1   Re: bg-2018-100, "Plant responses to volcanically-elevated CO_2 in two Costa Rican forests", Revision 3

2   Dear Dr Gillikin, Associate Editor,

3

4   We here submit our revised manuscript, "**Plant responses to volcanically-elevated CO_2 in two Costa
5   Rican forests**".

6   We would like to thank you for your help throughout the editorial process, and would also like to thank
7   the two anonymous referees for their helpful and positive reviews. While the paper only required minor
8   revisions this time, we believe that these revisions have strengthened the paper due to the addition of
9   the excellent references suggested by the referees and some other recently published articles that
10   support our research.

11   The reviewers recognize the great potential for this method to contribute to major developments in both
12   volcanology and ecology, while highlighting a few areas that would further strengthen the paper. We have
13   made some notable changes as suggested by the referees to increase clarity and reinforce the basis for
14   our interpretation of our results. We have updated the document name to REV3, and all changes made
15   since the previous version (REV2) have been tracked.

16   If you need any further information from us, we are more than happy to provide it. Thank you for again
17   for considering our manuscript for publication in *Biogeosciences*.

18

19   On behalf of the co-authors,

20   Robert Bogue and Florian M Schwandner

AUTHOR – General Response to Referee #3 (Report #1): We thank the referee for their well thought out review and their suggestion of several helpful references of which we were previously unaware. In this revision, we have added further discussion of previous use of natural springs for similar studies and some of the advantages volcanoes offer compared to springs, for this type of project. The reviewer was correct that our discussion of previous studies which utilized ^{14}C was overly brief, so we have expanded that section to include more specific information on several studies which have found interesting results with that method. Their suggestion of including Houlié et al. 2007 and Seiler et al. 2017 was appreciated, as we were not familiar with these articles, but they are quite interesting in the context of our results and strengthen our claim that volcanic CO_2 can have positive on effects local ecosystems. We have also added some material on the use of ^{13}C at FACE sites, which provides support for our interpretation that our observed variances in $\delta^{13}C$ are likely caused by elevated levels of CO_2 with a different isotopic signature.

AUTHOR – General Response to Referee #4 (Report #2): We would like to thank the referee for spotting a few formatting mistakes and suggesting some areas which needed additional clarity. We have edited the first few mentions of the species studied in the paper to clarify how many species were actually studied and which species they are.

AUTHOR's note: A variety of minor changes have been made throughout the document, such as removing unnecessary commas and minor wording changes. These changes have all been tracked but are not specifically commented on in the following responses.

Referee #3 (Comment #1): *The use of volcanoes as experiments is certainly novel and of interest, but affected by the same problems, i.e., many other interacting factors, as the use of natural springs - as mentioned by the authors. This point should be discussed in the paper. Also, some fundamental work done at natural springs may help in interpreting the results and should be looked at (rather than Paoletti et al., which is confusing with tropospheric ozone effects): Miglietta and Körner Oecologia 1993, Hättenschwiler et al. GlChBiol 1997, Tognetti et al. New Phytol 2000, and there is even a book on natural springs by Raschi, Miglietta, Tognetti pioneering such works in Tuscany.*

AUTHOR reply: The references suggested were quite helpful and have been added to the manuscript. The reviewer is correct that the previous work on springs and how it relates to our work should have been further discussed in the paper, and we have made changes to correct that.

AUTHOR's changes in revised manuscript: We added these references to our first mention of CO_2 springs in the paper (line 45-46). A reference to Tognetti et al. 2000 was also added to discussion of nitrogen limitation in elevated CO_2 conditions in section 4.2 We have also added some discussion of the spring studies and the potential advantages of using volcanoes, including a recent meta-analysis paper which compared spring studies to FACE experiments, in section 4.4 (Lessons learned for future studies).

Referee #3 (comment #2): *I was also wondering if there is any work done on carbon stable isotopes at FACE sites, which might help in the discussion.*

AUTHOR reply: We searched the literature and found a reference from 2005 which used ^{13}C as a tracer of the amount of artificial CO_2 being assimilated by trees at a FACE experiment. There are other studies which have used ^{13}C to trace carbon cycling at FACE experiments, but most of the other ones we found focused

72 on plants other than trees or soil carbon, so we used this reference and added some discussion of it. We
73 believe this will provide some additional context for our interpretation of our isotope results.

74 **AUTHOR's changes in revised manuscript:** We added a reference to Körner et al. 2005 and some
75 discussion of it to Section 4.1 (Long-term plant uptake of volcanic CO_2).

76 **Referee #3 (comment #3):** *In my opinion, the results are of real remarkable importance because suggest*
77 *a possible future utlization of 13C stable isotopes, leaf fluorescence and chlorophyll content in vegetation*
78 *to detect changes in deep volcanic degassing processes. That's novel, promising and exciting! Is it the first*
79 *time it is shown? If so, it should be stated. Please, look at the NDVI on Mt. Etna and in Congo by Houlié et*
80 *al. EPSL 2007 and its interpretation by Seiler et al. PLoS ONE 2017.*

81 **AUTHOR reply:** We were previously unaware of these two papers and would have included them if we
82 had been aware of them because they are directly relevant to our work and provide some support for our
83 claim that volcanic CO_2 has significant impacts on trees. We have added some discussion of these papers
84 and how they relate to our work.

85 **AUTHOR's changes in revised manuscript:** We added some discussion of these two papers to the
86 introduction. We also mention it to help our interpretation of results in section 4.2 (Short-term response
87 to eCO_2). We added a citation to it near the end of section 4.4 (Lessons learned for future studies) to
88 support our claim that we may be able to use trees to detect changes in degassing and volcanic activity in
89 section 4.4.

90 **Referee #3 (comment #4):** *One of the reviewers of the ms during the first round of review pointed out how*
91 *14C may help in detecting the impact of fossil CO2 on trees, and the authors reply that it is expensive,*
92 *which is right and good. However, in the discussion, some deeper analysis on what was found by other*
93 *studies using 14C might probably help.*

94 **AUTHOR reply:** We agree that a better understanding of these previous studies would help readers
95 understand the motivations for our study and our interpretations of the results. As such, we have added
96 discussion of several of these studies of ^{14}C content of tree rings in a variety of volcanic settings. Some of
97 these studies even found direct correlations between ^{13}C and ^{14}C, strengthening our case that ^{13}C can be
98 used as a cheaper effective tracer of volcanic CO_2.

99 **AUTHOR's changes in revised manuscript:** We added significant discussion of previous studies in the
100 introduction. We also added some text discussing the link between ^{13}C and ^{14}C in trees that have
101 assimilated volcanic CO_2 in section 4.4.

102 **Referee #3 (comment #5):** *In the supplementary material the reference Allard et al is without publication*
103 *year.*

104 **AUTHOR reply:** We have fixed it in the revised version.

105 **AUTHOR's changes in revised manuscript:** The reference information has been corrected.

106

107 **Referee #4 (comment on line 23-24):** *add species names*

108 **AUTHOR reply:** We have added the species names and clarified the number of species studied.

109   **AUTHOR's changes in revised manuscript:** Species names and number of species studied have been
110   added to this sentence.

111   **Referee #4 (comment on line 83):** *there are two or three species?*

112   **AUTHOR reply:** We studied three species. We realize this was confusing when compared with the
113   statement in the abstract that the previous comment was about. We think the changes discussed in the
114   previous comment have made it clearer about how many species were studied.

115   **AUTHOR's changes in revised manuscript:** No additional changes have been made, as the changes made
116   for the previous comment are enough to clarify the number of species studied.

117   **Referee #4 (comment on line 90):** *Careful with this asseveration, for example Barva volcano is the largest*
118   *volcanic mastiff in Central America, with an approximate area of 1120 to 1500 km2 (Alvarado, 2011).*

119   **AUTHOR reply:** We realize that this statement was perhaps difficult to quantify. It also is not important
120   to the overall point of the paper, so we have removed it and revised the sentence.

121   **AUTHOR's changes in revised manuscript:** We have changed this sentence to focus more on the two
122   volcanoes that we studied, rather than comparing them to uncertain figures for all volcanoes generally.

123   **Referee #4 (comment on line 182):** *erase comma*

124   **AUTHOR reply:** This comment was an error and has been deleted.

125   **AUTHOR's changes in revised manuscript:** The necessary changes have been made.

126   **Referee #4 (comment on line 195):** *.*

127   **AUTHOR reply:** There was a period missing from the end of the sentence, which we have added.

128   **AUTHOR's changes in revised manuscript:** We have added the period.

129   **Referee #4 (comment on line 232):** *separate upper slopes*

130   **AUTHOR reply:** "Upperslopes" was mistakenly typed as a single word in the manuscript. We have fixed it.

131   **AUTHOR's changes in revised manuscript:** "Upperslopes" is now correctly typed as "upper slopes".

132   **Referee #4 (comment on line 244):** *Campion et al. (2010).*

133   **AUTHOR reply:** This reference was incorrectly formatted and has been adjusted.

134   **AUTHOR's changes in revised manuscript:** We have formatted the reference correctly.

REV3 (2019-02-17)

164   **Abstract.** We explore the use of active volcanoes to determine the short- and long-term effects of elevated CO_2 on

165   tropical trees. Active volcanoes continuously but variably emit CO_2 through diffuse emissions on their flanks,

166   exposing the overlying ecosystems to elevated levels of atmospheric CO_2. We found tight correlations (r^2=0.86 and

167   r^2=0.74) between wood stable carbon isotopic composition and co-located volcanogenic CO_2 emissions for two of

168   three investigated species *(Oreopanax xalapensis* and *Buddleja nitida)*, which documents the long-term

169   photosynthetic incorporation of isotopically heavy volcanogenic carbon into wood biomass. Measurements of leaf

170   fluorescence and chlorophyll concentration suggest that volcanic CO_2 also has measurable short-term functional

171   impacts on select species of tropical trees. Our findings indicate significant potential for future studies to utilize

172   ecosystems located on active volcanoes as natural experiments to examine the ecological impacts of elevated

173   atmospheric CO_2 in the tropics and elsewhere. Results also point the way toward a possible future utilization of

174   ecosystems exposed to volcanically elevated CO_2 to detect changes in deep volcanic degassing by using selected

175   species of trees as sensors.

176   **1 Introduction**

177   Tropical forests represent about 40% of terrestrial Net Primary Productivity (NPP) worldwide, store 25% of biomass

178   carbon, and may contain 50% of all species on Earth, but the projected future responses of tropical plants to globally

179   rising levels of CO_2 are poorly understood (Leigh et al., 2004; Townsend et al., 2011). The largest source of uncertainty

180   comes from a lack of understanding of long-term CO_2 fertilization effects in the tropics (Cox et al., 2013). Reducing

181   this uncertainty would significantly improve Earth system models, advances in which would help better constrain

182   projections in future climate models (Cox et al., 2013; Friedlingstein et al., 2013). Ongoing debate surrounds the

183   question of how much more atmospheric CO_2 tropical ecosystems can absorb—the "CO_2 fertilization effect" (Gregory

184   et al., 2009; Kauwe et al., 2016; Keeling, 1973; Schimel et al., 2015).

