16 **Abstract**

17

18 Forests are the main source of biomass production from solar energy and take up globally
19 around 2.4 ± 0.4 PgC per year. Future changes in climate may affect forest growth and
20 productivity. Currently, state-of-the-art Earth system models use prescribed wood harvest rates
21 in future climate projections. These rates are defined by integrated assessment models (IAMs)
22 only accounting for regional wood demand and largely ignoring the supply side from forests.
23 Therefore, we assess how global growth and harvest potentials of forests change when they are
24 allowed to respond to changes in environmental conditions. For this, we simulate wood harvest
25 rates oriented towards the actual rate of forest growth. Applying this growth-based harvest rule
26 (GB) in "JSBACH", the land component of the Max-Planck-Institute's Earth System Model,
27 forced by several future climate scenarios, we realized a growth potential twice to four times
28 ($3-9 \text{ PgCy}^{-1}$) the harvest rates prescribed by IAMs ($1-3 \text{ PgCy}^{-1}$). Limiting GB to managed forest
29 area (MF), we simulated a harvest potential of $3-7 \text{ PgCy}^{-1}$, two to three times higher than IAMs.
30 This highlights the need to account for the dependence of forest growth on climate. To account
31 for long term effects of wood harvest as integrated in IAMs, we added a life cycle analysis
32 showing that the higher supply with MF as an adaptive forest harvesting rule may improve the
33 net mitigation effects of forest harvest during the 21st century by sequestering carbon in
34 anthropogenic wood products.

39 1. Introduction

40 Forest ecosystems play a major role in taking up global CO₂ emissions and affect global climate
41 conditions through a range of complex biophysical and biogeochemical processes. Forests are
42 the main source of biomass production from solar energy through photosynthesis and are
43 estimated to take up globally around $2.4 \pm 0.4 \text{ PgCy}^{-1}$ (Pan et al., 2011). A large part of this
44 uptake can be attributed to direct and indirect human interference: Direct human impact by
45 forest management creates young forests sequestering carbon during regrowth (Houghton et al.,
46 2012), and provides material for fossil-fuel substitution (Nabuurs et al., 2007). However, forest
47 utilization and interaction of management with large-scale natural disturbances, such as forest
48 fires, may emit tonnes of CO₂ immediately to the atmosphere and act as a source of CO₂
49 emissions (Bonan, 2008). Indirect human impact alters environmental conditions, in particular
50 climate and atmospheric CO₂ concentrations, which historically has caused a carbon uptake by
51 the terrestrial vegetation (Le Quéré et al., 2018). Any change in environmental conditions
52 affects forest growth, risks of hazards, and productivity and, consequently, the amount of wood
53 that can be harvested (Temperli et al., 2012; Sohngen and Tian, 2016).

54 The effects of changes in environmental conditions on the state of the biosphere are represented
55 in state-of-the-art Earth system models (ESMs). However, the description of forest management
56 in these models is largely independent of environmental changes: So far, ESMs employ
57 prescribed wood harvest amounts. These are derived from national statistics for the historical
58 period and from global integrated assessment models (IAMs) for future scenarios. IAMs
59 determine the wood harvest rates based on the supply of woody materials from vegetation and
60 demands of regional industries and population (van Vuuren et al., 2011). However, changes in
61 the supply via forest growth and changed structural conditions especially under climate change
62 and increasing CO₂ concentrations are ignored. The main drivers of these models are economic,
63 i.e. market price, and population growth scenarios and forest harvest decisions are only reactive

64 to the assumed socioeconomic scenarios and do not take forest ecosystem dynamics and growth
65 into account.

66 In this study we investigate the relevance of changes in environmental conditions for the growth
67 potential of forests and subsequently their harvest potentials. Moreover, we explore the
68 ecological potential of world forest resources for wood production and the implications for
69 carbon mitigation. To assess growth and harvest potentials, we investigate forest growth under
70 various future climate scenarios. We allow forests to be harvested and to regrow in response to
71 the respective changes in environmental conditions, in all scenarios such that the growth
72 increment is removed each year, i.e. the biomass stocks are neither reduced nor increased. We
73 call this “growth-based” harvesting (GB). Removing the annual increment mirrors the forest
74 management concept of “sustained yield”. Managing for sustained yield is a strong
75 sustainability policy applied in sustainable forest management, which aims to maintain forest
76 stocks as natural capital and controls wood extraction (Luckert and Williamson, 2005).
77 According to the sustained yield concept, the maximum wood harvest rate to utilize forest
78 resources equals the actual rate of forest growth. Exceeding regrowth rates would result in the
79 exploitation of forest ecosystems and would decrease forest yield and productivity. On the other
80 hand, minimalistic usage, i.e. falling below regrowth rates, would not be an optimal allocation
81 of forest resources from the perspective of production. However, the traditional concept of
82 sustained yield management, as defined above, does not account for changes in the growth rates
83 (Luckert und Williamson, 2005), although forest growth rates are highly dependent on the
84 environmental conditions (Collins et al., 2018). It has been noted before that any decision about
85 forest management should take into account the effects of changes in climate and CO₂
86 concentrations on forest growth (Yousefpoor et al., 2012; Hickler et al., 2015; Sohngen and
87 Tian, 2016; Sohngen et al., 2016) and consequently on the harvest rate (Temperli et al., 2012;
88 Jönsson et al., 2015). Here we demonstrate how altered growth potentials translate into higher
89 harvest potentials under an adaptive growth-based harvest. We first idealize the concept for this

