S.1 Estimating aboveground biomass from forest inventories.

For trees with no height measurement, a site specific DBH height model was used to infer tree height in each site, as described in previous studies (Feldpauch et al., 2012; Meyer et al., 2013,). Wood density was extracted from the global wood density database for tropical trees (Chave et al., 2009; Zanne et al., 2009) for each tree, based on its level of botanical identification (species, genus, family). Trees with no botanical identification were assigned the average wood density of the plot. Average wood density of each site was calculated as the unweighted average of all trees within a site, or was taken from a previous study in the case of Cotriguaçu (Fearnside, 1997). Average wood density of large trees was calculated as the unweighted average of trees with DBH ≥50 cm in each site. Tree level AGB was aggregated at the plot level using a commonly used allometric regression model for moist tropical forests (Eq. (S1), Chave et al., 2005), except for La Selva and Chocó, for which a model for wet tropical forest (Eq. (S2), Chave et al., 2005) and a local allometric model (Eq. (S3), Duque et al., 2017) were used, respectively.

$$AGB_{\_moist} = 0.0509 \times \rho\, DBH^2 H \hspace{3cm} (S1)$$

$$AGB_{\_wet} = 0.0776 \times (\rho\, DBH^2 H)^{0.940} \hspace{2cm} (S2)$$

$$AGB_{\_Chocó} = 0.089 \times (\rho\, DBH^2 H)^{0.951} \hspace{2cm} (S3)$$

where trunk diameter (DBH in cm) is measured during the inventory, tree height (H, in m) is either measured in the field or estimated from a local DBH–H model, and specific gravity or wood density (ρ in g cm^{-3}) is known for each tree. AGB (in kg of dry biomass) of individual trees estimated using the former equations was used to calculate plot level AGB density (Mg ha^{-1}) by summing over the biomass of all stems within each plot. Ground estimated AGB density is henceforth referred to as AGB$_{inv}$. Estimating AGB with these allometric models has been

38   reported to have a standard error of 12.5 % when using height as a parameter, against 19.5 %

39   when height is not available (Chave et al., 2005).