185   Free Air CO_2 Enrichment (FACE) experiments have been conducted to probe this question, but none have

186   been conducted in tropical ecosystems (e.g. Ainsworth and Long, 2005; Norby et al., 2016). Some studies have used

187   CO_2-emitting natural springs to study plant responses to elevated CO_2, but these have been limited in scope due to the

188   small spatial areas around springs that experience elevated CO_2 (Hattenschwiler et al., 1997; Körner and Miglietta,

189   1994; Paoletti et al., 2007; Saurer et al., 2003). These studies have suffered from several confounding influences,

190   including other gas species that accompany CO_2 emissions at these springs, human disturbances, and difficulty with

191   finding appropriate control locations. Additionally, none have been conducted in the tropics (Pinkard et al., 2010). A

192   series of studies in Yellowstone National Park (USA) used its widespread volcanic hydrothermal CO_2 emissions for

193   the same purpose, though it is not in the tropics (Sharma and Williams, 2009; Tercek et al., 2008). Yellowstone was

194   particularly suitable for this type of study, due to its protected status as a National Park, and because the large areas

195   of CO_2 emissions made control points more available (Sharma and Williams, 2009; Tercek et al., 2008). These studies

196   reported changes in rubisco, an enzyme central to CO_2 fixation, and sugar production in leaves similar to results from

197   FACE experiments, suggesting that volcanically-influenced areas like Yellowstone have untapped potential for

198   studying the long-term effects of elevated CO_2 on plants.

Deleted: (Paoletti et al., 2007; Saurer et al., 2003)

Deleted: fixation, and

Tropical ecosystems on the vegetated flanks of active volcanoes offer large and diverse ecosystems that could make this type of study viable. Well over 200 active volcanoes are in the tropics (Global Volcanism Program, 2013) and many of these volcanoes are heavily forested. However, fewer of these tropical volcanic forests have sufficient legal protection to be a source of long-term information, and the effects of diffuse volcanic flank gas emissions on the overlying ecosystems remain largely unknown. Most previous studies focused on extreme conditions, such as tree kill areas associated with extraordinarily high CO_2 emissions at Mammoth Mountain, CA (USA) (Biondi and Fessenden, 1999; Farrar et al., 1995; Sorey et al., 1998). However, the non-lethal effects of cold volcanic CO_2 emissions—away from the peak emission zones, but still in the theorized fertilization window—have received little attention, and could offer a new approach to studying the effects of elevated CO_2 on ecosystems (Cawse-Nicholson et al., 2018; Vodnik et al., 2018). The broad flanks of active volcanoes experience diffuse emissions of excess CO_2 because the underlying active magma bodies continuously release gas, dominated by CO_2 transported to the surface along fault lines (Chiodini et al., 1998; Dietrich et al., 2016; Farrar et al., 1995). This process has frequently been studied to understand the dynamics of active magma chambers and to assess potential volcanic hazards (Chiodini et al., 1998; Sorey et al., 1998). These emissions are released through faults and fractures on the flanks of the volcano (Burton et al., 2013; Pérez et al., 2011; Williams-Jones et al., 2000)(see Supplementary Figure S1). Volcanic flanks through which these gases emanate are broad, covering typically 50-200 km^2, often supporting well-developed, healthy ecosystems. Some of these faults tap into shallow acid hydrothermal aquifers, but by the time these gases reach the surface of most forested volcanoes, soluble and reactive volcanic gas species (e.g., SO_2, HF, HCl, H_2S) have been scrubbed out in the deep subsurface, leading to a diffusely emanated gas mix of predominantly CO_2 with minor amounts of hydrogen, helium, and water vapor reaching the surface (Symonds et al., 2001).

Trees in these locations are continuously exposed to somewhat variably elevated concentrations of CO_2 (eCO_2), although the specific effects of this eCO_2 on the trees are not well understood. Volcanic CO_2 has no ^{14}C and a δ^{13}C signature typically ranging from around -7 to -1 ‰, which is distinct from typical vegetation and noticeably enriched in ^{13}C compared to typical atmospheric values (Mason et al., 2017). If trees incorporate volcanic CO_2, then the stable carbon isotopic composition of wood may document the long-term, possibly variable influence of volcanic CO_2 during the tree's growth. With this tracer available, volcanic ecosystems could become a valuable natural laboratory to study the long-term effects of elevated CO_2 on ecosystems, especially in understudied regions like the tropics. Several studies have found correlations between variations in volcanic CO_2 flux and plant ^{14}C records at Mammoth Mountain, Yellowstone, and Naples which agreed well with previous observations at these well-studied sites (Cook et al., 2001; Evans et al., 2010; Lefevre et al., 2017; Lewicki et al., 2014). The Mammoth Mountain and Yellowstone studies linked seismic swarms and accompanying increases in CO_2 flux to decreases in ^{14}C content in tree rings in 1 or 2 trees, demonstrating the methods utility for uncovering yearly-scale variations in volcanic CO_2 fluxes (Cook et al., 2001; Evans et al., 2010; Lewicki et al., 2014). The Naples study instead focused on using ^{14}C in grasses as short term (2 to 6 month) monitors of volcanic CO_2 flux, which is useful for volcanic monitoring due to the time-integrated signal they provide (Lefevre et al., 2017). A study of plants growing at Furnas volcano found very strong (r^2>0.85) correlations between depletions in ^{14}C and enrichments in ^{13}C from volcanic CO_2 in three species of plants, although this study also had a relatively limited (5 samples per species) dataset (Pasquier-Cardin et al., 1999).

The previously mentioned Naples study also found some correlation between ^{13}C and ^{14}C, although it was not as strong as the study in Furnas (Lefevre et al., 2017; Pasquier-Cardin et al., 1999). Additionally, short-term effects of eCO_2 might be revealed by plant functional measurements at the leaf scale, where the additional CO_2 could increase carbon uptake in photosynthesis. A series of studies at Mt. Etna in Italy and Mt. Nyiragongo in the Democratic Republic of the Congo found linear anomalies in NDVI (normalized difference vegetation index), a measure of vegetation greenness (Houlié et al., 2006). One to two years after the appearance of the NDVI anomalies, flank eruptions occurred directly along the line of the anomaly, indicating a plant response to the volcano's pre-eruptive state which may be due to increased CO_2 emissions in the buildup to the eruption (Houlié et al., 2006). A follow-up study found that the trees on Mt. Etna were relatively insensitive to changes in temperature and water availability, strengthening the case that volcanic influence was indeed responsible for the NDVI anomaly (Seiler et al., 2017).

Here we provide preliminary results on the short- and long-term non-lethal impacts of diffuse volcanic CO_2 emissions on three species of tropical trees on the flanks of two active volcanoes in Costa Rica. We also explore the viability of studying volcanically-influenced ecosystems to better understand potential future responses to elevated CO_2 and suggest adjustments to our approach that will benefit future, similarly-motivated studies.

2 Methods

2.1 Investigated locations and sampling strategy

Irazú and Turrialba are two active volcanoes located ~25 and 35 km east of San José, Costa Rica (Fig. 1). These two volcanoes are divided by a large erosional basin. The forested portions of the two volcanoes cover approximately 315 km^2. The vast majority of the northern flanks of Irazú and Turrialba are covered in legally protected dense old-growth forest, while the southern flanks are dominated by pasture land and agriculture. Turrialba rises 3,300 m above its base and has been active for at least 75,000 years with mostly fumarolic activity since its last major eruption in 1866 (Alvarado et al., 2006). It has experienced renewed activity beginning in 2010, and its current activity is primarily characterized by a near-constant volcanic degassing plume, episodic minor ash emissions, and fumarolic discharges at two of the summit craters, as well as significant diffuse and fumarolic gas emissions across its flanks, focused along fault systems (Martini et al., 2010). Turrialba's CO_2 emissions in areas proximal to the crater were calculated at 113 $\pm$ 46 tons/d (Epiard et al., 2017). The Falla Ariete (Ariete fault), a major regional fault, runs northeast-southwest through the southern part of Turrialba's central edifice and is one of the largest areas of diffuse CO_2 emissions on Turrialba (Epiard et al., 2017; Rizzo et al., 2016). Atmospheric CO_2 has an average $\delta^{13}C$ value of -9.2 ‰ at Turrialba, and the volcanic CO_2 released at the Ariete fault has significantly heavier $\delta^{13}C$ values clustered around -3.4 ‰ (Malowany et al., 2017).

Irazú has been active for at least 3,000 years and had minor phreato-magmatic eruptions in 1963 and a single hydrothermal eruption in 1994. Currently, Irazú's activity primarily consists of shallow seismic swarms, fumarolic crater gas emissions, small volcanic landslides, and minor gas emissions on its northern forested flank (Alvarado et al., 2006; Barquero et al., 1995). Diffuse cold flank emissions of volcanic CO_2 represent the vast majority of gas

8

283 discharge from Irazú, as the main crater releases 3.8 t d^{-1} of CO_2 and a small area on the north flank alone releases 15

284 t d^{-1} (Epiard et al., 2017). Between the two volcanoes, a major erosional depression is partially occupied by extensive

285 dairy farms and is somewhat less forested than their flanks.

286   In this study, we focused on accessible areas between 2,000 and 3,300 m on both volcanoes (Fig. 1). On

287 Irazú, we sampled trees and CO_2 fluxes from the summit area to the north, near the approximately north-south striking

288 Rio Sucio fault, crossing into the area dominated by dairy farms on Irazú's lower northeastern slope. Of significant

289 importance for this type of study is that all active volcanoes on Earth continuously emit CO_2 diffusely through fractures

290 and diffuse degassing structures on their flanks, at distances hundreds to thousands of meters away from the crater

291 (Dietrich et al., 2016; Epiard et al., 2017), and this elevated CO_2 degassing persists continuously and consistently over

292 decades to centuries (Burton et al., 2013; Delmelle and Stix, 1999; Nicholson, 2017). There is no inherent seasonal or

293 meteorological variability of the source gas pressure, and no dependence on shallow soil or vegetation chemistry or

294 biology (though increased soil moisture in the rainy season, wind, and atmospheric pressure can modulate gas

295 permeability of the shallow soil) (Camarda et al., 2006). The soil overlying deep reaching fracture systems acts as a

296 diffuser through which the volcanic gas percolates and enters the sub-canopy air. For our study sites, portions of the

297 volcanoes with active "cold" CO_2 degassing have already been assessed and mapped previously (Epiard et al., 2017;

298 Malowany et al., 2017).

299   Our sampling locations on Irazú were located along a road from the summit northward down into this low-

300 lying area. On Turrialba, we focused on an area of known strong emissions but intact forests on the SW slope, uphill

301 of the same erosional depression, but cross-cut by the major NE-SW trending active fracture system of the Falla Ariete.