90 study in that GB is applied world-wide irrespective of the accessibility of the forest for forest
91 management activities, but allowing for dependence of wood harvest on altered climate
92 conditions and CO₂ concentrations. In a second, post-processing, step we link these results to
93 actual harvest potentials by overlaying information on the accessibility of forest areas, where
94 accessibility refers to any hindrance to use the forest, be it due to conservation or biodiversity
95 aspects, restricted accessibility due to distance from transport ways or topographical obstacles.
96 For this step we overlay the map of managed forest area by Kraxner et al. (2017). Kraxner et
97 al. (2017) used FAO definition for primary forest and as naturally regenerated forest of native
98 species, where there are no clearly visible indications of human activities and the ecological
99 processes are not significantly disturbed. Using a map of today's managed forest as proxy for
100 accessibility in the future must be seen as a conservative approach, as technological means to
101 access forests are generally increasing over time.

102 Keeping in mind the above-mentioned problem of not accounting for changing environmental
103 conditions in global forest utilization modelling, the goal of this study is to establish a modeling
104 framework that allows harvesting rates to respond interactively to environmental changes. We
105 further assess the maximum potential of global forest resources for wood production and the
106 long-term CO₂ mitigation effects of wood harvest, which are implicitly (defining future wood
107 harvest rate based on RCPs' storyline for mitigation) or explicitly (e.g. using wood for
108 bioenergy production) the drivers of forest utilization in IAMs. We compare the outcome of the
109 growth-based harvest with the outcome when applying prescribed wood harvest amounts from
110 three different Representative Concentration Pathways (RCPs) realized by IAMs and
111 commonly used by ESMs as an external forcing (Hurtt et al., 2011). Since harvested material
112 is used in the IAMs to estimate the amount of bioenergy wood, which in turn is needed in the
113 IAMs to analyze energy and carbon mitigation policies, we perform a first-order assessment of
114 the CO₂ consequences of altering the harvest rates in response to climate. Similarly and to

115 determine the mitigation potential by wood products we allocate the harvested material to
116 products of different lifetimes according to FAO country-specific statistics (FAOSTAT, 2016).
117 The change in atmospheric carbon content resulting from the release of CO₂ by the decay of
118 these products is quantified accounting for compensating fluxes by the ocean and the terrestrial
119 vegetation (Maier-Reimer and Hasselmann, 1987). This impulse response function approach
120 approximates the uptake of emissions by natural sinks in land/ocean, independent of the source,
121 and is a common tool to estimate the fraction of emissions held by the atmosphere over time
122 after the emission occurred (e.g. O'Halloran et al., 2012; Pongratz et al., 2011).

123 The net mitigation effect of wood harvest is then defined as the difference between the total
124 amount of harvested material and the change in atmospheric carbon content.

125 2. Materials and methods

126 2.1. Dynamic global vegetation model JSBACH

127 We implemented the GB harvesting rule in JSBACH, the land component of the MPI-ESM
128 (Reick et al., 2013). In the applied version of JSBACH vegetation is represented by 12 plant
129 functional types (PFTs) including six woody PFTs. Each PFT is globally endowed with
130 properties in relation to integrated processes in JSBACH and PFT-specific phenology, albedo,
131 morphology, and photosynthetic parameters (Pongratz et al., 2009). Organic carbon is stored in
132 three vegetation pools: living tissue as “green”, woody material as “wood”, sugar and starches
133 as “reserve pool”, and two soil pools with a fast (about 1 year) and a slow (about 100 years)
134 turnover time (Raddatz et al., 2007). Wood harvest activities do not change the area or
135 characteristics of different PFTs, but affect the carbon pools of woody PFTs (forests and shrubs)
136 by removing carbon from the wood pool, resembling trees' stem and branches removal via
137 harvesting (Reick et al., 2013). Harvest thus affects the vegetation carbon stocks, but the model
138 does not represent a feedback of the harvest activity on the forest productivity.

139 We applied JSBACH in ‘offline’ mode, i.e. not coupled to the atmosphere, but driven by the
140 CMIP5 output of the MPI-ESM (Giorgetta et al., 2013) from experiments with CO₂ forcing
141 according to three different RCP scenarios (RCP2.6, RCP4.5 and RCP8.5) for the year 2006-
142 2100. We used a T63/1.9° horizontal resolution and conducted our simulations with
143 disturbances due to fire and wind. The simulations were conducted without dynamic vegetation
144 and without land-use transitions to prevent changes in the areas occupied by the different PFTs
145 and to be thus able to isolate the effects of forest management activities. Further details on the
146 model version and the simulation setup are given in the supplementary material (S1).

