficiently wet, and thus a source of CH₄ emissions. As the grid-averaged
1585 simulated soil wetness (w) of the top soil layer increases, above a given lower threshold (w_{low})
1586 in a grid cell, its wetland fraction (f_w) is assumed to increase linearly until some specified
1587 higher soil wetness threshold (w_{high}) up to a maximum value equal to the flat fraction (f_s) in a
1588 grid cell.

1589

$$f_w = \max\left(0, \min\left(f_s, \left(\frac{w-w_{low}}{w_{high}-w_{low}}\right) f_s\right)\right) \quad (A1)$$

1590

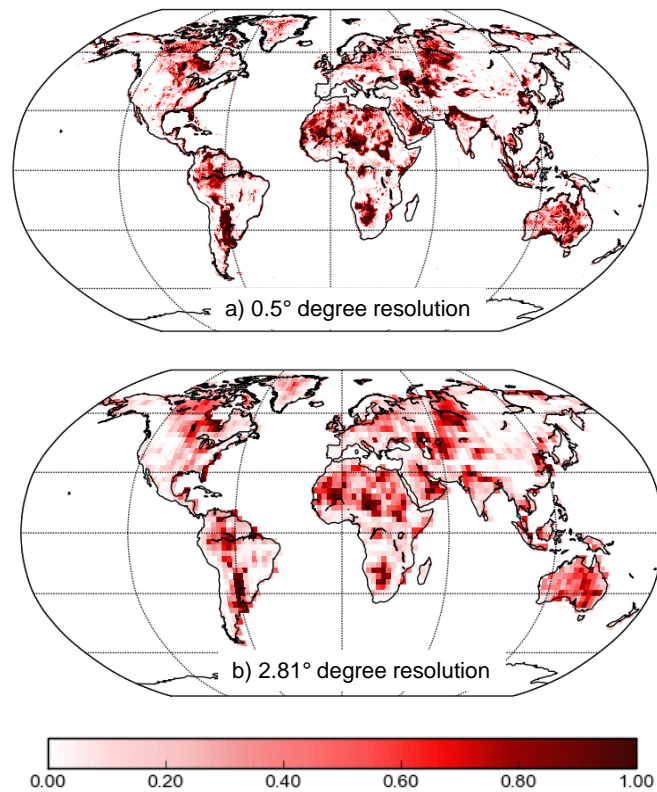

1591 Soil wetness ($w = \frac{\theta_l}{\theta_p}$) itself is defined as the ratio of volumetric liquid soil moisture content
1592 (θ_l) to the soil porosity (θ_p) for the top soil layer. The remaining fraction of the grid cell
1593 ($1 - f_w$) is considered as the upland fraction. As simulated liquid soil moisture in the top soil
1594 layer responds to changes in environmental conditions the dynamic wetlands expand and
1595 contract. The upper and lower soil wetness thresholds are summarized in Table A1 and
1596 adapted to yield realistic geographical and latitudinal distribution of wetland extent compared
1597 to observation-based estimates.

1598

1599

1600

Grid cell fraction with slope < 0.2% which can potentially become a wetland, climate permitting

1601

1602 Figure A1: Fraction of grid cell with slopes less than the threshold of 0.002 (i.e. 0.2% slope)
1603 at a) 0.5° and b) 2.81° spatial resolutions, respectively.

1604

1605 **Table A1:** The upper and lower soil wetness thresholds for three latitudinal bands used in
1606 equation (1) to determine fractional wetland coverage in a given grid cell.

1607

1608

	Latitudinal band		
	40°N to 90°N	35°S to 40°N	90°S to 35°S
w_{low}	0.45	0.55	0.70
w_{high}	0.90	0.99	0.99

1633 fire.

1634

1635

1636

1637

1638

1639 Figure C1: Time evolution of simulated net primary productivity (NPP) and heterotrophic
1640 respiration in the historical simulation both of which increase in response to increase in
1641 atmospheric CO₂ concentration. The thin lines show annual values while the thick lines
1642 represent their 10-year moving average. When fire CO₂ emissions are added to heterotrophic
1643 respiration the total amount is equal to NPP especially during 1850s as the case should be
1644 when the system is in equilibrium and net atmosphere-land CO₂ flux (equal to NPP –
1645 heterotrophic respiration – fire emissions) is near zero. Later in the 20th century and early 21st
1646 century, NPP is greater than the sum of heterotrophic respiration and fire CO₂ emissions,
1647 which creates the sink over land that is currently observed.

1648

1649

1650

1651

1652

1653

1654 Figure C2: Comparison of global area burned from the transient 1851-2015 historical
1655 simulation (dark yellow line). The thick dark yellow line is the 10-year moving average.
1656 Observation-based area burned (black line) are based on the GFED 4.1s data set. Model
1657 results are also compared to decadal charcoal index from version 3 of the Global Charcoal
1658 Database (purple line). Charcoal index is a proxy for burning and not for area burned per se
1659 and therefore only provides a qualitative measure.

1660