302 We sampled three main areas of the Falla Ariete, each approximately perpendicularly transecting the degassing fault

303 along equal altitude; the upper Ariete fault, the lower Ariete fault, and a small basin directly east of the old Cerro

304 Armado cinder cone on Turrialba's south-western flank. We took a total of 51 tree samples (17 were excluded after

305 stress screening) at irregular intervals depending on the continued availability and specimen maturity of three species

306 present throughout the transect.

307   All transects are in areas experiencing measurable CO_2 enhancements from the Falla Ariete, but not high

308 enough in altitude to be in areas generally downwind of the prevailing crater emissions plume (Epiard et al., 2017).

309 We avoided areas that experience ash fall, high volcanic SO_2 concentrations, local anthropogenic CO_2 from farms, or

310 that were likely to have heavily acidified soil. Excessively high soil CO_2 concentrations can acidify soil, leading to

311 negative impacts on ecosystems growing there (McGee and Gerlach, 1998). Because such effects reflect by-products

312 of extreme soil CO_2 concentrations rather than direct consequences of elevated CO_2 on plants, we avoided areas with

313 CO_2 fluxes high enough to possibly cause noticeable CO_2-induced soil acidification. Light ash fall on some days likely

314 derived from atmospheric drift, as we were not sampling in areas downwind of the crater. The ash fall did not in any

315 noticeably way affect our samples, as trees showing ash accumulation on their leaves or previous damage were the

316 exception and avoided. Altitude, amount of sunlight during measurements, and aspect had no consistent correlations

317 with any of the parameters we measured.

2.2 Studied tree species

Our study focused on three tree species found commonly on Turrialba and Irazú: *Buddleja nitida*, *Alnus acuminata*,
and *Oreopanax xalapensis*. *B. nitida* is a small tree with a typical stem diameter (DBH) ranging from 5 to 40 cm that
grows at elevations of 2,000-4,000 m throughout most of Central America (Kappelle et al., 1996; Norman, 2000). The
DBH of the individuals we measured ranged from 11.5 to 51.3 cm, with an average of 29.85 cm. It averages 4-15 m
in height and grows primarily in early and late secondary forests (Kappelle et al., 1996; Norman, 2000). *A. acuminata*
is a nitrogen-fixing pioneer species exotic to the tropics that can survive at elevations from 1,500-3,400 m, although
it is most commonly found between 2,000-2,800 m (Weng et al., 2004). The trees we measured had DBH ranging
from 14.3 to 112 cm, with an average of 57.14 cm. *O. xalapensis* thrives in early and late successional forests, although
it can survive in primary forests as well (Kappelle et al., 1996; Quintana-Ascencio et al., 2004). It had the smallest
average DBH of the three species, ranging from 6.6 to 40.9 cm, with an average of 22.71 cm.

2.3 CO_2 concentrations and soil diffuse flux measurements

Soil CO_2 flux was measured with an accumulation chamber near the base of the tree (generally within 5 meters, terrain
permitting) at three different points and then averaged to provide a single CO_2 flux value to compare to the [13]C
measurement of the corresponding tree sample. This technique is intended to provide a simple relative way to compare
the CO_2 exposure of different trees, as a tree with high CO_2 flux near its base should experience consistently higher
CO_2 concentrations than a tree with lower CO_2 flux. We also measured concentrations at ground level and $1.5 – 2.0$
m above ground level, though these were expectedly highly variable in time and location. We analyzed CO_2 fluxes,
not concentrations, because the diffuse emissions of excess volcanic CO_2 through the soil, fed from a deep magma
source and location-dependent on constant deep geological permeability, are highly invariant in time compared to
under-canopy air concentrations. In contrast, instantaneous concentration measurements in the sub-canopy air are
modulated by many factors including meteorology, respiration of vegetation and animals, uptake by plants for
photosynthesis, and diurnal dynamic and slope effects. An approach of instantaneous highly variable concentration
measurements is thus not representative of long-term exposure. The approach of measuring the largely invariant soil-
to-atmosphere volcanic CO_2 fluxes is much more representative of long-term exposure, varying mostly spatially and
the site-to-site differences are therefore more representative of the lifetime of exposure of the trees.

We used a custom-built soil flux chamber system which contained a LI-COR 840A non-dispersive infrared CO_2 sensor
(LI-COR Inc., Lincoln NE, USA) to measure soil CO_2 flux. A custom-built cylindrical accumulation chamber of
defined volume was sealed to the ground and remained connected to the LI-COR sensor. The air within the
accumulation chamber was continuously recirculated through the sensor, passing through a particle filter. The sensor
was calibrated before deployment and performed within specifications. We recorded cell pressure and temperature,
ambient pressure, air temperature, GPS location, time stamps, location description, wind speed and direction, relative
humidity, and slope, aspect, and altitude as ancillary data. In typical operation, each measurement site for flux
measurements was validated for leaks (visible in the live data stream display as spikes and breaks in the CO_2

concentration slope), and potential external disturbances were avoided (such as vehicle traffic, generators, or breathing animals and humans). Measurements were recorded in triplicate for at least 2 minutes per site. Data reduction was performed using recorded time stamps in the dataset, with conservative time margins to account for sensor response dead time, validated against consistent slope sections of increasing chamber CO_2. Fluxes were computed using ancillary pressure and temperature measurements and the geometric chamber constant (chamber volume at inserted depth, tubing volume, and sensor volume). Care was taken to not disturb the soil and overlying litter inside and adjacent to the chamber.

2.4 Leaf function measurements

Chlorophyll fluorescence measurements were conducted on leaves of all three species during the field campaign to obtain information on instantaneous plant stress using an OS30p+ fluorometer (Opti-Sciences Inc., Hudson, NH, USA). Five mature leaves from each individual tree were dark adapted for at least 20 minutes to ensure complete relaxation of the photosystems. After dark adaptation, initial minimal fluorescence was recorded (F_o) under conditions where we assume that photosystem II (PSII) was fully reduced. Immediately following the F_0 measurement, a 6,000 μmol m^{-2} s^{-1} saturation pulse was delivered from an array of red LEDs at 660 nm to record maximal fluorescence emission (F_m), when the reaction centers are assumed to be fully closed. From this, the variable fluorescence was determined as $F_v/F_m = (F_m-F_o)/F_m$. F_v/F_m is a widely used chlorophyll fluorescence variable used to assess the efficiency of PSII and, indirectly, plant stress (Baker and Oxborough, 2004). The five F_v/F_m measurements were averaged to provide a representative value for each individual tree. Some trees had less than five measurements due to the dark adaptation clips slipping off the leaf before measurements could be taken. Ten trees had four measurements, and another six had three measurements.

Chlorophyll concentration index (CCI) was measured with a MC-100 Apogee Instruments chlorophyll concentration meter (Apogee Instruments, Inc., Logan, UT, USA). CCI was converted to chlorophyll concentration (μmol m^{-2}) with the generic formula derived by Parry et al., 2014. Depending on availability, between three and six leaves were measured for CCI for each tree, and then averaged to provide a single value for each tree. If leaves were not within reach, a branch was pulled down or individual leaves were shot down with a slingshot and collected. Photosynthetically active radiation was measured at each tree with a handheld quantum meter (Apogee Instruments, Logan, UT, USA) (Table S2). Stomatal conductance to water vapor, g_s (mmol m^{-2} s^{-1}) was measured between 10:00-14:00 hours using a steady-state porometer (SC-1, Decagon Devices, Inc., Pullman, WA, USA), calibrated before use and read in manual mode. This leaf porometer was rated for humidity<90%, and humidity was sometimes above this limit during our field work. Consequently, we have fewer stomatal conductance measurements than our other data types.

2.5 Isotopic analysis

We collected wood cores from 31 individual trees at a 1.5 m height using a 5.15 mm diameter increment borer (JIM GEM, Forestry Suppliers Inc., Jackson, MS, USA). Since no definable tree rings were apparent, we created a fine

11

389 powder for isotope analysis by drilling holes into dried cores using a dry ceramic drill bit (Dremel) along the outermost

390 5 cm of wood below the bark, which was chosen to represent the most recent carbon signal for ^{13}C analyses. The fine

391 powder (200 mesh, 0.2 – 5 mg) was then mixed and a random sample was used to extract ^{13}C/^{12}C ratios (to obtain

392 δ^{13}C values against the VPDB standard), which we estimated to be representative of at least the last 2-3 years, based

393 on analogous literature growth rate values: *O. xalapensis* and *A. acuminata* range from 0.25 - 2.5 cm/y and 0.6 - 0.9

394 cm/y, respectively (Kappelle et al., 1996; Ortega-Pieck et al, 2011). These rates result in a 5 cm range of at least 2 and

395 5.5 years, though the high rates were determined for very young trees under very different conditions and it is explicitly

396 unknown in our study. Since we only sample the most recent years, no isotopic discrimination against atmospheric

397 ^{13}C due to preferential diffusion and carboxylation of ^{12}C, was conducted. Rather, we assume that δ^{13}C values are

398 representative of the relative amount of volcanic CO_2 vs. atmospheric CO_2 sequestered by the tree over the period of

399 growth represented in the sample. δ^{13}C values were determined by continuous flow dual isotope analysis using a

400 CHNOS Elemental Analyzer and IsoPrime 100 mass spectrometer at the University of California Berkeley Center for

401 Stable Isotope Biogeochemistry. External precision for C isotope determinations is ±0.10 ‰. Ten δ^{13}C measurements

402 did not have corresponding soil CO_2 flux measurements due to the flux measurements being unavailable for the final

403 two days of sampling, and another 5 samples were from trees that showed signs of extreme stress, such as browning

404 leaves or anomalously low fluorescence measurements. Since the purpose of our study was to explore the non-lethal

405 effects of volcanic CO_2 on trees, during analysis we excluded all trees that were observed in the field to show visible

406 signs of stress, or that were not fully mature. After these exclusions, all remaining tree cores with co-located CO_2 flux

407 measurements were from Turrialba.

