Abstract. In this study we report particulate organic carbon (POC) export fluxes for different biogeochemical basins of the North Atlantic as part of the GEOTRACES GA01 expedition (GEOVIDE, May-June 2014). Surface POC export fluxes were deduced by combining export fluxes of total ^{234}Th with the POC to ^{234}Th ratio of sinking particles at the depth of export. Particles were collected in two size classes ($> 53 \mu\text{m}$ and $1\text{-}53 \mu\text{m}$) using *in-situ* pumps and the large size fraction was considered as representative of sinking material. Surface POC export fluxes revealed latitudinal variations between provinces ranging from $1.4 \text{ mmol m}^{-2} \text{ d}^{-1}$ in the Irminger basin where the bloom was close to its maximum, to $12 \text{ mmol m}^{-2} \text{ d}^{-1}$ near the Iberian Margin where the bloom had already declined. In addition to the state of progress of the bloom, variations of the POC export fluxes were also related to the phytoplankton size and community structure. In line with previous studies, the presence of coccolithophorids and diatoms appeared to enhance the POC export flux, while dominance of pico-phytoplankton cells, such as cyanobacteria, resulted in lower fluxes. The POC export to primary production (PP) ratio strongly varied regionally and was generally low ($\leq 14 \%$), except at two stations located near the Iberian margin (35%) and within the Labrador basin (38%), which were characterized by unusual low *in-situ* PP. We thus conclude that the North Atlantic during the GEOVIDE cruise was not as efficient in exporting carbon from the surface, as reported earlier by others. Finally, we also estimated the POC export at 100 m below the surface export depth to investigate the POC transfer efficiencies. This parameter was also highly variable amongst regions, with the highest transfer efficiency at sites where coccolithophorids dominated.

1. Introduction

Through the sinking of particulate biogenic material, the biological carbon pump (BCP) plays a major role on the sequestration of carbon-rich particles in the ocean interior. The North Atlantic harbors one of the most productive spring phytoplankton bloom of the world's ocean (Esaias et al., 1986; Longhurst, 2010), generating an important pulse of biogenic sinking particles (Buesseler et al., 1992; Honjo and Manganini, 1993; Le Moigne et al., 2013a),

39 which accounts up to 18% of the global BCP (Sanders et al., 2014). Yet, a substantial range of carbon export
40 efficiencies (1-47%) has been reported by earlier studies at different locations of the North Atlantic (Buesseler et
41 al., 1992; Buesseler and Boyd, 2009; Ceballos-romero et al., 2016; Herndl and Reinthaler, 2013; Lampitt et al.,
42 2008; Moran et al., 2003; Mouw et al., 2016; Thomalla et al., 2008), directly questioning about how carbon export
43 efficiency varies at a trans-Atlantic scale and what are the controlling factors.

44 The international GEOTRACES program aims to measure trace elements and isotopes along full-depth ocean
45 sections through each of the major ocean basins in order to provide maximum scientific rewards on a global scale
46 (GEOTRACES, 2006). The GEOVIDE GA01 section in the high-latitude North Atlantic (15 May - 30 June 2014;
47 R/V Pourquoi Pas?), was a French contribution to this global survey. The studied area crossed five basins
48 differentiated by their distinct biogeochemical and hydrodynamic characteristics: the Iberian basin, the west
49 European basin, the Icelandic basin, the Irminger basin and the Labrador basin (Fig.1).

50 The low nutrient availabilities (surface nitrate and silicate concentrations $< 1 \mu\text{mol L}^{-1}$; nutrient analyses according
51 to Aminot and K erouel, 2007) in the Iberian basin limits the biomass development giving the opportunity to pico-
52 phytoplankton, such as cyanobacteria, to grow (~ 35% of the total Chl-*a* at Station 13; Tonnard et al., in prep.;
53 pigment analyses according to Ras et al., 2008), a situation which is typical for the North Atlantic subtropical gyre
54 (Moore et al., 2008; Zehr and Ward, 2002). The Iberian basin can also be influenced by a local upwelling, close
55 to the Iberian margin (Costa Goela et al., 2016; Z niga et al., 2016; <http://marine.copernicus.eu/>) and potentially
56 fueling the area with nutrient-rich, but upwelling was not active during GEOVIDE (Shelley et al., 2016).