147 2.2.RCPs wood harvest

148 The current standard module for anthropogenic land cover and land-use change in JSBACH is
149 based on the harmonized land-use protocol (Reick et al., 2013), which provides land-use
150 scenarios for the period 1500-2100 (Hurtt et al., 2011). As part of this protocol, a set of globally
151 gridded harvest maps from the IAM implementations of the RCPs is provided (Hurtt et al.,
152 2011). The prescribed wood harvest rate maps are defined to meet regional timber and
153 bioenergy demand driven by the increasing population (as the model MESSAGE simulates for
154 RCP8.5, Riahi et al., 2011), assumptions about population and labor productivity (Model
155 GCAM for RCP4.5, Brenkert et al., 2003), or demand, trade and supply of agricultural products
156 and wood based bio-energy (model IMAGE for RCP2.6, van Vuuren et al., 2011). The RCP
157 wood harvest rates are all based on the demand for wood and bioenergy as the main driver of
158 decisions by IAMs on forest harvest, neglecting changing availability of forest resources under
159 environmental changes. For example, RCP8.5 applies the forest sector model DIMA (Riahi et
160 al., 2011), which is a spatial model for simulating forestry processes to meet specific regional
161 demand on wood and bioenergy. RCP4.5 bases wood harvest rates solely on the price of carbon
162 affected by emissions and mitigation potentials of forestry and agricultural activities (Hurtt et
163 al., 2011). Finally, RCP2.6 relies on the forecasted demand on timber and fuelwood from forest
164 resources and applies a series of forest management rules (plantation, clear cutting, selective

165 logging) to meet this demand as the only driver of wood harvest rate in the IMAGE model
166 (Stehfest et al., 2014). In JSBACH simulations, the harvest prescribed in these maps is fulfilled
167 taking above-ground carbon of all vegetation pools and all PFTs proportionally to the different
168 pool sizes. In this study, however, we concentrate on the carbon harvested from the wood pool
169 of the woody PFTs, which by far contributes most of the harvested volume.

170 2.3. Growth-based (GB) harvesting rule to estimate growth potentials

171 As an alternative for the prescribed harvest maps, we implemented the GB harvesting rule,
172 which allows for adaptive wood harvesting reacting to changes in wood increments, and
173 accordingly dependent on climate and CO₂ conditions. We define the GB rule as the allowance
174 to harvest specific volumes of wood to the extent of the average increment (i.e. the average
175 annual growth). Applying GB, we aim to stabilize the wood carbon pool in the woody PFTs at
176 the level of a selected reference period. In the current paper we selected the maximum level for
177 the present period (1996-2005) simulated with JSBACH (see S1). Using a reference level
178 determined from the last ten years of the historical simulation allows us to keep the standing
179 wood on the present level and to account for the dependence of forest growing stocks (carbon
180 pools) to disturbances, silvicultural interventions and varying environmental conditions. Under
181 the GB harvesting rule, the wood harvest is only allowed to reduce the wood carbon pool down
182 to the reference level. Aside from environmentally driven decreases, the wood carbon pool thus
183 nearly remains constant over the whole simulation time.

184

185 2.4. Simulation runs with JSBACH

186 We conducted six simulations (Table 1) from 2006-2100, all starting from the same initial state
187 (see S1). The simulations differ in the applied harvest rule and in their climate and CO₂ forcing.
188 While the different RCP harvest maps were applied in simulations with the corresponding MPI-

189 ESM RCP forcing, each MPI-ESM RCP forcing was additionally run applying the GB
190 harvesting rule.

191 **Table 1**

192 2.5. Growth-based harvesting restricted to managed forests (MF)

193 To infer from the growth potentials simulated under GB how much biomass could potentially
194 be harvested (harvest potentials), we conduct a post-processing step overlaying a map that
195 masks out forest areas subject to conservation, infrastructural limits, or not being influenced by
196 human activities so far due to other reasons (Kraxner et al., 2017). Applying nearest neighbor
197 interpolation on the 1 km² spatially explicit map of primary forest intensity (0%-100%; Fig. 6
198 in Kraxner et al., 2017) we derived a T63 map of primary forest area. This static map was used
199 to filter the growth-based harvest determined in the GB simulations for 2006 to 2100, to only
200 account for managed forests (MF) in the mitigation assessment.

201 2.6. Analysis of wood harvest impacts on forest disturbances and natural mortality

202 To analyze the mechanisms driving differences in GB and RCP wood harvest amounts we can
203 formulate changes in above-ground wood carbon stocks over time (dC_w/dt) as carbon gains
204 from net primary production allocated to the wood pools (NPP_w) minus losses due to natural
205 disturbances and anthropogenic management (i.e., wood harvest, h):

$$206 \quad \frac{dC_w}{dt} = NPP_w - \frac{C_w}{\tau} - h \quad (1)$$

207 In this conceptual formulation, the loss due to natural disturbances depends on the size of the
208 carbon stock and a time constant (τ). As net primary production in our model does not depend
209 on harvest, GB growth potentials (p_{GB}) and RCP harvest can be related as

$$210 \quad p_{GB} = h_{RCP} + \left(\frac{C_{wRCP}}{\tau_{RCP}} - \frac{C_{wGB}}{\tau_{GB}} \right) + \left(\frac{dC_{wRCP}}{dt} - \frac{dC_{wGB}}{dt} \right) \quad (2)$$

211 The amount of growth potential under GB can thus be split into several terms: The first term is
212 the reference harvest rate of the RCPs. The second term accounts for the difference in loss due
213 to natural disturbances in the RCP and the GB simulation. In JSBACH this can further be split
214 into differences in losses due to background mortality, such as self-thinning of forests, due to
215 fire, and due to windbreak. JSBACH explicitly integrates two modules for the simulation of
216 fire and wind disturbances depending on climate and carbon pools. The third term accounts for
217 the changes in the above-ground wood pool realized over time in the simulations. As shown
218 below, the RCP harvest results in an increase of above-ground woody biomass over the 21st
219 century for all three scenarios. For GB, on the other hand, dC_{WGB}/dt should theoretically be
220 close to zero over time as GB aims to sustain the above-ground carbon pools of woody PFTs;
221 however, reductions in NPP due to less favorable climatic conditions or increased disturbances
222 can entail negative dC_{WGB}/dt . To summarize, GB includes the RCP wood harvest and,
223 moreover, makes use of additionally accumulated carbon and eventually reduced mortalities to
224 adapt harvest decisions to the novel climate and forest growing conditions.