408 **2.6 Sulfur dioxide probability from satellite data**

409 To assess the likelihood of trees having been significantly stressed in the past by volcanic sulfur dioxide (SO_2) from

410 the central crater vents, we took two approaches. First, we were guided by in-situ measurements taken in the same

411 areas by Jenkins et al. (2012), who assessed the physiological interactions of SO_2 and CO_2 on vegetation on the upper

412 slopes of Turrialba and demonstrated a rapid exponential decay of SO_2 away from the central vent. Second, for long-

413 term exposure we derived the likelihood of exposure per unit area using satellite data sensitive to SO_2 (Fig. 2). The

414 Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER), launched in December 1999 on

415 NASA's Terra satellite, has bands sensitive to SO_2 emission in the thermal infrared (TIR), at ~60 m x 60 m spatial

416 resolution. We initially used ASTER Surface Radiance TIR data (AST_09T), using all ASTER observations of the

417 target area over the entirety of the ASTER mission (October 2000 until writing in late 2017). The TIR bands were

418 corrected for downwelling sky irradiance and converted into units of W m^{-2} µm^{-1}. For each observation, an absorption

419 product is calculated by subtracting SO_2-insensitive from SO_2-sensitive bands:

420 $$S^t = (b_{10} + b_{12}) - 2 \cdot b_{11} \tag{1}$$

421 Where S is the SO_2 index, t is an index representing the time of acquisition, b_{10} is the radiance at band 10 (8.125 -

422 8.475 µm), b_{11} is the radiance at band 11 (8.475 - 8.825 µm), and b_{12} is the radiance at band 12 (8.925 - 9.275 µm).

423 This is similar to the method of Campion et al. (2010). The granules were then separated into day and night scenes,

12

Deleted: s lopes

Deleted: ,

426 projected onto a common grid, and then thresholded to $S > 0.1$ W m^{-2} μm^{-1}, and converted into a probability. The

427 output is a spatial dataset that describes the probability of an ASTER observation showing an absorption feature above

428 a 0.1 W m^{-2} μm^{-1} threshold across the entirety of the ASTER observations for day or night separately. The number of

429 scenes varies per target, but they tend to be between 200-800 observations in total, over the 17 year time period of

430 satellite observations. However, certain permanent features, such as salt pans, show absorption features in band 11

431 and therefore have high ratios for the algorithm used. We therefore used a second method that seeks to map transient

432 absorption features. For this method, we subtract the median from each S^t, yielding a median deviation stack. By

433 plotting the maximum deviations across all observations, we then get a map of transient absorption features, in our

434 case this is mostly volcanic SO_2 plumes, which map out the cumulative position of different plume observations well.

435 To speed up processing, some of the retrieval runs were binned in order to increase the signal-to-noise ratio, since the

436 band difference can be rather noisy.

437 **2.7 Modelling the anthropogenic CO_2 influence from inventory data**

438 We assessed the likelihood of anthropogenic CO_2, enhancements of air from San Jose, Costa Rica's capital and main

439 industrial and population center, influencing our measurements. We used a widely applied Flexible Particle Dispersion

440 Model (Eckhardt et al., 2017; Stohl et al., 1998, 2005; Stohl and Thomson, 1999) in a forward mode (Stohl et al.,

441 2005), Flexpart, to simulate the downwind concentrations of CO_2 in the atmosphere (e.g., Belikov et al., 2016), due

442 to inventory-derived fossil fuel (FF) emissions in our study area for the year 2015 (Fig. 2). The National Centers for

443 Environmental Prediction (NCEP) - Climate Forecast System Reanalysis (CFSR) 2.5° horizontal resolution

444 meteorology (Saha et al., 2010b, 2010a), and 1-km Open-Source Date Inventory for Anthropogenic CO_2 (ODIAC;

445 Oda and Maksyutov, 2011) emissions for 2015 were used to drive the Flexpart model. The CO_2 concentrations were

446 generated at a 1 km spatial resolution within three vertical levels of the atmosphere (0-100, 100-300, 300-500 meters)

447 that are possibly relevant to forest canopies in Costa Rica. However, to assess the magnitude of enhancements we only

448 used CO_2 concentrations observed within the lowest modelled level of the atmosphere, from 0-100 meters. Validation

449 of the model with direct observations was not required because we were only interested in ensuring that anthropogenic

450 CO_2 dispersed upslope from San José was not having a significant effect on our study area, we were not aiming to

451 capture intra-canopy variability, typically at tens to hundreds of ppm variable, which is not relevant to the better

452 mixed, distal single-digit or less ppm signal from San Jose. The actual concentration of CO_2 and any biogenic influence

453 in the modelled area was irrelevant because the spatial distribution of anthropogenic CO_2 was the only factor relevant

454 for this test. 2015 was used as a representative year for simulating the seasonal cycle of CO_2 concentrations that would

455 be present in any particular year.

456 **3 Results**

457 **3.1 Volcanic CO_2 emissions through the soil**

458 We measured CO_2 flux emitted through the soil at 66 points over four days (Fig. 1). The first eight points were on

459 Irazú, and the rest were located near the Ariete fault on Turrialba. Mean soil CO_2 flux values over the entire sampling

13

460 area varied from 3 to 37 g m^{-2} day^{-1}, with an average of 11.6 g m^{-2} day^{-1} and a standard deviation of 6.6 g m^{-2} day^{-1}. A

461 12-bin histogram of mean CO_2 flux shows a bimodal right-skewed distribution with a few distinct outliers (Fig. 3).

462 Fluxes were generally larger on Irazú than on Turrialba. This result agrees with previous studies which showed that

463 the north flank of Irazú has areas of extremely high degassing, whereas most of our sampling locations on Turrialba

464 were in areas that had comparatively lower diffuse emissions (Epiard et al., 2017; Stine and Banks, 1991). We used a

465 cumulative probability plot to identify different populations of CO_2 fluxes (Fig. 3) (Cardellini et al., 2003; Sinclair,

466 1974).

467 We created an inventory-based model of anthropogenic CO_2 emissions from the San José urban area, parts

468 of which are less than 15 km from some of our sampling locations (Fig. 2). Our model shows that CO_2 emitted from

469 San José is blown west to south-west by prevailing winds. Our study area is directly east of San José, and as such is

470 unaffected by anthropogenic CO_2 from San Jose, which is the only major urban area near Turrialba and Irazú. Since

471 the trees sampled are spatially close to each other, they are exposed to the same regional background CO_2 variability.

472 Additionally, we used ASTER data to map probabilities of SO_2 across Costa Rica, as a possible confounding factor.

473 The active craters of both Turrialba and Irazú emit measurable amounts of SO_2, which is reflected by the high SO_2

474 probabilities derived there (Fig. 2). Tropospheric SO_2 quickly converts to sulfate, a well-studied process intensified

475 by the presence of volcanic mineral ash, plume turbulence, and a humid tropical environment (Oppenheimer et al.,

476 1989; Eatough et al., 1994); furthermore, the bulk of the SO_2 emissions is carried aloft. Consequently, any remaining

477 SO_2 causing acid damage effects on trees at Turrialba is limited to a narrow band of a few 100 m around the mostly

478 quietly steaming central vent, which has been thoroughly ecologically evaluated for acid damage (Jenkins et al., 2012).

479 D'Arcy (2018) has assessed this narrow, heavily SO_2-affected area immediately surrounding the central crater vent of

480 Turrialba, which we avoided, and our sampling sites are mostly within their control zone not considered majorly

481 affected by SO_2, but where diffuse CO_2 degassing dominates the excess gas phase (Epiard et al, 2017). Our study area

482 is on the flanks of the volcano, where ASTER-derived SO_2 probability is minimal, and SO_2 influence not detectable

483 on the ground (Jenkins et al., 2012; Campion et al., 2012). Most other volcanoes in Costa Rica emit little to no SO_2

484 on a decadal time scale, shown by the low or non-existent long-term SO_2 probabilities over the other volcanoes in

485 Costa Rica (white polygons in Fig. 2).

486 **3.2 Tree core isotopes**

487 Bulk wood $\delta^{13}C$ measurements of all samples in this study, independent of exposure, ranged from -24.03 to -28.12 ‰,

488 with most being clustered around -26 ‰ (Fig. 4). A 5-bin histogram of all $\delta^{13}C$ measurements shows a slightly right-

489 skewed unimodal normal distribution, with an average of -26.37 ‰ and a standard deviation of 0.85 ‰. *A. acuminata*

490 and *O. xalapensis* have nearly identical averages (-26.14 and -25.97 ‰, respectively), while *B. nitida* has a noticeably

491 lighter average of -27.02 ‰. Diffuse excess CO_2 emissions throughout the investigation areas reflect a deep volcanic

492 source which typically varies little in time (Epiard et al., 2017), but such diffuse emissions spatially follow geological

493 subsurface structures (Giammanco et al., 1997). Their temporal variability therefore reflects long-term low-amplitude

494 modulation of the volcanic heavy-$\delta^{13}CO_2$ signal, and their spatial distribution is mostly constant over tree lifetimes

14

495   (Aiuppa et al., 2004; Peiffer et al., 2018; Werner et al., 2014), providing a constant long-term spatial gradient of CO_2

496   exposure to the forest canopy. Our data show that in areas where CO_2 flux is higher, the wood cores contained

497   progressively higher amounts of ^{13}C for two of the three species. Interestingly, our tree core δ^{13}C showed no

498   relationship with instantaneous stomatal conductance for any species, indicating that no stress threshold was exceeded

499   during measurement across the sample set.

3.3 Plant function (Fluorescence, Chlorophyll, Stomatal Conductance)

501   Our measurements and literature data confirm that ecosystems growing in these locations are consistently exposed to

502   excess volcanic CO_2, which may impact chlorophyll fluorescence, chlorophyll concentrations, and stomatal

503   conductance of nearby trees. After excluding visibly damaged trees, leaf fluorescence, expressed as Fv/Fm, was very

504   high in most samples. Fv/Fm ranged from 0.75 to 0.89, with most measurements clustering between 0.8 and f0.85

505   (Fig. 5). The fluorescence data has a left-skewed unimodal distribution. The leaf fluorescence (Fv/Fm) values for *A.*

506   *acuminata* had a strong positive correlation with soil CO_2 flux (r^2=0.69, p<.05), while the other two species showed

507   no correlation. No confounding factors measured were correlated with Fv/Fm for any species. In general, *B. nitida*

508   had the highest Fv/Fm values, and *A. acuminata* and *O. xalapensis* had similar values except for a few *O. xalapensis*

509   outliers. Chlorophyll concentration measurements were highly variable, ranging from 260 to 922 $\mu mol\ m^{-2}$, with an

510   average of 558 $\mu mol\ m^{-2}$ and a standard deviation of 162 $\mu mol\ m^{-2}$ (Fig. 6). Chlorophyll concentration had a

511   complicated right-skewed bimodal distribution, likely due to the noticeably different averages for each species. *A.*

512   *acuminata* and *O. xalapensis* both displayed weak correlations between chlorophyll concentration and soil CO_2 flux

513   (r^2=0.38 and r^2=0.28, respectively), but their trendlines were found to be almost perpendicular (Fig. 6). As CO_2 flux

514   increased, *A. acuminata* showed a slight increase in chlorophyll concentration, while *O. xalapensis* had significant

515   decreases in chlorophyll concentration. *B. nitida* individuals growing on steeper slopes had significantly lower

516   chlorophyll concentration measurements (r^2=0.42, p<.05) than those on gentler slopes, a trend not expressed by either

517   of the other two species (r^2=0.01 for both), demonstrating no significant influence of slope across the majority of

518   samples. Stomatal conductance ranged from 83.5 to 361 $mmol\ H_2O\ m^{-2}\ s^{-1}$, with an average of 214 $mmol\ H_2O\ m^{-2}\ s^{-1}$

519   and a standard deviation of 73.5 $mmol\ H_2O\ m^{-2}\ s^{-1}$. Distribution was bimodal, with peaks around 150 and 350

520   $mmol\ H_2O\ m^{-2}\ s^{-1}$. *A. acuminata* had a moderate positive correlation (r^2=0.51) with soil CO_2 flux, but it was not

521   statistically significant due to a lack of data points (Fig. 7) – however this is a result consistent with the observed

522   higher chlorophyll concentration (Fig. 6). The other two species displayed no correlation with soil CO_2 flux. *B. nitida*

523   had a moderate negative correlation (r^2=0.61) with slope, similar to its correlation between chlorophyll concentration

524   and slope.