40

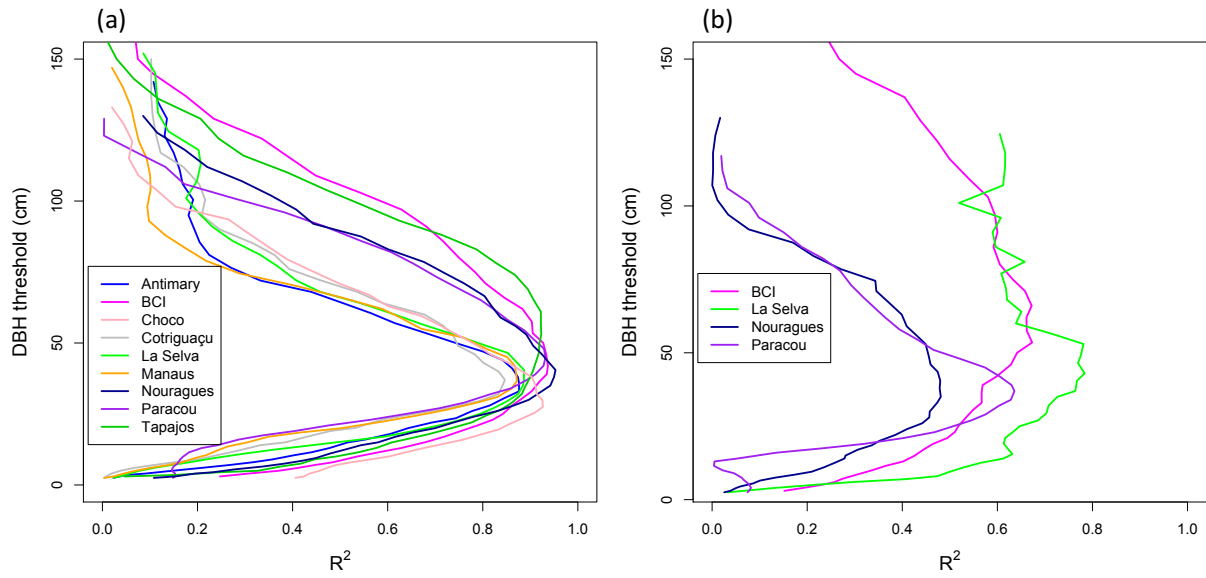

Figure S4. Distribution of R^2 between DBH thresholds and AGB_{Lidar} in 1 ha subareas (a) and AGB_{inv} in 1ha inventory
plots (b). DBH was calculated from tree height using Chave's E factor model (Chave et al., 2014)

61

62

S.2 LCA and ground data

We looked at the relation between LCA and other stand level metrics: AGB_{inv} of large trees, stand basal area, Lorey's height (H_L), and the number of large trees. Lorey's height is defined by

$H_L = \frac{\sum_{i=1}^{N} BA_i H_i}{\sum_{i=1}^{N} BA_i}$ where H_i is the height of stem i, and BA_i is the basal area of stem i. Weighting tree height with basal area increases the relative importance of large trees in a stand (Lefsky, 2010).

There was a significant correlation between LCA and AGB_{inv} in all calibration sites ($R^2_{max} = 0.77$ in La Selva), and even more so between LCA and AGB_{inv} of large trees ($R^2_{max} = 0.83$ in La Selva) (Table S4). LCA correlated with Lorey's height, especially at La Selva but less so at Nouragues ($R^2_{LaSelva} = 0.86$, $R^2_{Nouragues} = 0.21$). We also found that LCA and total basal area are correlated. The relationship between LCA and the number of large trees is significant in all sites, but it is lower than other structural metrics in Paracou ($R^2 = 0.32$). Among study sites, La Selva and BCI show higher correlations between LCA and ground derived metrics. The strong correlation of LCA with plot level AGB_{inv} as well as with AGB_{inv} of large trees suggested that a model based on LCA can be used as an estimator of AGB.

79 **Table S4** : Coefficients of correlation (R^2) between LCA and ground data derived metrics : AGB_{inv}, AGB_{inv} of
80 trees≥50 cm DBH, basal area, Lorey's height and number of large trees in BCI, La Selva, Nouragues and Paracou.

	BCI	La Selva	Nouragues	Paracou
AGB_{inv}	0.64	0.77	0.48	0.64
AGB_{50}	0.68	0.83	0.47	0.69
BA	0.63	0.53	0.41	0.43
LH	0.57	0.86	0.21	0.63
N_{70}	0.64	0.76	0.46	0.32

81

82

83 **S.3 Contribution of Large Trees to AGB$_{inv}$**

84 First, we explored the role of wood density as a key variable in allometric models to scale the

85 tree volume or size to AGB$_{inv}$ (Brown et al., 1989; Chave et al., 2005; Chave et al., 2014,

86 Ngomanda et al., 2014). We examined the variations of wood density as a function of DBH

87 classes in all sites and for all trees greater than 10 cm arranged in 10 cm DBH bins.

88 We then assessed the proportion of large trees by examining the DBH frequency distribution of

89 trees at different sites using the field inventory data, and compared it to the distribution of

90 AGB$_{inv}$ for the same DBH ranges, using 1 cm bins to create DBH classes.

91 **Results**

92 <u>DBH and wood density</u>: At BCI, mean wood density decreased significantly with increasing

93 DBH ($p<0.001$, $R^2 = 0.92$), which is consistent with the results of a previous study (Chave et al.,

94 2004). On the contrary, at Chocó, mean wood density increased significantly with increasing

95 DBH ($p<0.001$, $R^2 = 0.8$). No significant trend was found at the other study sites (Fig. S5). These

96 results show that stand average wood density and wood density of large trees are not

97 significantly different in four sites and can therefore be used interchangeably in a model using

98 these data. However, using one or the other will have an impact on the results of a model

99 calibrated using data from BCI or Chocó. Mean wood density of trees ≥50 cm is 0.49 in BCI (vs.