225 2.7. Accounting for the mitigation potential of forest management in the Earth system

226 We account for long term effects of wood harvest, as in IAMs, by approaching a life cycle
227 analysis. Many wood products have lifetimes of decades to centuries. Here, we assess the effect
228 on atmospheric carbon content when harvested carbon is transferred, at least to a part, to longer-
229 lived product pools, instead of entering the atmosphere immediately. We compare this
230 “mitigation effect” achievable by the wood products harvested under the GB concept after the
231 map of managed forest area is overlaid (MF) to those achievable according to the three RCP
232 harvest maps. To this end, we distinguish three anthropogenic wood product pools -- bioenergy,
233 paper, and construction -- with 1, 10, and 100 year life times, respectively, as are typically
234 assumed in global modeling studies (Houghton et al., 1983; McGuire et al., 2001).

235 To allocate the wood biomass harvested in our JSBACH simulations to different product pools,
 236 we made use of FAO country-specific statistics reporting wood production in fourteen different
 237 categories (FAOSTAT, 2016). For our analysis, we assume that the production technology and
 238 allocated percentage of each country's total wood production to these fourteen categories
 239 remains constant at 2005 levels over the 21st century and used these percentages to allocate
 240 wood biomass harvest from JSBACH (remapped to countries - see a calculus example in
 241 supplementary material S2). The fourteen categories are then assigned to the three distinguished
 242 anthropogenic wood product pools. We assume that the harvested material entering one of these
 243 three product pools in a year decays at a rate of 1/lifetime, i.e. that all material used for
 244 bioenergy is respired to the atmosphere within the same year it is harvested, while the material
 245 entering the paper and construction pool is emitted at a constant rate over the following 10 or
 246 100 years, respectively. The emissions at a given year for paper and construction pools are
 247 therefore composed of a fraction of that year's harvest, but also of the legacy of material
 248 harvested earlier, yielding annual emissions E from all three product pools as follows:

$$249 \quad E(t) = f_b h(t) + \sum_{s=t-9}^t \frac{1}{10} f_p h(s) + \sum_{s=t-99}^t \frac{1}{100} f_c h(s) \quad (1)$$

250 Here, f for bioenergy (b), paper (p), and construction wood (c) are the fractions with which the
 251 harvested biomass is assigned to the product pools (see S2). We call E “emissions from product
 252 decay” in the following.

253 To account for the fact that the emissions from product decay leave the atmosphere over time
 254 to be taken up by the terrestrial biosphere and the ocean, we apply the response function (Eq.
 255 2) by Maier-Reimer and Hasselmann (1987). Convolution of this response function with the
 256 time series of annual emissions from product decay until year t results in the change in
 257 atmospheric carbon content in that year, C(t) (Eq. 3).

258

$$259 \quad G(t) = A_0 + \sum_{p=1}^4 A_p \exp^{-t/\tau_p} \quad (2)$$

260 $C(t) = \int_0^t G(t-s) \cdot E(s) ds$ (3)

261

262 Emissions are present in the atmosphere as they occur and, therefore, $G(0) = 1$ and $A_0 = 1 -$
263 $\sum_p A_p$. The constants A_p and the time constants τ_p are fitted for $p > 0$ using one of the best fits
264 found by Maier-Reimer und Hasselmann (1987): the sum of four exponential terms with time
265 constants τ_1, τ_2, τ_3 and τ_4 of approximately 1.9, 17.3, 73.6, and 362.9 years, and constants $a_1,$
266 a_2, a_3 and a_4 of 0.098, 0.249, 0.321, and 0.201. Accordingly, Equation 2 is an exponential
267 function that accounts for the uptake of CO₂ by ocean and land over time and Eq. (3) integrates
268 the accumulated amount of total CO₂ concentrations in the atmosphere at each time step
269 regarding past and present emissions. The mitigation effect of wood products is then determined
270 as the difference between the harvested material and the change in atmospheric carbon content.

271 3. Results

272 3.1. Comparison of GB and RCP harvesting

273 Above-ground woody biomass is simulated to increase by the end of the 21st century for the
274 RCP wood harvest (Figure 1a), despite an increase of the amounts of wood harvest (Figure 1b).
275 This implies that the changes in environmental conditions lead to a larger accumulation of
276 woody biomass than is removed by the increased harvest. Depending on the RCP, the simulated
277 increase in above-ground woody biomass may reach 133% (425 PgC in 2100) of the initial
278 level in 2005 (320 PgC) for RCP8.5 and substantially higher levels of 128% and 117% for
279 RCP4.5 and RCP2.6, respectively (Figure 1a). The temporal pattern of this increase, with strong
280 increase only in the first half of the century for RCP2.6 or throughout the century for RCP8.5,
281 reflects the projected evolution of changes in CO₂ and climate (Collins et al., 2018).