57 In the subpolar region, in the Irminger and Labrador basins, phytoplankton growth is strongly light-limited
58 seasonally (Riley, 1957) and the key parameter for alleviating these limitations is the progressive shoaling of the
59 mixed layer. There, micro-phytoplankton, such as diatoms, dominate the phytoplankton bloom ($\geq 50\%$ of the total
60 Chl-*a*; Tonnard et al., in prep.). Both basins were influenced by strong hydrodynamic features, such as the Irminger
61 gyre, the Eastern Greenland Current (EGC), the Western Greenland Current (WGC), the Labrador Current (LC;
62 Zunino et al., 2017) and the subduction of the Labrador Seawater (LSW) which was particularly intense (1700 m-
63 deep convection) during the winter 2013-2014 (Kieke and Yashayaev, 2015).

64 Between the subtropical and subpolar regions, the west European and Icelandic basins represent a transition zone
65 where nutrients and/or light can limit primary production (Henson et al., 2009). During GEOVIDE, the silicic acid
66 stock was low ($\leq 1 \mu\text{mol L}^{-1}$) leading to the growth of nano-phytoplankton, such as haptophytes including
67 coccolithophorids (between 45 and 80% of the total Chl-*a*; Tonnard et al., in prep.). This region is influenced by
68 the Eastern Reykjanes Ridge Current (ERRC) and by the North Atlantic Current (NAC) with the southernmost
69 sub-branch evolving in a cyclonic eddy and the sub-arctic front (SAF). SAF separates cold and fresh waters from
70 the subpolar region and the warm and salty waters from the subtropical region (Zunino et al., 2017).

71 The North Atlantic is thus a heterogeneous basin in terms of nutrient status, phytoplankton communities and
72 hydrodynamic features.

73 This is of a crucial importance as ecosystem structure is thought to play an important role on the BCP. Guidi et al.
74 (2009) suggested that phytoplankton composition explained 68% of the variance in POC flux at 400 m. High
75 export efficiencies are reported in productive regions where diatoms dominate, but the exported material is
76 relatively labile and prone to remineralisation leading to low transfer efficiency and low deep export flux (Guidi
77 et al., 2009). Conversely, in oligotrophic regions, where diatoms are largely absent, primary production is low and
78 mostly regenerated. Consequently, export efficiencies are low but the eventual exported material is likely less

79 prone to dissolution - remineralisation, resulting in high transfer efficiencies (Henson et al., 2012; Lam et al., 2011;
80 Lima et al., 2014; Marsay et al., 2015). Phytoplankton size structure has also been shown to be an important factor
81 in controlling the POC export fluxes. Guidi et al. (2015) highlighted that the exported POC was more refractory
82 and the remineralisation depth was deeper when the fraction of micro-phytoplankton decreased or the fraction of
83 pico-phytoplankton increased.

84 Due to the complex impact of these biogeochemical factors on the POC export and according to the distinct
85 features of each biogeochemical basin, the efficiency of the North Atlantic to transfer POC to the deep ocean
86 deserves more study.

87 In this context, we investigated POC export fluxes derived from the Thorium-234 (^{234}Th) approach along a transect
88 in the high-latitude North Atlantic, from the Iberian margin to the sub-arctic Irminger and Labrador Seas. ^{234}Th , a
89 highly particle reactive element with a short half-life (24.1 d), is widely used to explore particle export over short
90 time events such as phytoplankton blooms (Bhat et al., 1969; Buesseler et al., 1992; Coale and Bruland, 1985;
91 Cochran and Masqué, 2003). A deficit of ^{234}Th with respect to its radioactive parent ^{238}U (conservative in seawater)
92 is usually observed in the upper water column where particles sink. In the subsurface waters any excess of ^{234}Th
93 relative to ^{238}U , is taken to reflect particle break-up and remineralisation by heterotrophic bacteria and/or
94 zooplankton (Buesseler et al., 2008; Maiti et al., 2010; Savoye et al., 2004). A ^{234}Th flux can be converted into a
95 POC flux by using the POC: ^{234}Th ratio of sinking particles at the depth of export (Buesseler et al., 2006).