4 Discussion

4.1 Long-term plant uptake of volcanic CO_2

527   Turrialba and Irazú continuously emit CO_2 through their vegetated flanks, but prior to this study it was unknown if

528   the trees growing there were utilizing this additional isotopically heavy volcanic CO_2. All tree cores with

15

Deleted: 0

Deleted: 0

Deleted: 0

Deleted: 0

533 corresponding CO_2 flux measurements were from areas proximal to the Ariete fault on Turrialba, where atmospheric

534 and volcanic $\delta^{13}C$ have significantly different values (-9.2 and -3.4 ‰, respectively) (Malowany et al., 2017). If the

535 trees assimilate volcanic CO_2 through their stomata, then we would expect wood $\delta^{13}C$ to trend towards heavier values

536 as diffuse volcanic CO_2 flux increases. Studies at FACE sites have found that altering the isotopic composition of the

537 air by artificially adding CO_2 with a different carbon isotope composition than the atmosphere leads to significant

538 changes in the $\delta^{13}C$ value of plant matter and tree rings growing there, leading us to expect similar effects from the

539 naturally added volcanic CO_2 (Körner, 2005). It is worth noting that the FACE CO_2 ($\delta^{13}C$ = -29.7 ‰), is significantly

540 depleted in ^{13}C compared the atmosphere whereas volcanic CO_2 is enriched ($\delta^{13}C$ = -3.4 ‰ at Turrialba) compared to

541 atmosphere (Körner, 2005). After excluding damaged samples and stressed trees, $\delta^{13}C$ was strongly correlated with

542 soil CO_2 flux for both *B. nitida* and *O. xalapensis* (Fig. 4). *A. acuminata* did not have a statistically significant

543 correlation between soil CO_2 flux and $\delta^{13}C$, likely because it had the fewest data points and a minimal range of CO_2

544 and $\delta^{13}C$ values. The difference in regression slope between *B. nitida* and *O. xalapensis* (Fig. 4) may be due to

545 physiological differences across traits or species, and/or due to differences in exposure owing to canopy height

546 differences. Resolving this question would require a much larger multi-species sample size which could only be

547 sufficiently obtained using remote sensing methods. The strong positive correlations between CO_2 flux and

548 increasingly heavy $\delta^{13}C$ values suggest that the trees have consistently photosynthesized with isotopically heavy

549 excess volcanic CO_2 over the last few years and are therefore growing in eCO_2 conditions. Assuming that most of the

550 variations in $\delta^{13}C$ are caused by incorporation of heavy volcanic CO_2, we can calculate the average concentration of

551 the mean volcanic excess CO_2 in the air the plants are exposed to, with a mass balance equation (Eq. 2):

552
$$C_v = \frac{(\delta_b - \delta_t)}{(\delta_a - \delta_v)} C_a \tag{2}$$

553 where C_v is the mean volcanic excess component of the CO_2 concentration in air, C_a is the atmospheric "background"

554 (i.e., non-volcanic) CO_2 concentration, δ_a is atmospheric $\delta^{13}C$, δ_b is the most negative $\delta^{13}C$ measurement for the species

555 being studied, δ_t is the $\delta^{13}C$ value for the tree that volcanic CO_2 exposure is being calculated, and δ_v is $\delta^{13}C$ of the

556 volcanic CO_2. Background wood $\delta^{13}C$ is the value of the point for each species with the lowest CO_2 flux (Fig. 4), and

557 the other wood $\delta^{13}C$ measurement is any other point from the same species. Values for δ_v, δ_a, and C_a are taken from

558 Malowany et al., 2017. For the tree core with the highest measured CO_2 flux for *O. xalapensis*, this equation yields a

559 mean excess volcanic CO_2 concentration of 115 ppm, bringing the combined mean atmospheric (including volcanic)

560 CO_2 concentration tree exposure to potentially around ~520 ppm. For *B. nitida* this equation yields 133 ppm of mean

561 excess volcanic CO_2 at the highest flux location, for a combined total mean of potentially ~538 ppm CO_2. These

562 numbers may be on the high side as the calculation assumes that carbon isotope discrimination remains constant for

563 all trees within a given species, but they serve as estimate of the approximate magnitude of the average amount of

564 CO_2 that these trees are exposed to. A ^{14}C tree ring study at Mammoth Mountain found an average yearly volcanic

565 excess CO_2 exposure of 20-70 ppm over a 15-year period (Lewicki et al., 2014). Turrialba is significantly more active

566 than Mammoth Mountain, so trees growing in high emission areas of Turrialba may be exposed to similar or higher

567 amounts of CO_2 than the tree in the Mammoth Mountain study. Additional measurements of tree core $\delta^{13}C$ and

568 associated soil CO_2 fluxes would help corroborate our observations, which were based on a limited number of data

16

571 points. Though tree ring ^{14}C content in volcanically active areas has been linked to variations in volcanic CO_2
572 emissions, and comparing patterns of δ^{13}C to ^{14}C measurements for the same wood samples could provide additional
573 confirmation of this finding (Evans et al., 2010; Lefevre et al., 2017; Lewicki et al., 2014), this additional dimension
574 was outside the scope of this exploratory study. However, beyond such pattern confirmation, using ^{14}C dating of trees
575 exposed to naturally isotopically distinct excess CO_2 is, in fact, unfortunately not a reliable method for these
576 environments due to the well-known δ^{14}C deficiency in trees exposed to excess volcanic CO_2 which is isotopically
577 "dead" with respect to ^{14}C, creating spurious patterns that preclude dating by ^{14}C (e.g., Lefevre et al., 2017; Lewicki
578 et al., 2014).

579 Our data demonstrate that CO_2 fluxes through the soil may be a representative relative measure for eCO_2
580 exposure of overlying tree canopies. Forest canopy exposure to volcanic CO_2 will vary over time, as will volcanic
581 eCO_2, once emitted through the soil into the sub-canopy atmosphere, the gas experiences highly variable thermal and
582 wind disturbances which significantly affect dispersion of CO_2 on minute to minute, diurnal, and seasonal timescales
583 (Staebler and Fitzjarrald, 2004; Thomas, 2011). These processes cause in-canopy measurements of CO_2 concentration
584 to be highly variable, making instantaneous concentration measurements in a single field campaign not representative
585 of long-term relative magnitudes of CO_2 exposure. Soil CO_2 fluxes are less tied to atmospheric conditions, and are
586 primarily externally modulated by rainfall which increases soil moisture and therefore lowers the soil's gas
587 permeability (Camarda et al., 2006; Viveiros et al., 2009). These fluxes can also be affected by variations in barometric
588 pressure, but both of these factors are easily measurable and therefore can be factored in when conducting field work
589 (Viveiros et al., 2009). Assuming the avoidance of significant rainfall and pressure spikes during sampling
590 (measurements were conducted in the dry season and no heavy rains or significant meteorological variations in
591 pressure occurred during field work), measuring the input of CO_2 into the sub-canopy atmosphere as soil CO_2 fluxes
592 is therefore expected to better represent long-term input and exposure of tree canopies to eCO_2 than direct
593 instantaneous measurements of sub-canopy CO_2 concentration. Previous studies at Turrialba have shown that local
594 volcanic CO_2 flux is relatively constant on monthly to yearly timescales (de Moor et al., 2016). Therefore, current soil
595 CO_2 fluxes should give relatively accurate estimates of CO_2 exposure over time. This paper corroborates that
596 expectation by demonstrating strong spatial correlations between volcanically enhanced soil CO_2 emissions with co-
597 located stable carbon isotope signals of these emissions documented in the trees' xylem.

598 A study at the previously mentioned Mammoth Mountain tree kill area examined the connection between
599 δ^{13}C and volcanic CO_2 fluxes, but focused on the difference between trees killed by extreme CO_2 conditions and those
600 that were still alive (Biondi and Fessenden, 1999). They concluded that the changes in δ^{13}C that they observed were
601 due to extreme concentrations of CO_2 (soil CO_2 concentrations of up to 100%) impairing the functioning of root
602 systems, leading to closure of stomata and water stress (Biondi and Fessenden, 1999). CO_2 does not inherently harm
603 trees, but the extreme CO_2 concentrations (up to 100% soil CO_2) at the Mammoth Mountain area caused major soil
604 acidification, which led to the tree kill (McGee and Gerlach, 1998). We have evidence that those acidification
605 processes are not affecting our δ^{13}C measurements, and that variations in our δ^{13}C measurements are more likely to
606 be caused by direct photosynthetic incorporation of isotopically heavy volcanic CO_2. Our δ^{13}C measurements have no

Formatted: Font: (Default) Times New Roman, 10 pt, Subscript

statistically significant correlation with stomatal conductance, which suggests that our heavier $\delta^{13}C$ measurements are not linked to stomatal closure. None of the trees included in the analysis (displayed obvious signs of stress, from water or other factors, as indicated by their high fluorescence and chlorophyll concentration values and lack of visible indicators of stress; specifically, our values of Fv/Fm ~0.8 indicate that PSII was operating efficiently in most of the trees we measured (Baker and Oxborough, 2004). The Mammoth Mountain tree kill areas have several orders of magnitude higher CO_2 fluxes (well over 10,000 g m^{-2} day^{-1}) than the areas we sampled (up to 38 g m^{-2} day^{-1}), making it much more likely that stress from soil acidification would be causing stomatal closure and affecting wood $\delta^{13}C$ measurements at Mammoth Mountain (Biondi and Fessenden, 1999; McGee and Gerlach, 1998; Werner et al., 2014). In contrast, most of the diffuse degassing at Turrialba does not lead to soil acidification or pore space saturation, as is evident in our own and others' field data (e.g., Epiard et al 2017). Thus, changes in our $\delta^{13}C$ values are best explained by direct photosynthetic incorporation of isotopically heavy volcanic CO_2. To the best of our knowledge, this is the first time that a direct correlation between volcanic soil CO_2 flux and wood $\delta^{13}C$ has been documented. Future studies should explore this correlation further, as our findings are based on a limited sample size.