282 For the GB rule, woody biomass remains more or less constant over time (Figure 1a), as the
283 average annual increment is removed by harvest by definition of the GB rule (see Methods).

284 Consequently, the growth potential of global forest resources under GB is simulated to be as
285 high as 9 PgCy⁻¹ at the end of the century subject to the realization of RCP8.5 climatic
286 conditions, or about 4 to 6 PgCy⁻¹ for the other two scenarios (Figure 1b). About two thirds of
287 the growth potential lie in managed forest areas and are thus potentially harvestable (Figure 1b,
288 MF-harvest curves). The MF harvest potentials are thus twice to three times (3-7 PgCy⁻¹) as
289 high as those of prescribed wood harvest simulated by IAMs for the RCPs. Note that, as
290 described in the methods, managed forest areas refer to the present-day state and may expand
291 in the future, which would further increase the harvest potential. These figures are harvestable
292 wood biomass amount and differ from commercially useable timber including bioenergy, paper,
293 and construction woody biomass (see 2.7 and 3.3).

294 We map the geographical distribution of RCP harvest as well as growth and harvest potential
295 under the GB harvesting rule applied to all global forest (GB) and managed forest areas (MF)
296 to recognize regional hotspots (Figure 2). Central Latin America including the accessible parts
297 of the Amazon forests, large parts of North America, the accessible parts of central Africa,
298 eastern Asia and Europe including Russia can be recognized under all climate scenarios as
299 hotspots for allocation of simulated harvest activities. The large harvest potentials of the supply-
300 based harvest in the tropics contrast with the patterns of the demand-based RCP harvest; in
301 particular in RCP2.6 and RCP4.5 much of the global harvest is provided from eastern North
302 America, central Europe and East Asia. A reasonable proportion of GB harvest amount in the
303 tropics is masked out in MF as inaccessible forest area; nevertheless the tropics contribute a
304 large harvest potential from wood supply side in both GB and MF.

305 **Figure 1**

306 **Figure 2**

307 3.2.Separation of the processes underlying the growth potentials under future climate
308 scenarios

309 The harvest potential under the GB harvesting rule in JSBACH exceeds RCPs wood harvest
310 defined by IAMs not only because of taking into account changes in growth rates caused by
311 changed environmental conditions, but also due to avoided mortality and disturbances (see
312 methods section). Figure 3 shows the separation of the growth potential underlying the GB
313 harvest into changes in standing wood as compared to RCP harvest, avoided background
314 mortality, natural fire, and wind disturbances, and the amount prescribed originally by RCPs.
315 The largest contribution to the growth potential under the GB harvesting rules exceeding the
316 RCP harvest is the lower background mortality, which is directly related to lower accumulation
317 of woody biomass (see Figure 1a). This lower accumulation also leads to the decreased carbon
318 losses from fire and wind disturbances. Depending on the climate scenario (RCPs) the simulated
319 reduction of mortality and disturbances add up to 2-5 PgCy⁻¹ at the end of the century. Under
320 the RCP harvest, woody biomass is simulated to mostly increase beyond what is required by
321 the increasing harvest rates (see Figure 1). Harvesting this “surplus”, i.e. the increase of
322 standing biomass over time by applying RCP harvest rates and harvesting less biomass than the
323 annual increment provides, also contributes to the larger growth potentials under the GB
324 harvesting rule. The temporal evolution is different from that of avoided mortality and
325 disturbances, reflecting the projected changes in CO₂ and climate. Greater fluctuation of the
326 growth potential compared to the RCPs’ annual wood harvest amounts is because of the direct
327 dependency of the forest’s productivity on climate fluctuations.

328 **Figure 3**

329 3.3.Mitigation potential of GB versus RCP wood harvest

330 We show the mitigation potential of forest resources in the 21st century under growth-based
331 harvesting of global forest (GB) and managed forest (MF) areas versus the RCP wood harvest

332 prescribed from IAMs in Figure 4. Due to the larger harvested amounts, the mitigation potential
333 is higher for GB and MF compared to RCP harvest and the magnitude depends on the
334 underlying climate scenario. The advantage of growth-based harvesting lies in storing a larger
335 amount of carbon in wood products whilst keeping above-ground woody carbon pools constant.
336 These aspects are largely ignored by IAMs. Table 2 below shows the net mitigation potentials
337 of world forest resources (GB and MF against RCP harvest) by wood harvest at the middle and
338 end of the 21st century (2050 and 2100). The highest mitigation effect is achieved in the GB8.5
339 scenario with 140.6 PgC and 379.1 PgC up to 2050 and 2100, respectively. These figures
340 account for 278% and 287% more global carbon storage than in the RCP8.5 scenario with
341 prescribed RCP wood harvest with 50.6 and 132.1 PgC mitigation up to 2050 and 2100,
342 respectively. Only considering current managed forests, the mitigation effect realized for MF8.5
343 still reaches a maximum mitigation potential of 109.3 and 295.8 PgC up to 2050 and 2100,
344 respectively.