96 In this study, we discuss carbon export fluxes determined at the base of the deficit zone according to the
97 biogeochemical properties found in each basins, with special emphasis on the stage and intensity of the bloom as
98 well as on the phytoplankton community structure. Using estimates of primary production from shipboard
99 incubations and satellite-derived Chl-*a*, we explore surface export efficiencies at different time scales over the
100 studied area. In addition and using deep carbon export, we investigate POC transfer efficiency in the upper
101 mesopelagic.

102 2. Methods

103 2.1. Total ^{234}Th and ^{238}U

104 Total ^{234}Th activities were determined from 4 L unfiltered seawater samples collected with 12L Niskin bottles.
105 Usually, 17 or 18 depths were sampled between the surface and 1000-1500 m, except at Stations 26 and 77 where
106 only 9 and 15 depths were sampled, respectively (Table S1). Deep samples (between 1000 and 3500 m) were taken
107 for the calibration of the low level beta counting (Rutgers van der Loeff et al., 2006) based on the knowledge that
108 ^{234}Th and ^{238}U are generally in secular equilibrium at such depths (in this study, the deep ocean average $^{234}\text{Th}/^{238}\text{U}$
109 ratio = 1.00 ± 0.02 ; $n=15$). Seawater samples were processed following the method developed by Pike et al. (2005).
110 Samples were acidified at pH 2 and spiked with a ^{230}Th yield monitor in order to estimate the ^{234}Th recovery during
111 the sample processing. After 12 hours of equilibration, pH was increased to 8.5 and KMnO_4 and MnCl_2 (analytical
112 grade, Merck) were added to form a manganese oxide precipitate. After a further 12 hours of equilibration, samples
113 were filtered on quartz-microfiber discs (QMA, Sartorius, 1 μm nominal porosity, 25 mm diameter). On board,
114 filters were dried overnight, mounted on nylon holders, and covered with Mylar and aluminum foil. The activity
115 of ^{234}Th on each sample was counted using low level beta counters (RISØ, Denmark). Beta activity counting was
116 continued until a relative standard deviation (RSD) $\leq 2\%$ was reached. At the home-laboratory, residual beta

117 activity was measured for each sample after a delay of six ^{234}Th half-lives (~ 6 months) and these residual counts
118 were subtracted from the gross counts obtained on-board. All samples were then processed for Th recovery using
119 ^{229}Th as a second yield tracer. To do so, filters were dismantled from the nylon holders and transferred to clean
120 30 mL teflon vials (Savillex). All samples were spiked with ^{229}Th , dissolved in a mix of 8M HNO_3 /1M H_2O_2
121 (suprapur grade, Merck), heated overnight and filtered through Acrodisc® syringe filters (Pall, Nylon membrane,
122 nominal porosity=0.2 μm , diameter=25 mm). Part of the filtrate was pre-concentrated by evaporation and the
123 residue diluted in 1.4 M HNO_3 (suprapur grade, Merck). ^{230}Th and ^{229}Th concentrations were measured by sector
124 field inductively coupled plasma mass spectrometry (SF-ICP-MS, Element 2, Thermo Scientific) in low resolution
125 mode. Each sample was analyzed 3 times and the precision of the ^{230}Th : ^{229}Th ratios averaged 1.2% (RSD), which
126 is within the range indicated by Pike et al. (2005). The total ^{234}Th recovery, involving all the steps described above,
127 was $91 \pm 14\%$ (n=200). Uncertainty of total ^{234}Th activity, estimated from error propagation, was between 0.04
128 and 0.10 dpm L^{-1} .

129 The ^{238}U activity was deduced from salinity using the Eq. 1, given by Owens et al. (2011):

$$130 \quad {}^{238}\text{U} = 0.0786 \times S - 0.315 \quad (1)$$

131 where ^{238}U is the ^{238}U activity in dpm L^{-1} and S is salinity.