4.2 Short-term species response to eCO₂

Short-term plant functional responses at the leaf level to elevated CO_2 were highly species-dependent. *B. nitida* had no statistically significant functional responses to soil CO_2 flux and *O. xalapensis* only had a weak negative correlation between soil CO_2 flux and chlorophyll concentration (Fig. 6.). *A. acuminata*, a nitrogen fixing species, was the only species with a consistent and positive functional response to elevated CO_2, displaying a strong positive correlation with fluorescence and a weak positive correlation with chlorophyll concentration and stomatal conductance (Figs. 5-7). Previous studies which linked changes in NDVI to pre-eruptive volcanic activity on the flanks of Mt. Etna and Mt. Nyiragongo support our observation of a correlation between plant function and volcanic CO_2 flux (Houlié et al., 2006; Seiler et al., 2017). This link raises the question of why only one of three species displayed strong functional responses to volcanic CO_2. The lack of response in *B. nitida* and *O. xalapensis* could be due to nitrogen limitation, a factor that would not affect *A. acuminata* due to its nitrogen fixing capability. Previous studies have found that nitrogen availability strongly controls plant responses to both naturally and artificially elevated CO_2 concentrations in a variety of ecosystems, including grasslands and temperate forests (Garten et al., 2011; Hebeisen et al., 1997; Lüscher et al., 2000; Norby et al., 2010; Tognetti et al., 2000). Nitrogen limitation has been posited to be an important factor in tropical montane cloud forests and may be contributing to the lack of responses in *B. nitida* and *O. xalapensis* (Tanner et al., 1998). Due to the exploratory nature of our study, we do not have a large enough dataset to conclude that the nitrogen fixing capability of species like *A. acuminata* is the cause for its positive response to volcanically elevated CO_2 concentrations, as has been speculated before (Schwandner et al., 2004), but it is a possible correlation that deserves further investigation.

4.3 Time constraints

To support these results, we further assessed the possibility of effects of time constraints on growth rates and isotopic signals, despite the compelling spatial variability of the independent variable (naturally isotopically labelled excess

648 volcanic CO_2) in our study (Helle and Schleser, 2004; Verheyden et al., 2004). As tropical trees typically lack tree
649 rings, it is difficult to directly constrain the precise time period that the data represent. However, since we sampled
650 from the outside in, all the samples appear to at least have the most recent growth period in common. To assess how
651 far back in time our samples could likely represent, we compared our sampled core depths to reported growth rates
652 for the same species in similar environments. Reported growth rates for two of our species, *O. xalapensis* and *A.*
653 *acuminata*, range from 0.25 - 2.5 cm y-1 and 0.6 - 0.9 cm y-1, respectively (Kappelle et al., 1996; Ortega-Pieck et al.,
654 2011). Given that our samples are bulk measurements of the outer 5 cm of wood, each sample would represent between
655 2 and 5.5 years, although the conditions that these growth rates were measured in were different than in our study.
656 Clear time constraints would be necessary for higher resolution analysis, but this need is somewhat mitigated by the
657 continuous, long-term, and over multiple decades mostly invariant nature of diffuse volcanic CO_2 emissions, which is
658 completely independent of any non-volcanic environmental influences on growth rates. By providing an upper and
659 lower bound in the expected growth span represented in our samples, we believe that these samples represent similar
660 time frames during the continuous exposure to excess volcanic CO_2 over the lifetimes of the trees sampled. Due to the
661 continuous nature of the volcanic CO_2 enhancement, we are not investigating and analyzing transient events, and our
662 results instead represent spatial variability in excess CO_2 availability averaged over similar time periods.

663

664 Although we do not believe our samples represent a long enough time period for long term variations in $\delta^{13}C$ (Seuss
665 effect) to be relevant, if it does affect our samples it would be beneficial for detection of volcanic CO_2 as the Seuss
666 effect is gradually increasing the gap between atmospheric and volcanic $\delta^{13}C$. Since our $\delta^{13}C$ values likely represent
667 several years of growth, small scale temporal variations in excess volcanic CO_2 release are unlikely to significantly
668 impact the results. Larger trees tend to grow slower than smaller trees, so the outer 5 cm of wood should represent a
669 longer time period on larger trees. Thus, if temporal variations had a significant effect on our $\delta^{13}C$ measurements, we
670 would expect this to be represented by some correlation between DBH and $\delta^{13}C$, which is not present for any species
671 studied. Three of the five *B. nitida* individuals measured were very large (150-190 cm DBH), whereas the other two
672 are much smaller (11.5 and 15.3 cm DBH). Although the age and growth rates of these two groups of trees likely vary
673 significantly, we found no correlation between DBH and $\delta^{13}C$; though we did find a strong correlation between the
674 completely independent diffuse excess (volcanic) CO_2 flux and wood $\delta^{13}C$. Furthermore, the relationships presented
675 are on a per species basis to avoid complications resulting from different growth rates across species. This is important
676 because $\delta^{13}C$ values provide an integral value of assimilated carbon by the entire tree (not just individual leaves). The
677 depth of tree core sample was identical for each species (the outermost part of the trunk) and we can safely assume
678 that the volcanic CO_2 exposure has been consistent over the time period under investigation.

679

680 Because individual time variability of growth rates can possibly affect these signals as well, future studies that attempt
681 to study tree ring isotopes in this context at higher resolutions will likely require stricter and more detailed time
682 constraints and cell-level stress analysis, to average out the effects of long term variations in $\delta^{13}C$ (Seuss effect),

19

683   seasonal cycles, potential short-term transient stress-induced growth rate variations, effects of water use efficiency
684   (WUE), and potential short-term variations in CO_2 flux, all of which may result in time-averaged isotopic shifts over
685   different growth periods (Helle and Schleser, 2004; Verheyden et al., 2004). We include these notes as guidance in
686   Section 4.4: Lessons Learned for Future Studies. Despite the additional difficulty of conducting higher time resolution
687   analysis, this type of study holds great potential for attempting to reconstruct volcanic CO_2 histories and to study its
688   potential fertilization effect, due to the completely independent nature of the volcanic excess CO_2 supply to the sub-
689   canopy air.

690 **4.4 Lessons Learned for Future Studies**

691   This exploratory study reveals significant new potential for future studies to utilize the volcanically enhanced CO_2
692   emissions approach to study tropical ecosystem responses to eCO_2—one of the largest uncertainties in climate
693   projections. Costa Rica's volcanoes are host to large areas of relatively undisturbed rainforest, making them ideal
694   study areas for examining responses of ecosystems to eCO_2. However, there are several challenges future studies
695   should take into consideration if attempting to expand upon this preliminary study. Given the enormous tropical
696   species diversity and the need to control for confounding factors, large datasets will be needed to answer these
697   questions conclusively. One open question for example is how WUE in upper and lower canopy leaves of same and
698   different individuals within a species may affect isotopic sequestration of CO_2. Since the excess volcanic CO_2 is
699   naturally isotopically labelled, this could be assessed by a much more detailed by-individual tree leaf, branch, and
700   xylem core study coupled with long-term measurements of evapotranspiration, heat stress, and stomatal conductance,
701   the latter of which in our study showed no significant correlation with the $\delta^{13}C$ signal in the wood cores across spatial
702   gradients. Field data can be difficult to acquire in these rugged and challenging environments. A remote sensing
703   approach using airborne measurements, validated by targeted representative ground campaigns, could provide
704   sufficiently large data sets to represent species diversity and conditions appropriately. Many of the datatypes that
705   would be useful for this type of study can be acquired from airborne platforms, and remote sensing instruments can
706   quickly produce the massive datasets required to provide more comprehensive answers to these questions. A recent
707   meta-analysis showed that studies at natural CO_2 producing springs and FACE experiments have found similar results
708   in a variety of plant traits, which significantly strengthens the case that volcanoes are a potentially extremely valuable
709   resource for determining plant responses to elevated CO_2 concentrations (Saban et al., 2019). While the spring studies
710   have yielded valuable results, volcanoes could offer several advantages over springs for future studies. Active
711   volcanoes are significantly larger systems than non-volcanic springs and often feature several CO_2-producing springs
712   and also several dry gas seeps, which offers more data, more control points to compare to, greater species diversity,
713   and greater potential for comprehensive measurements of a statistically meaningful dataset from remote sensing
714   platforms. Due to their volcanic hazards potential, volcanoes are also more likely to already have long-term
715   volcanological monitoring programs for CO_2 fluxes and ecological disturbances, which may be utilized to analyze the
716   long-term effects of enhanced levels of CO_2 emissions on these volcanically active tropical ecosystems.

726 Our results also offer significant new tools for the volcanology, where reconstructing past volcano behavior through
727 eruption histories is hampered by severe preservation gaps in the stratigraphic record. A strong link between $\delta^{13}C$ and
728 volcanic CO_2 could be a game-changer by establishing long-term histories of volcanic CO_2 emission variations. These
729 proxy signals could be traced back in time using living and preserved dead trees, in order to fill gaps in the historical
730 and monitoring records – a boon for volcano researchers and observatories to improve eruption prediction capabilities
731 (Newhall et al., 2017; Pyle, 2017; Sparks et al., 2012). While variations in tree ring ^{14}C content have been shown to
732 correlate well with variations in volcanic CO_2 flux (Evans et al., 2010; Lefevre et al., 2017; Lewicki and Hilley, 2014),
733 ^{14}C is relatively expensive to measure, limiting the spatial and temporal coverage of data that can be acquired, ^{13}C is
734 an inexpensive alternative to ^{14}C and can be measured at more laboratories, allowing for substantially more data to be
735 acquired. Some previously mentioned studies (Lefevre et al., 2017; Pasquier-Cardin et al., 1999) have found
736 correlations between ^{13}C and ^{14}C in plants that have incorporated volcanic CO_2, strengthening the potential for using
737 ^{13}C in this type of study. Further development of the ^{13}C approach to tracking volcanic CO_2 emissions would prove
738 beneficial to future studies attempting to use plants to study large areas and time scales of volcanic degassing.
739 Independent validation, and calibration by wood core dendrochronology via ^{14}C, tree rings, or chemical event tracers
740 like sulfur isotopes, could significantly advance the concept of using wood carbon as archives of past degassing
741 activity. Crucially, these tree ring archives could provide temporal records of degassing at dangerous volcanoes which
742 have previously been poorly monitored or not monitored at all, significantly improving the accuracy of hazard
743 assessments. Furthermore, knowledge of the short-term real-time response of leaves to diffusely emitted eCO_2, which
744 is more likely to represent deeper processes inside volcanoes than crater-area degassing (Camarda et al., 2012), may
745 permit the use of trees as sensors of transient changes in volcanic degassing indicative of volcanic reactivation and
746 deep magma movement possibly leading up to eruptions (Camarda et al., 2012; Houlié et al., 2006; Pieri et al., 2016;
747 Schwandner et al., 2017; Seiler et al., 2017; Shinohara et al., 2008; Werner et al., 2013). To the best of our knowledge,
748 we are the first to propose utilizing the combination of short-term leaf functional responses to volcanic CO_2 with long-
749 term changes in $\delta^{13}C$ values of wood for assessment of past and present volcanic activity in a single study.