345 **Table 2**

346 **Figure 4**

347 4. Discussion

348 RCPs define wood harvest in each region according to scenarios realized by IAMs about social
349 and economic developments in the 21st century, but independent of ecological capacities of
350 forest ecosystems (van Vuuren et al., 2011; Riahi et al., 2011; Hurtt et al., 2011; Stehfest et al.,
351 2014). Although the growth-based harvesting rule realizes potentially a larger wood harvest
352 amount than the RCPs, it remains as per definition a sustained-yield forest harvesting approach
353 and guarantees sustainability of the current ecological conditions at each region with respect to
354 standing biomass. However, as a consequence, regions with low standing biomass, for example
355 due to extensive historical harvest, will maintain these low biomass levels. Below we discuss
356 the effectivity of GB in adapting to new environmental conditions and the mitigation potential

357 and highlight the missing issues in our simulation analysis, especially about the provisioning of
358 multiple goods and services (e.g. biodiversity, forest health), and the future research themes
359 about integration of diversified management strategies in ESMs.

360 Accounting for the climate state in simulating future forest harvest is crucial (Temperli et al.,
361 2012; Sohngen and Tian, 2016). Accordingly, the novelty of the applied GB in this study is the
362 dynamic nature of this management approach based on the ecology of forest ecosystems and
363 climatic and atmospheric conditions. According to Schelhaas et al. (2010), an accelerated level
364 of wood harvest to reduce the vulnerability of European old forests to wind and fire disturbances
365 is needed to stop the current built-up of growing stock. Applying GB in this study realized an
366 increased wood harvest rate for European forests (see Figure 2) showing first signs of carbon
367 sink saturation and high vulnerability to natural disturbances (Nabuurs and Maseret, 2013).
368 Global studies of this nature are largely missing due to the lack of data and forest ecosystems
369 complexity on global scale. Our idealized simulations suggest that GB does not only effectively
370 safeguard sustainability of the current forest biomass on the global scale, but also positively
371 affects the resistance of forest resources against natural disturbances and efficiently utilizes
372 forest growth and productivity potentials (see Figure 3). Our estimates are, of course, sensitive
373 to the choice of reference level: In this study, we applied the maximum current (1996-2005)
374 above-ground wood biomass as the reference level. Any changes in this reference may affect
375 the realized harvest potentials and should be carefully defined regarding ecological potentials
376 and economic implications.

377 In our simulations, future environmental changes are mostly beneficial for accumulation of
378 forest biomass, apparent from increasing standing biomass in the RCP harvest scenarios or the
379 increase of GB and MF harvest rates over the 21st century. This is in line with other studies
380 projecting above-ground forest carbon storage to increase in the future (e.g. Tian et al., 2016).
381 These effects of environmental changes on forest growth are largely missing in the IAMs

382 providing the wood harvest scenarios to dynamic global vegetation models (DGVMs) and
383 ESMs (see our description of IAMs in Sec. 2.2). IAMs do not account for the fact that the
384 demand side may also be influenced by the availability of the resource and, accordingly, the
385 increased biomass stocks projected for the future would likely lead to larger wood harvest rates
386 than IAMs simulate by assuming present-day growth conditions. The extent to which
387 accounting for environmental changes may influence estimates of harvestable material (e.g.
388 apparent from comparisons of GB and MF harvest potentials under RCP2.6 as compared to
389 RCP8.5, see Figure 1) highlights the need to include these effects in models, such as IAMs, that
390 estimate future wood harvest. Our study is limited to considering biomass growth, albeit in
391 interaction with soil conditions also responding to the altered climate. In reality, harvest
392 decisions would consider further variables that depend on environmental conditions, such as
393 the maximum soil expectation value, which are not explicitly simulated neither in our model
394 nor in IAMs.

395 Note that the estimates of GB wood harvest as provided by our model are not meant as plausible
396 estimates of actual future harvest, which as described before depends not just on resource
397 availability and accessibility of areas, but is demand driven by other economic and political
398 considerations. Limiting GB to available managed forest area, MF realized less harvest
399 potential than GB, however, still a larger amount than RCP and with a higher mitigation
400 potential (see Table 2). Also, actual future harvest will interact with other land-use decisions
401 such as changes in forest cover due to agricultural expansion, but also afforestation. We have
402 further not accounted for the effects of wood harvest on biodiversity, forest health, and other
403 ecosystem services. Chaudhary et al. (2015) state that the effect of forest management on the
404 species richness, for example, highly depends on the management regime applied. They refer
405 to literature reporting a positive effect of logging activities on species richness as a result of
406 establishing early successional colonizers. Additionally, applying selective logging approaches
407 (e.g. future crop trees of targeted species) for forest management may enhance forest recovery

408 and reduce unintended changes in species composition (Luciana de Avila et al., 2017). Instead
409 of actual forest harvest that considers all these aspects in its decision-making, our study
410 provides an estimate of the ecological potentials for wood harvest. However, the change in
411 resource potentials with climate change forms the ecological basis for realistic decision-making.