132 **2.2. Particulate ^{234}Th and POC sampling and analysis**

133 Suspended particles were collected using *in-situ* large-volume filtration (100-1600 L) systems (Challenger
134 Oceanics and McLane pumps; ISP hereafter for “*in-situ* pumps”) through paired 142 mm-diameter filters: a 53 μm
135 mesh nylon screen (SEFAR-PETEX®; polyester) and a 1 μm pore size quartz-microfiber filter (QMA, Sartorius),
136 respectively. The small size fraction (1-53 μm) is referred to hereafter as SSF and the large size fraction (> 53 μm)
137 as LSF. Prior to the cruise, filters were cleaned as follows: PETEX screens were soaked in 0.6 M HCl (Normapur,
138 Merck), rinsed with Milli-Q water, dried at ambient temperature in a laminar flow hood, and stored in clean plastic
139 bags; QMA filters were pre-combusted at 450 °C for 4 h and stored in aluminum foils until use. ISP were deployed
140 between 15 and 800 m on a stainless steel cable and the pumping time was approximatively 2-3 h (Table S2).

141 After collection, filters were processed on board. The 142 mm PETEX screen was cut into quarters using a clean
142 scalpel and two quarters were processed in this study. Particles were rinsed-off from the PETEX screen using 0.45
143 μm filtered seawater under a laminar flow hood. For one quarter of the PETEX screen, the rinsed-off particles
144 were re-filtered on a silver filter (SterliTech, porosity=0.45 μm , diameter=25 mm) and for the other quarter on a
145 GF/F filter (Whatman®, porosity=0.7 μm , diameter=25 mm). The QMA filters were sub-sampled with a perspex
146 punch of 25 mm diameter. Silver, GF/F and QMA filters were dried overnight and prepared for beta counting (see
147 section 2.1). After counting the residual beta activity (~ 6 months later), samples were prepared for POC,
148 particulate nitrogen (PN) analyses along with their $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ isotopic compositions (here we present only POC
149 data). Filters were dismantled from filter holders and fumed with HCl vapor overnight inside a glass desiccator to
150 remove the carbonate phase. Samples were dried, packed in precombusted (450 °C overnight) silver cups, and
151 analyzed with an elemental analyzer – isotope ratio mass spectrometer (EA-IRMS, Delta V Plus, Thermo
152 Scientific). Acetanilide standards were used for the calibration. The detection limits and C blanks were respectively
153 0.63 and 0.80 μmol for Ag filters (n=11) and were 0.49 and 1.52 μmol for QMA filters (n=13).

154 The POC concentrations and ^{234}Th activities compared well between silver and GF/F filter types pointing to the
 155 rather homogenous distribution of the particles on the Petex screen ($^{234}\text{Th}_{\text{GFF}} = 0.63 \times ^{234}\text{Th}_{\text{silver}} + 0.01$ with $r^2=0.88$,
 156 $p\text{-value}<0.01$ and $n=58$; and $\text{POC}_{\text{GFF}} = 0.86 \text{ POC}_{\text{silver}} + 0.08$ with $r^2=0.90$, $p\text{-value}<0.01$ and $n=58$; Fig. S1),
 157 although concentrations from GF/F filters were systematically lower than those from silver filters, most likely
 158 because of the different pore size filter (0.7 μm for GF/F filter vs 0.45 μm for silver filter).

159 2.3. Export fluxes of ^{234}Th

160 Thorium-234 activity in surface waters can be described using a simple mass balance equation (Savoie et al.,
 161 2006), which accounts for production from ^{238}U decay, ^{234}Th decay, sinking flux and transport as follow:

$$162 \quad \frac{dA_{\text{Th}}}{dt} = \lambda A_{\text{U}} - \lambda A_{\text{Th}} - P + V \quad (2)$$

163 where A_{Th} is the activity of total ^{234}Th in dpm L^{-1} ; A_{U} is the salinity-derived activity of ^{238}U in dpm L^{-1} , λ is the
 164 ^{234}Th decay constant (0.0288 d^{-1}); P is the net removal of ^{234}Th on sinking particles in $\text{dpm L}^{-1} \text{ d}^{-1}$; V is the sum of
 165 the advective and diffusive fluxes in $\text{dpm L}^{-1} \text{ d}^{-1}$.