100 stand average WD = 0.54 g cm^{-3}) and 0.66 in Chocó (vs. stand average WD = 0.60 g cm^{-3}).

101
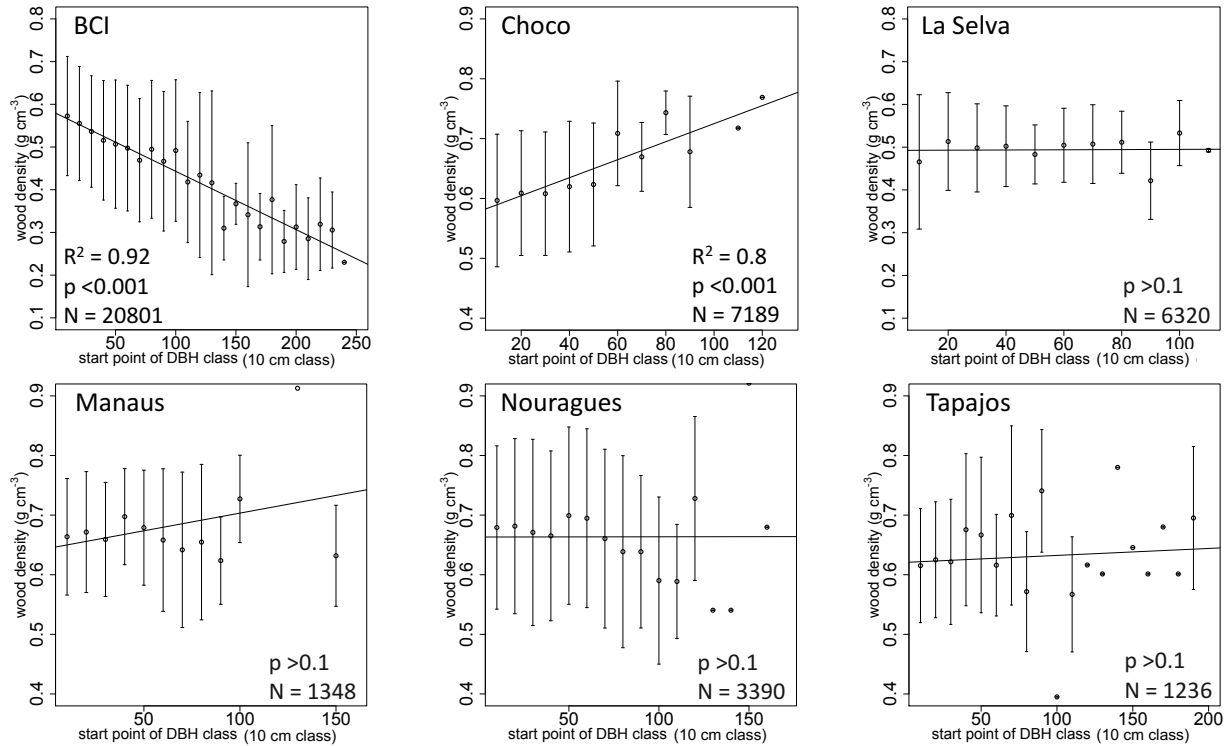

Figure S5. Wood density and DBH classes in BCI, Chocó, La Selva, Manaus, Nouragues and Tapajós. The decrease in mean wood density is significant in BCI ($p<0.001$, $R^2 = 0.92$). The increase in mean wood density is significant in Chocó ($p<0.001$, $R^2 = 0.8$) but there is no significant wood density change across DBH classes in the other sites ($p>0.1$). Points with no standard deviation bars mean that only one tree was present in the class.

We found that using mean wood density of trees ≥50 cm DBH in our LCA model gives slightly better results than using mean wood density (see Eq. (3)), with R^2 of 0.78, RMSE of 45.34 Mg ha⁻¹ and bias of -0.36 Mg ha⁻¹.