412 There is uncertainty in simulating ecosystem response to environmental changes. Regional
413 forest inventories show an increase in biomass due to historical environmental changes
414 (excluding effects of land-use change) (Pan et al., 2011). The largest sinks are found by these
415 studies to be in the tropical regions, coinciding with our simulated regions of largest potentials
416 for additional wood harvest. Also the other regions showing larger potential for wood harvest
417 under GB and MF than RCP, such as North America, Europe, Russia and East Asia, currently
418 exhibit carbon uptake due to historical environmental changes. This gives some confidence in
419 the robustness of our results, in particular since most models project the carbon sink in
420 vegetation to continue for the future; however, its magnitude is uncertain (Sitch et al., 2008). A
421 large source of uncertainty is the strength of the CO₂-fertilization effect (Kauwe et al., 2013;
422 Hickler et al., 2015;), which reflects in a large spread across models in estimates of global total
423 (vegetation plus soil) terrestrial carbon stocks (Arora et al., 2013) and of vegetation productivity
424 (Zaehle et al., 2014). To better assess these effects, we additionally simulated the future GB
425 and MF harvest potentials under present-day climate and CO₂ conditions (see simulations of
426 GBpd and MFpd in the supplementary material (S1)). These simulations led to a wood harvest
427 potential larger than that with RCPs harvest rates and rather constant harvest over time (~3.2
428 and 2.7 PgC annually for GBpd and MFpd, respectively, see S1-Figure 1). The harvest amount
429 of GBpd is equal to RCP8.5 harvest amount at the end of the century in our simulations.

430 Differences between GBpd and MFpd and the simulations forced by the different RCPs as well
431 as differences among the latter illustrate the effects of changes in climate and CO₂ concentration
432 on forest growth and resulting harvest potentials. The differences in wood harvest amounts
433 between the harvest simulations based on GB and MF and those with prescribed RCP wood

434 harvest rates in the first simulation year show differences of applying the supply-based harvest
435 rule (GB and MF) versus the demand-based RCPs under current environmental conditions. The
436 geographic allocation of growth and harvest potentials for GBpd and MFpd (see S1-Figure 2)
437 resembles those under RCPs, however, with higher global values. That the GBpd and MFpd
438 harvest potential are higher than the RCP harvest implies that the larger potentials as compared
439 to RCP harvest are partly attributable to the harvest simulated by IAMs not using the full
440 sustained, ecological potential (e.g. due to real-world demand). However, the harvest potentials
441 under RCP climate all grow substantially larger than the harvest potential under present-day
442 climate. This depicts the isolated effect of environmental changes, particularly CO₂ fertilization,
443 on the simulated potential harvest.

444

445 A further uncertainty in the model we used is that our model did not explicitly account for a
446 nitrogen cycle. Nitrogen may become a limiting factor for the additional uptake of carbon in
447 vegetation, although future climate change might also lead to higher nutrient availability due to
448 faster decomposition rates (Friedlingstein and Prentice, 2010). Further, nitrogen deposition may
449 reduce nitrogen limitation (Churkina et al., 2010), and it is not predictable if artificial
450 fertilization of managed forests may find wide-spread application in the future. Overall,
451 therefore, quantifications of effects of future climate change on global carbon stocks derived
452 from individual models have to be treated with care. Our model includes present-day nitrogen
453 limitation implicitly by choice of photosynthetic parameters and includes structural limits
454 prohibiting development of wood densities beyond observational values. Tests with a similar
455 model version as ours but representing an explicit nitrogen cycle suggest a rather small
456 sensitivity of the land carbon cycle to nitrogen limitation under CO₂ increases and climate
457 changes in the range of the RCP scenarios investigated here (Goll et al., 2017). The increase in
458 gross primary production (GPP) over the industrial era of our model (or similar versions) lie at
459 the high end, but within the range of a wide range of other models (Anav et al., 2013); recent

460 evidence from long-term atmospheric carbonyl sulfide (COS) records shows that models with
461 high GPP growth are most consistent with observations (Campbell et al., 2017). The location
462 of the largest potentials of GB and partly MF harvest simulated in our study being in the tropical
463 forests is consistent with the large carbon sinks derived from inventories for past environmental
464 change (Pan et al., 2011).

465 GB harvest was simulated to mitigate 255-380 PgC, depending on the realized RCP, through
466 wood product usage for the period 2006-2100 from global forest resources. Moreover, it
467 accounted for sustaining the above-ground wood carbon pool at the reference level of 1996-
468 2005. A comprehensive mitigation study, however, should take into account the total carbon
469 balance of forest ecosystems including soil plus litter carbon. Growth enhanced by
470 environmental changes, as simulated to lead to accumulation of woody biomass in the RCP
471 harvest simulations (Fig. 1a), may lead to larger input to the soil (if not removed by wood
472 harvest). However, soil carbon pools respond differently to environmental changes than forest
473 biomass. In particular, soil carbon models generally assume enhanced soil respiration under
474 higher temperatures (Friedlingstein et al., 2006), which may substantially offset the additional
475 carbon uptake by the vegetation (Ciais et al., 2013). As these processes act the same in our
476 simulations of GB, MF and RCP harvesting rules (as they share the same climate scenarios),
477 effects of environmental changes on soil carbon will likely not substantially affect our
478 comparison of GB, MF and RCP harvest in relative terms, but may alter the net carbon balance
479 in each of them. Further, the usage of wood products implies removal of carbon off-field. This
480 can lead to depletion of soil plus litter carbon stocks. Observational data generally found small
481 decreases of soil carbon, but substantial reduction of deadwood material (Erb et al., 2017). Such
482 effects must be expected to be stronger for GB and MF harvest with its larger harvested biomass
483 than for RCP harvest, reducing on-site carbon stocks, but consequently also soil respiration.
484 Estimating a mitigation potential based on the net carbon balance of vegetation, soil plus litter
485 and product pools therefore would depend on the actual size of soil and vegetation carbon pools