166 Assuming steady state (constant total ^{234}Th activity with time) and neglecting the physical term V (Buesseler et
 167 al., 1992), the net export flux of particulate ^{234}Th can be determined using the following equation:

$$168 \quad P = \lambda \int_0^z (A_{\text{U}} - A_{\text{Th}}) dz \quad (3)$$

169 where P is the integrated flux of ^{234}Th from the surface to the depth z in $\text{dpm m}^{-2} \text{ d}^{-1}$. Eq. 3 has been solved for z
 170 taken as the depth (Eq) at the base of the ^{234}Th deficit zone (Eq = depth where ^{234}Th activity is back to secular
 171 equilibrium with ^{238}U) as well as for z representing the base of the primary production zone (PPZ), i.e. the depth
 172 where *in-situ* fluorescence was only 10% of its maximum value (Owens et al., 2014). The Eq depth matched
 173 relatively well with the PPZ depth, and on average, difference between both was only 16 m, with the largest
 174 difference ($\sim 60 \text{ m}$) at Stations 1, 32 and 51 (Fig. 2). Considering that there can be export (or remineralisation)
 175 below or above the PPZ depth, only the export fluxes at the Eq depth will be discussed as they represent the fully-
 176 integrated depletion of ^{234}Th in the upper waters and thus the maximal export. The validity of the assumptions
 177 used for solving Eq. 3 is discussed in Section 4.1.

178 In Section 4.1.2, we attempt to calculate the ^{234}Th fluxes at the Eq depth by using a non-steady state (NSS) model
 179 (Savoie et al., 2006), which can be described as follows:

$$180 \quad P = \lambda \left[\frac{A_{\text{U}} (1 - e^{-\lambda \Delta t}) + A_{\text{Th1}} e^{-\lambda \Delta t} - A_{\text{Th2}}}{1 - e^{-\lambda \Delta t}} \right] \quad (4)$$

181 where Δt is the time interval between two visits of a single station; A_{Th1} and A_{Th2} are the ^{234}Th activities at the first
 182 and second visits, respectively. Without time series data, the calculation should not be performed *sensu stricto*
 183 (Buesseler et al., 1992; Savoie et al., 2006) but we chose to set the initial conditions for each station, as done by
 184 Rutgers van der Loeff et al. (2011) in the South Atlantic. Satellite-derived PP data were used to estimate the starting
 185 date of the bloom (i.e., when there is a PP increase of 30% above the winter value) and ^{234}Th was assumed to be
 186 in equilibrium with ^{238}U at this time point. The time interval (Δt) for the calculations stretched from the bloom
 187 start until the sampling date. All physical terms were considered negligible.

188 To estimate the intensity of shallow remineralization, export flux was also calculated for the Eq+100 m depth
 189 horizon. In case of any ^{234}Th excess relative to ^{238}U (i.e., $^{234}\text{Th}/^{238}\text{U}$ ratio > 1) below the Eq depth due to
 190 remineralisation, export fluxes integrated until Eq+100 m will be less than when integrated until Eq. Following
 191 Black et al. (2017) the reduction of the ^{234}Th flux, R100, is expressed as:

$$192 \quad R100 = P_{\text{Eq}} - P_{\text{Eq}+100} \quad (5)$$

193 where R100 is the flux reduction in $\text{dpm m}^{-2} \text{d}^{-1}$ and P is the ^{234}Th export flux estimated at Eq or Eq+100.

194 **2.4. Scavenging fluxes of ^{234}Th**

195 To estimate the transfer rate of ^{234}Th from the dissolved to the particulate form, i.e., the scavenging flux of ^{234}Th
 196 (Coale and Bruland, 1985), we deduced the dissolved ^{234}Th activities by subtracting the particulate (SSF+LSF)
 197 from the total ^{234}Th activities, keeping in mind, though, that the sampling method for the total and particulate
 198 phases differed. Because the sampling resolution was different, total ^{234}Th data were averaged at the sampling
 199 depth of particulate ^{234}Th .

200 The mass balance equation for dissolved ^{234}Th can be written as follows:

$$201 \quad \frac{dA_{\text{Thd}}}{dt} = \lambda A_{\text{U}} - \lambda A_{\text{Thd}} - J + V \quad (6)$$

202 where A_{Thd} is the activity of dissolved ^{234}Th in dpm L^{-1} ; A_{U} and λ are defined in Eq. 2; J is the net removal flux
 203 from the dissolved to the particulate form (scavenging flux) in $\text{dpm L}^{-1} \text{d}^{-1}$; and V is the sum of the advective and
 204 diffusive fluxes in $\text{dpm L}^{-1} \text{d}^{-1}$.