<u>DBH and AGB</u> : The relationship between AGB_{inv} and the DBH frequency distribution was similar in BCI, La Selva, Nouragues and Tapajós (Fig. S6). In these sites, more than 50 % of the total AGB_{inv} was contributed by around 5 % (between 3 % and 6 %) of the stems, corresponding to a threshold DBH of 58 cm, 50 cm, 55 cm and 61 cm respectively for the four study sites. Similar results were found in a recent study focusing on the contribution on large trees to AGB in Central Africa (Bastin et al., 2015). Also, 80 % of the AGB stock was in trees with DBH ≥30 cm DBH at BCI, 26 cm at La Selva, 32 cm at Nouragues and 29 cm at Tapajós, which echoes

119   results published on BCI (Chave et al., 2001). These represent only 20 % of the total number of

120   trees in each site (only 15 % in Tapajós). Chocó and Manaus had far less large trees, 50 % of

121   their total AGB_{inv} being explained by respectively 10 % and 7 % of the total number of trees,

122   corresponding to a DBH greater than only 28 cm and 40 cm. In these two sites, 80 % of AGB_{inv}

123   is found in trees above 17 cm and 23 cm, respectively, representing 37 % and 31 % of their total

124   number of trees. These findings corroborate with previous studies from other sites and suggests

125   that large trees can explain AGB variations and could potentially be used to estimate biomass

126   without having to measure all trees in a plot (Bastin et al., 2015; Slik et al., 2013). Note that

127   some ground data from Manaus and Nouragues were included in Silk et al.'s dataset).
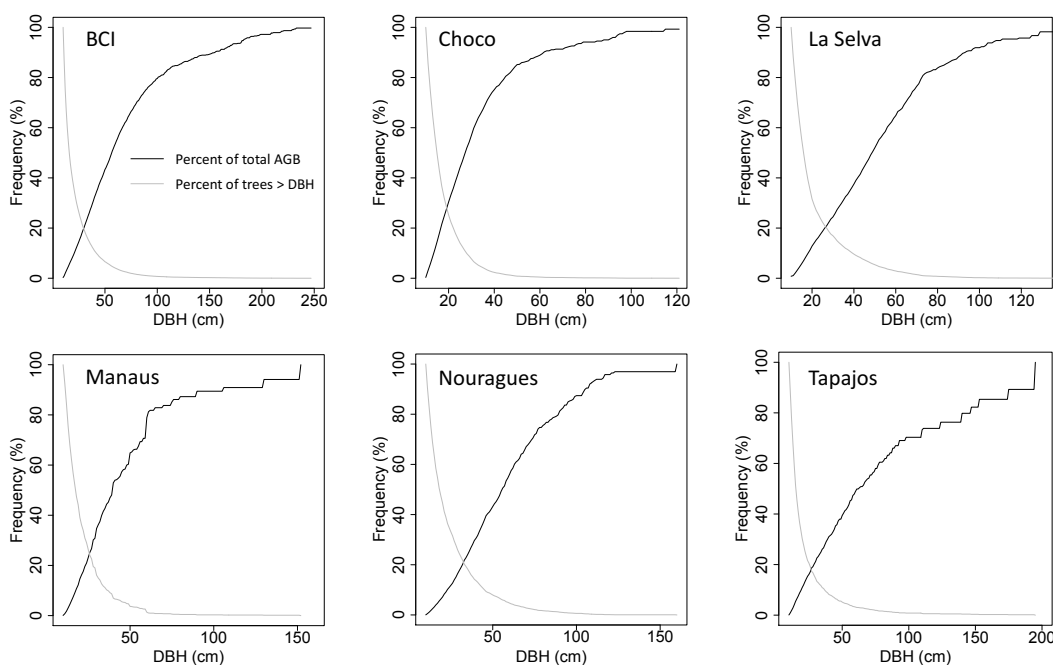

128
129   **Figure S6**. Cumulation of of AGB_{inv} and of number of trees (total number of trees ≥10 cm DBH) as a function of
130   DBH in BCI, Chocó, La Selva, Manaus, Nouragues and Tapajós plots.