750 **5 Conclusions**

751 Multiple areas of dense tropical forest on two Costa Rican active volcanoes are consistently and continuously exposed
752 to volcanically-elevated levels of atmospheric CO_2, diffusely cold-emitted through soils into overlying forests.
753 These isotopically heavy volcanic CO_2 emissions, which are mostly invariant, not accompanied by acidic gases, and
754 independent of processes affecting growth rates, are well correlated with increases in heavy carbon signatures in wood
755 cores from two species of tropical trees, possibly suggesting long-term incorporation of enhanced levels of
756 volcanically emitted CO_2 into biomass. Each tree studied was co-located with a soil CO_2 flux measurement and their
757 soil CO_2 flux signals vary spatially around a continuous long-term local natural excess volcanic CO_2 source, which
758 creates a local CO_2 gradient within which all the sampled trees are found. The excess volcanic CO_2 through local fault-
759 bound gas seeps provides continuous exposure to all sampled trees over time scales much greater than the lifetimes of
760 individual trees. Based on our limited exploratory measurements, confounding factors that are known to influence

769 $\delta^{13}C$ values in wood appear not to have significantly affected our measurements, indicating that the heavier wood $\delta^{13}C$
770 values could be caused by photosynthetic incorporation of volcanic excess CO_2. One of the three species studied (*A.*
771 *acuminata*) has consistent positive correlations between instantaneous plant function measurements and diffuse CO_2
772 flux measurements, indicating that short-term variations in elevated CO_2 emissions may measurably affect trees
773 growing in areas of diffuse volcanic gas emissions. These observations reveal significant potential for future studies
774 to use these areas of naturally elevated CO_2 to study ecosystem responses to elevated CO_2, and to use trees as sensors
775 of changing degassing behavior of volcanic flanks, which is indicative of deep magmatic processes.

776

777 *Data availability.* Data can be found in Table S1 and Table S2 in the supplement or can be requested from Florian
778 Schwandner (Florian.Schwandner@jpl.nasa.gov).

779

780 *Author contributions.* FMS and JBF designed the study, and RRB, FMS, JBF, and ED conducted the field work and
781 collected all samples and data with some of the equipment borrowed from GN, who helped interpret the results. TSM
782 processed the samples for analysis. JPL conducted the SO_2 analysis, wrote the related methods subsection, and helped
783 interpret the results. VY modelled the anthropogenic CO_2 emissions, wrote the related methods subsection, and helped
784 interpret the results. CAF created the combined figure showing the CO_2 and SO_2 results and assisted in writing the
785 manuscript. RRB wrote the publication, with contributions from all co-authors.

786

787 *Competing interests.* The authors declare that they have no conflict of interest.

1060
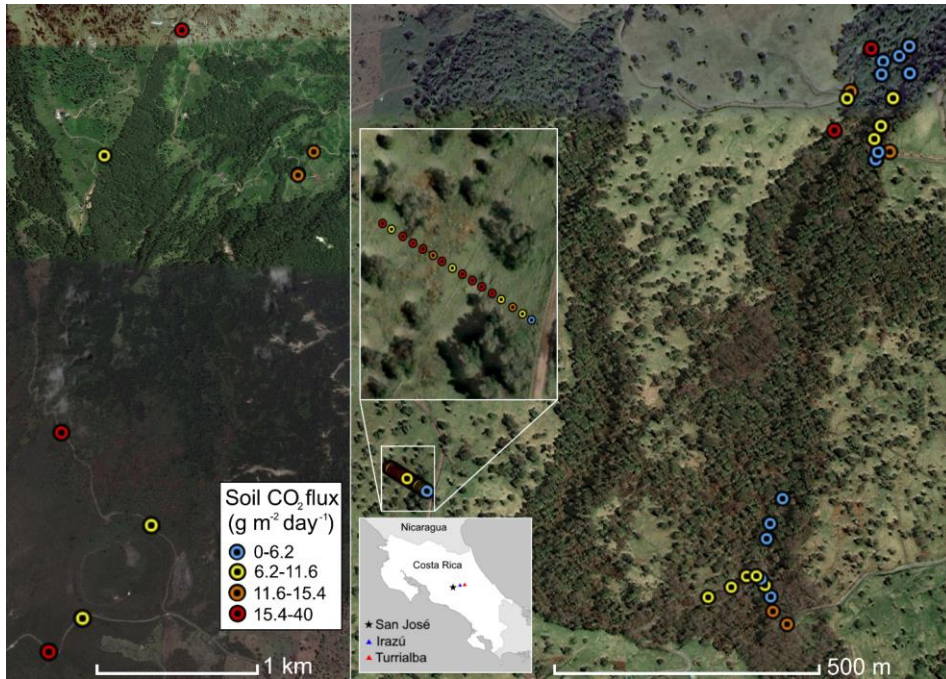

Fig. 1: Overview of measurement locations in two old-growth forests on the upper flanks of two active volcanoes in Costa Rica, Turrialba and Irazú. Distribution of mean soil CO$_2$ flux across north flank of Irazú (left) and south flank of Turrialba (right). Colors of dots correspond to flux populations (see Fig. 3).

1063

Fig. 2: The influence of two potentially confounding gases on our study area (right hand white polygon) in Costa Rica is low to non-existent: anthropogenic CO_2 from San José (blue to red color scale), and volcanic SO_2 (purple color scale). White polygons are drawn around locations of the forested active volcanic edifices in Costa Rica. The dashed red line indicates the rough border of the San José urban area. Prevailing winds throughout the year consistently blow all anthropogenic CO_2 away from our study area and from all other white polygons.
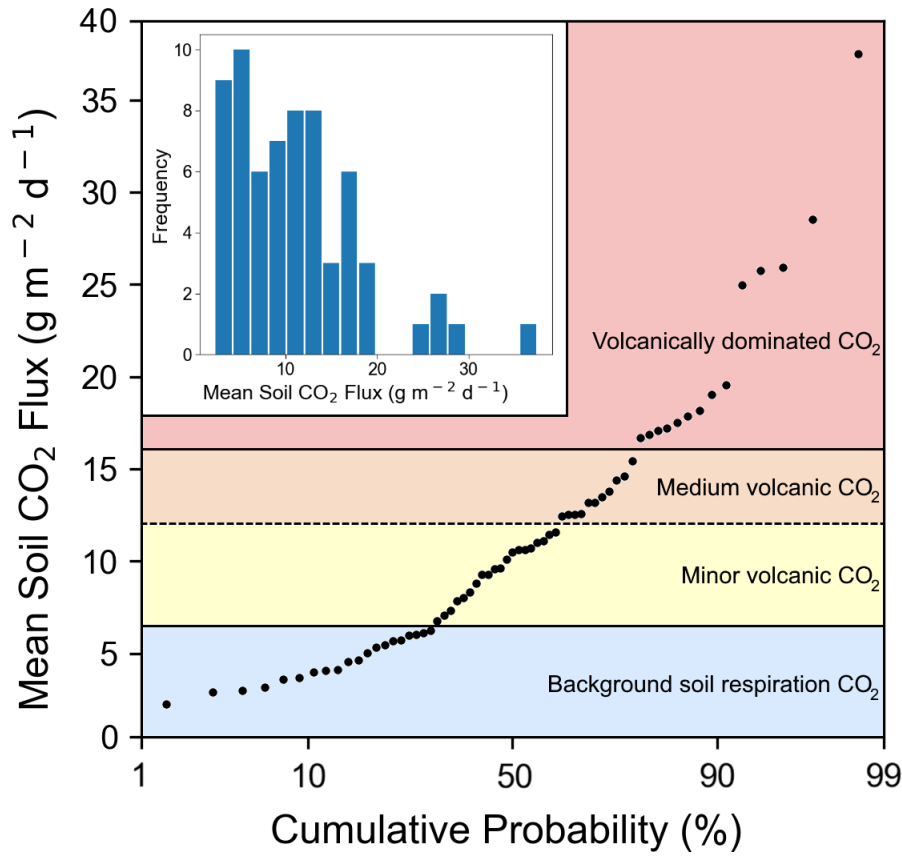