205 Using again the steady state assumption (dissolved ^{234}Th activities remain constant over time) and ignoring the
 206 physical terms (V), Eq. 6 becomes:

$$207 \quad J = \lambda \int_0^z (A_{\text{U}} - A_{\text{Thd}}) dz \quad (7)$$

208 where J in $\text{dpm m}^{-2} \text{d}^{-1}$ is the net flux of scavenging integrated to the depth z. In our case, the calculation was
 209 performed at the Eq depth for comparison with the ^{234}Th export flux (P in Eq. 3).

210 The comparison between the export flux (P) and scavenging flux (J) in terms of P/J ratio (export ratio) offers a
 211 valuable metric for estimating the export efficiency of ^{234}Th . A low P/J ratio (< 0.5) indicates that the removal of
 212 dissolved ^{234}Th is controlled by sorption onto suspended particles rather than export. Conversely, a high P/J ratio
 213 (> 0.5) indicates that ^{234}Th is preferentially exported rather than adsorbed and is thus efficiently removed from the
 214 upper waters.

215 **2.5. POC: ^{234}Th ratios and POC export fluxes**

216 We estimated POC export fluxes by multiplying the ^{234}Th export flux with the POC: ^{234}Th ratio, both determined
 217 at the Eq depth. A power law fit was used to determine the POC: ^{234}Th ratios at Eq (Fig. 3). Errors of the POC: ^{234}Th
 218 ratios extrapolated at the Eq depth are deduced from the power law fit, using a root sum squared method. This
 219 error is much larger than analytical errors of both POC concentrations and particulate ^{234}Th activities. POC fluxes

220 were determined by using the POC:²³⁴Th ratios of the LSF (> 53 μm) as well as the SSF (1-53 μm) samples, and
221 both estimations were compared (Table 2).

222 The POC fluxes were between 1.1 to 1.5 fold higher when using the SSF POC:²³⁴Th ratio, except at stations 1, 26
223 and 64. However, when considering the uncertainties, POC fluxes based on SSF and LSF POC:²³⁴Th ratios were
224 not significantly different, and as we did not have the possibility to compare the POC:²³⁴Th ratios with those from
225 sediment traps, we cannot affirm that the small particles participated to the export. As large and rapidly sinking
226 particles usually drive most of the export (Lampitt et al., 2001; Villa-Alfageme et al., 2016), most of the studies
227 dedicated to POC export fluxes in the North Atlantic used the POC:²³⁴Th ratios from the LSF (see Le Moigne et
228 al., 2013b; Puigcorbé et al., 2017). Therefore, only the POC fluxes determined with the POC:²³⁴Th ratios from the
229 LSF will be discussed (Table 3).

230 **2.6. In-situ primary production**

231 In order to determine the *in-situ* daily PP, stable isotope incubations were conducted using seawater collected at
232 different euphotic zone depths selected using photosynthetically active radiation (PAR) profiles, as described in
233 more detail in Fonseca-Batista et al. (2018). At each station, seawater was sampled from 3 to 6 depths (from 54 to
234 0.2% of surface PAR) and incubated on deck with a H¹³CO₃⁻ enriched substrate. After 24 h, incubated samples
235 were filtered through microglass fiber filters (MGF, 0.7 μm porosity, Sartorius). At the home-laboratory, POC
236 concentrations and isotopic composition were analyzed by EA-IRMS and uptake rates were deduced following the
237 Hama et al. (1983) method. Daily PP was then estimated by integrating the uptake rates from the surface down to
238 0.2% of surface PAR, which was located between 48 and 116 m depending on the station. The 0.2% of surface
239 PAR depth was roughly corresponding to the Eq depth (median difference between both depths: 20 ± 13 m)
240 although, a 42 m difference was observed at Station 1. Note that at Station 51, PP was determined 24 h after the
241 sampling of the total ²³⁴Th, particulate ²³⁴Th and POC.