486 and the lifetimes of products relative to the lifetimes of the on-site carbon, which are further
487 subject to a changing climate. There is not a unique life time for anthropogenic wood products
488 pools in the literature. Lifetime of construction wood, for example, spanning from 67 years in
489 Härtl et al. (2017), up to 160-200 years in van Kooten et al. (2007) are applied in recent studies.
490 Regarding global variation of carbon turnover rate, Carvalhais et al. (2013) find mean turnover
491 times of 15 and 255 years for carbon residing in vegetation and soil near to Equator and higher
492 Latitude over 75°, respectively. Regarding the uncertainty about life time of anthropogenic
493 wood pools, we stay consistent with the applied figures in FAO statistics (FAOSTAT, 2016)
494 and other land carbon budget studies (Houghton et al., 1983; McGuire et al., 2001).
495 Despite carbon fluxes being the focus of land-use change as mitigation tool (e.g., UNFCC,
496 2012), forest management may enhance or mitigate climate change by a range of other
497 mechanisms such as a change in surface albedo (e.g., Rautiainen et al., 2011; Otto et al., 2014)
498 or turbulent heat fluxes (e.g., Miller et al., 2011). Such biogeophysical effects needed to be
499 accounted for in a complete assessment of the mitigation potentials, as has been done for global
500 land cover change (Pongratz et al., 2011) or for forest management on local (Bright et al., 2011)
501 or regional scale (Naudts et al., 2016). These biogeophysical effects are particularly important
502 for the local climate (Winckler et al., 2017). In our study, we restrict estimates of mitigation
503 potential to carbon fluxes only and thus focus on the perspective of mitigating global
504 greenhouse gas concentrations. This further allows for a direct comparison of the wood harvest
505 scenarios provided as part of the RCPs.

506 Different from economic models, ESMs do not consider costs associated with early mitigation
507 measures and thereby implicitly assume a zero social discount rate, meaning that there is no
508 preference for immediate mitigation. However, the discount rate plays a major role to find
509 economically the most efficient mitigation action (Stern, 2007). van Kooten et al. (1999)
510 analyzed the sensitivity of investments for carbon sequestration to discount rate in western
511 Canada and found that applying zero discount may not provide enough incentive for increasing

512 carbon storage. However, most forest carbon cost studies are inconsistent in using terms,
513 geographic scope, assumptions, program definitions, and methods (Richards and Stokes, 2004)
514 and may not truly assess carbon sequestration potentials of forest ecosystems. Therefore, if
515 there were a social preference for prompt climate change mitigation, carbon sinks later in the
516 century should be discounted. Regarding the discussion on discount rate, Johnston and van
517 Kooten (2015) argue that applying sufficiently high discount rates in substituting biomass for
518 fossil fuels never leads to carbon neutrality.

519 5. Conclusions

520 We recommend that future research on integration of management strategies in DGVMs and
521 ESMS should regard ecological sustainability as well as socio-economic challenges. In reality
522 and today, forest management is more of a gamble than a scientific debate (Bellassen and
523 Luyssaert, 2014) and there is no consensus in applying a certain forest harvest rule (e.g. GB)
524 among forest owners, decision-makers and local users. The rationale to manage forest resources
525 sustainably and efficiently is generally recognized and implemented (Luckert and Williamson,
526 2005; Elbakidze et al., 2013). However, the process of forest management decision-making is
527 based on the past experiences with a business-as-usual strategy (BAU). Adaptation to future
528 environmental change and minimizing the risks associated with climate change impacts is
529 recently fully integrated in forest research (Lindner et al., 2014), however, remains in
530 experimental level in implementation (Yousefpour and Hanewinkel, 2015). Mitigation, in turn,
531 is of public interest and there are some attempts internationally to account for mitigation effects
532 of forest management in carbon policy. International programs such as the Kyoto protocol
533 encourage forest managers to store carbon in the forest stocks on the ground applying financial
534 instruments such as tax reduction and direct purchase of carbon offsets. Therefore, inclusion of
535 financial aspects in global forest management modelling and decision-making may help to put
536 scientific results into practice (Hanewinkel et al., 2013). This suggestion is in line with van

537 Vuuren et al. (2011) about the necessity of strengthening the cooperation between integrated
538 assessment models (IAMs) and Earth system modelling communities to improve the
539 understanding of interactions and joint development of environmental and human systems. Our
540 study is the first implementation to account for the climate-dependence of forest growth on
541 global scale for harvest potentials. It suggests the importance of considering this dependence:
542 the growth-based harvest approach (GB) as applied in this study may realize wood harvest
543 potentials twice to four times as high as those of prescribed wood harvest simulated by IAMs
544 for the RCPs and would closely triple the net mitigation effects of wood products. By limiting
545 GB to managed forests (MF), we simulated a lower harvest potential than GB, still two to three
546 times more than in the IAMs, which could double the net mitigation effect of wood harvest
547 potential in the 21st century. To move from estimates of potentials to actual harvest rates,
548 climate-dependent forest growth needs to be integrated with socio-economic factors to fully
549 incorporate economic aspects of forestry practices within a dynamic forest growth and yield
550 modelling system.

551 Code availability