Fig 3: Soil CO₂ flux into the sub-canopy air of forests on the Turrialba-Irazú volcanic complex is pervasively and significantly influenced by a deep volcanic gas source. At least four different overlapping populations of soil CO₂ flux were identified, using a cumulative probability plot, where inflection points indicate population boundaries (Sinclair 1974). 69% of sampling locations (45 total) are exposed to varying degrees of volcanically derived elevated CO₂. Populations are color-coded based on the same color scale as Fig. 1.
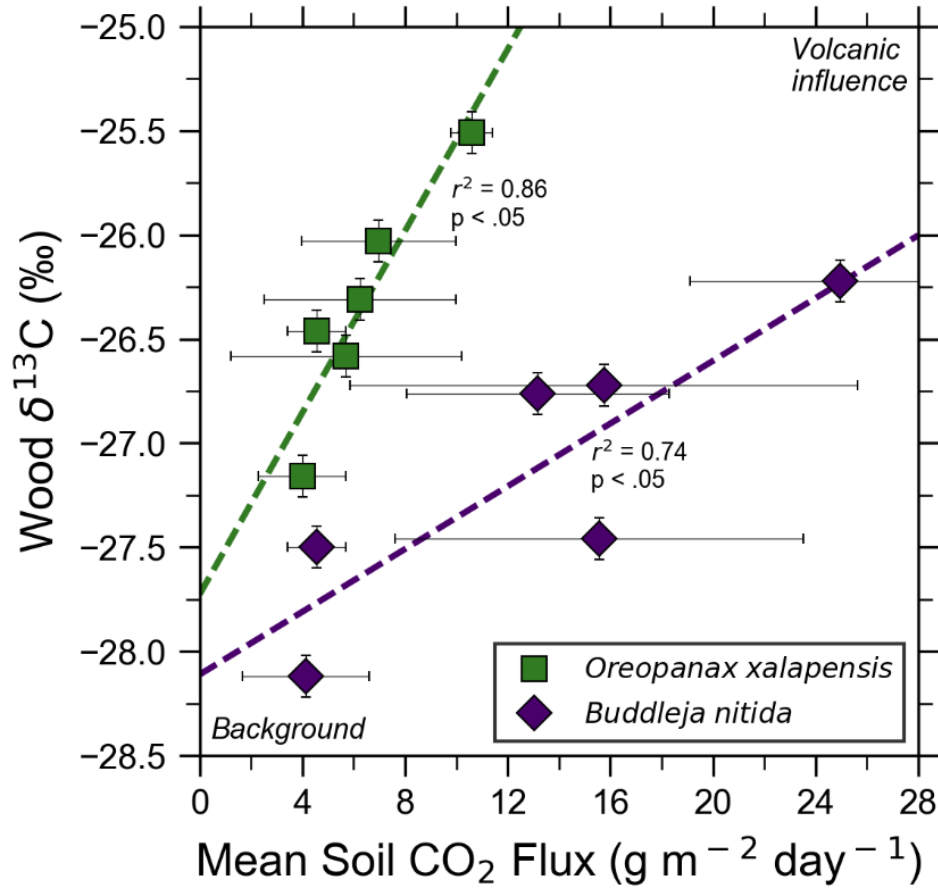

Fig 4: Bulk wood δ¹³C of trees on Costa Rica's Turrialba volcano shows strong correlations with increasing volcanic CO₂ flux for two species, *O. xalapensis* and *B. nitida*, indicating long-term photosynthetic incorporation of isotopically heavy volcanic CO₂. Stable carbon isotope ratio (δ¹³C) of wood cores are plotted against soil CO₂ flux measured immediately adjacent to the tree that the core sample was taken from. Background and volcanic influence labels apply to both axes – higher CO₂ flux and heavier (less negative) δ¹³C values are both characteristic of volcanic CO₂ emissions.
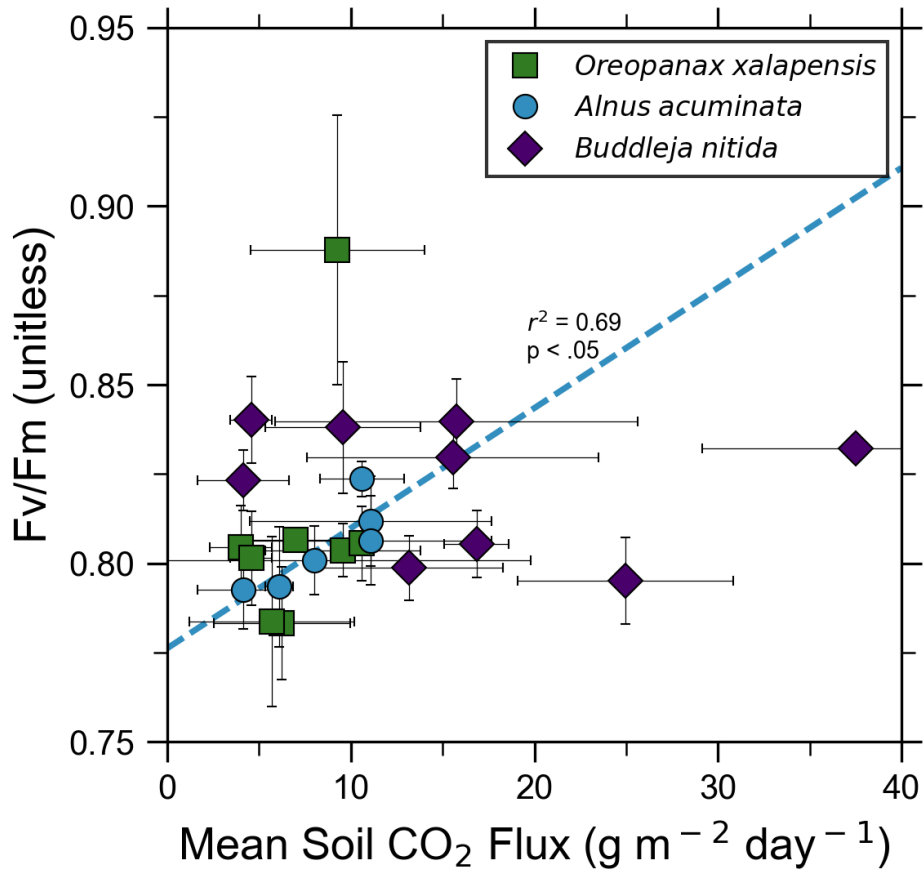

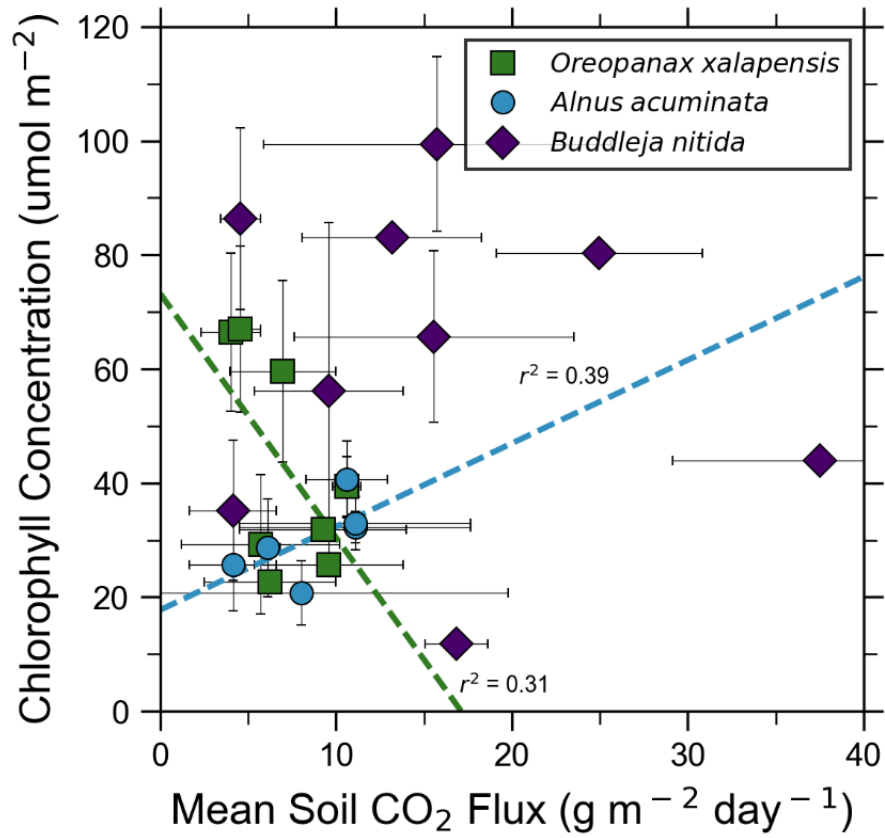

Fig. 5: Photosynthetic activity of some tree species in old-growth forests on the upper flanks of two active volcanoes in Costa Rica, Turrialba and Irazú, may show short-term response to volcanically elevated CO_2. Leaf fluorescence (Fv/Fm) and soil CO_2 flux were strongly correlated for *A. acuminata*, but not for other species.

Fig. 6: Some tree species in old-growth forests on the upper flanks of two active volcanoes in Costa Rica, Turrialba and Irazú, may express their short-term response to volcanically elevated CO_2 by producing more chlorophyll. A species that showed strong short-term response (*A. Acuminata*, Fig. 5) also shows a positive correlation between chlorophyll concentration and mean soil CO_2 flux.
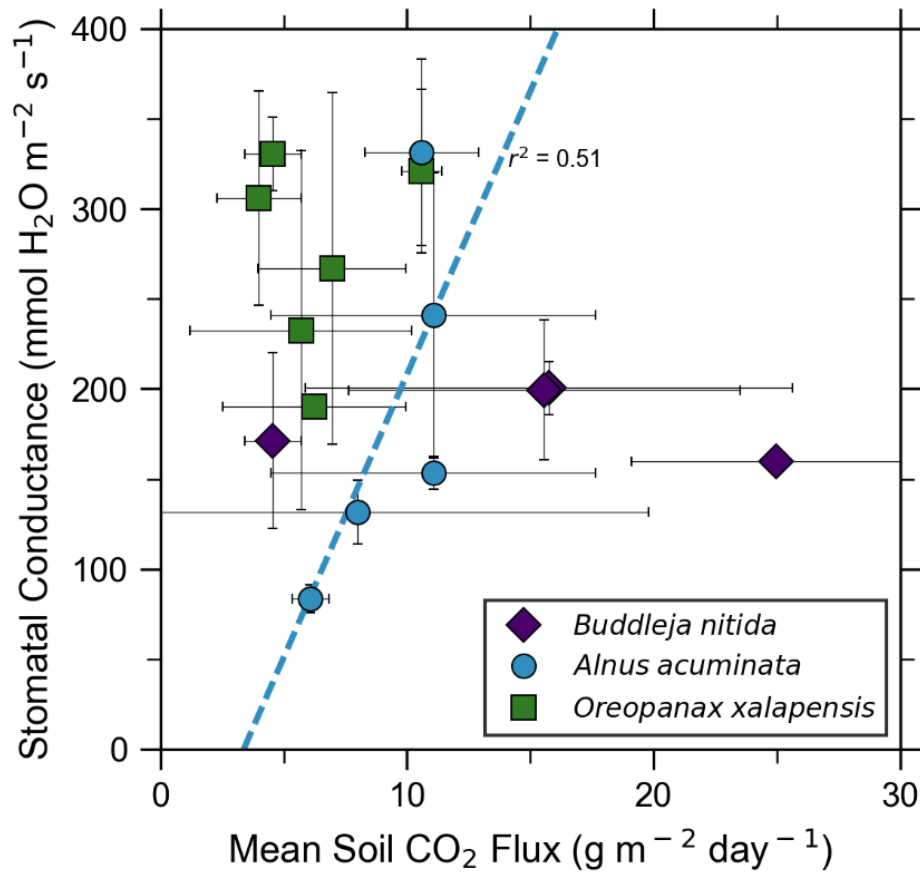

Fig. 7: Leaf stomatal conductance of a tree species that strongly responds to volcanically elevated CO_2 (Figs. 5, 6) has positive correlations with volcanic CO_2 flux, consistent with increased gas-exchange.