242 **2.7. Satellite primary production**

243 PP was also obtained from satellite data products with a 9 km spatial resolution and 8-day temporal resolution,
244 available from the Ocean Productivity website at Oregon State University
245 (http://www.science.oregonstate.edu/ocean_productivity/) and obtained from MODIS and SeaWiFS satellites.
246 Three different models can be used to obtain satellite-derived PP: the standard Vertically Generalized Production
247 Model (VGPM; Behrenfeld and Falkowski, 1997), the Eppley-VGPM (Eppley, 1972) and the Carbon-Based
248 Production Model (CbPM; Behrenfeld et al., 2005; Westberry et al., 2008). Among the model outputs, VGPM
249 derived PP (VGPM-PP) are closest to the *in-situ* PP measurements during our study (Fig. 4). Therefore, VGPM-
250 PP is used in later discussion.

251 VGPM-PP data were averaged over 5 × 5 pixel boxes corresponding to a surface area of 2025 km² (45 km×45 km)
252 centered on the different sampling stations and the VGPM-PP was averaged for the week (8 days), the month (32
253 days) and the whole productive period prior to the sampling date. The whole productive period is the period
254 between the bloom start (defined by a PP increase of 30% above the winter value) and the sampling date (Fig. 5).
255 Differences between the different VGPM-PP estimates were smaller than a factor of 1.5.

256 3. Results

257 3.1. The Iberian basin (Stations 1 and 13)

258 Stations 1 and 13 were sampled 10 to 12 weeks after the start of the bloom (Fig. 4). At these stations, PP increased
259 very early in the year (early to mid-March) and collapsed rapidly (end of March to mid-April). Within the Iberian
260 basin, low *in-situ* PP were determined (Table 3), with one of the lowest values measured at Station 1 ($33 \text{ mmol m}^{-2} \text{ d}^{-1}$) and a moderate PP at Station 13 ($79 \text{ mmol m}^{-2} \text{ d}^{-1}$; Fonseca-Batista et al., 2018; this issue).

262 In line with low *in-situ* PP, low POC concentrations and particulate ^{234}Th activities were determined in the Iberian
263 basin (Table S2). POC: ^{234}Th ratios were low in both size fractions at Station 13, while Station 1 had high ratios,
264 reaching $31 \mu\text{mol dpm}^{-1}$ in surface for the LSF (Fig. 3). Similarly, Station 13 had the lowest LSF POC: ^{234}Th ratio
265 extrapolated at Eq whereas Station 1 had one of the highest ratios (Table 3).

266 The $^{234}\text{Th}/^{238}\text{U}$ ratios were in the median of the range observed along the transect and reached minima of 0.68 and
267 0.70 in the upper 40 m at Stations 1 and 13, respectively (Fig. 2). Interestingly, these two stations vary also in their
268 total particulate ^{234}Th (sum of the SFF and LSF) over total ^{234}Th ratios with only 9% of the ^{234}Th in the particulate
269 phase at Station 1 and a ratio of 28% at Station 13 (in the median of those observed elsewhere along the transect).
270 At both stations, the ^{234}Th export fluxes at the Eq depth were slightly higher than the median value observed along
271 the transect ($1135 \text{ dpm m}^{-2} \text{ d}^{-1}$, $n=11$), reaching 1264 and $1418 \text{ dpm m}^{-2} \text{ d}^{-1}$ at Stations 1 and 13, respectively (Table
272 1). Compared to Station 1, the ^{234}Th scavenging flux was ~ 2 fold higher at Station 13 (1509 and $2898 \text{ dpm m}^{-2} \text{ d}^{-1}$,
273 respectively; Table 1). Consequently, the export ratio (P/J) was higher at Station 1, reaching 0.84, compared to
274 Station 13 (P/J ratio=0.49; Fig. 6). This indicates a balanced situation between P and J fluxes at Station 13 and a
275 more efficient export of ^{234}Th by sinking particles at Station 1.

276 Below Eq, significant excesses of ^{234}Th relative to ^{238}U (i.e., $^{234}\text{Th}/^{238}\text{U}$ ratio > 1.1) were observed at both stations,
277 indicating particle degradation (Fig. 2). However, significant shallow remineralisation was only observed at
278 Station 13 for which the R100 value was above uncertainty, reaching $410 \pm 218 \text{ dpm m}^{-2} \text{ d}^{-1}$ (Table 1). This
279 represents a flux reduction of 30% relative to the surface export flux.

280 Similarly, POC export fluxes varied between both stations with the highest (albeit with a strong associated error;
281 $12 \text{ mmol m}^{-2} \text{ d}^{-1}$ at Station 1) and one of the lowest ($2.2 \text{ mmol m}^{-2} \text{ d}^{-1}$ at Station 13) fluxes along the transect
282 observed within this basin.

283 3.2. The west European basin (Stations 21 and 26)

284 During 2014, the west European basin was the most productive with the highest PP peak observed at Station 21
285 ($403 \text{ mmol m}^{-2} \text{ d}^{-1}$), 13 days before the sampling. At Station 26, the sampling took place during a secondary PP
286 increase (Fig. 4 and 5). Altogether, sampling coincided with the bloom development in this basin, with *in-situ* PP
287 reaching 135 and $174 \text{ mmol m}^{-2} \text{ d}^{-1}$ at Stations 21 and 26, respectively (Table 3).

288 Along with high PP, relatively high surface POC concentrations and particulate ^{234}Th activities were measured
289 averaging $3.7 \mu\text{mol L}^{-1}$ and 0.2 dpm L^{-1} for the LSF and, $5.4 \mu\text{mol L}^{-1}$ and 0.5 dpm L^{-1} for the SSF (Table S2). For
290 both size fractions, POC: ^{234}Th ratios were high in the upper water column, reaching a maximum of $30 \mu\text{mol dpm}^{-1}$
291 for the LSF in surface waters at Station 21 (Fig. 3). At the Eq depth, the POC: ^{234}Th ratios for the LSF were in
292 the median of those determined along the transect ($4.4 \mu\text{mol dpm}^{-1}$, $n=11$) with nevertheless a lower ratio at Station
293 21 ($2.6 \mu\text{mol dpm}^{-1}$; Table 3).

294 The lowest $^{234}\text{Th}/^{238}\text{U}$ ratios were observed in the surface waters of the west European basin reaching minima of
295 0.57 and 0.77 at Stations 21 and 26, respectively (Fig. 2). Moreover, these low ratios were observed deeper in the
296 water column compared to the other basins. The integration of the ^{234}Th deficit from the surface to the Eq depth
297 led thus to high ^{234}Th export fluxes at both stations. The ^{234}Th export flux at Station 21 was one of the highest
298 observed along the transect, reaching $1873 \text{ dpm m}^{-2} \text{ d}^{-1}$ (Table 1). The ^{234}Th scavenging fluxes were also among
299 the highest observed along the transect, reaching 3917 and $2839 \text{ dpm m}^{-2} \text{ d}^{-1}$ at Stations 21 and 26, respectively
300 (Table 1). The resulting export ratio (P/J) was close to 0.5 for both stations, indicating a balanced situation between
301 export and scavenging fluxes.

302 Excess of ^{234}Th relative to ^{238}U below Eq, was observed at both stations, with $^{234}\text{Th}/^{238}\text{U}$ ratios reaching 1.14 at
303 300 m for Station 21 (Fig. 2; Table S1). Consequently, the R100 value at this station was significantly positive
304 ($360 \pm 255 \text{ dpm m}^{-2} \text{ d}^{-1}$; Table 1), representing a 20% ^{234}Th flux reduction.

305 Relatively high POC export fluxes at Eq were observed in the west European basin, reaching respectively 4.8 and
306 $7.9 \text{ mmol m}^{-2} \text{ d}^{-1}$ at Stations 21 and 26. For the same area, other studies reported similar POC export fluxes during
307 May (Thomalla et al., 2008), and July-August (Lampitt et al., 2008; Le Moigne et al., 2013). However, Buesseler
308 et al. (1992) report much higher POC fluxes (up to $41 \text{ mmol m}^{-2} \text{ d}^{-1}$) for April-May during the North Atlantic
309 Bloom Experiment, highlighting an important temporal variability of POC export flux in this basin (Fig. 7).

310 **3.3. The Icelandic basin (Stations 32 and 38)**

311 In general, the different fluxes in the Icelandic basin presented similar characteristics to those in the west European
312 basin.

313 The bloom period started in May, one month before the sampling and the bloom maximum occurred after the
314 cruise (Fig. 4). Nevertheless, the basin was highly productive at Station 32 with *in-situ* PP reaching $105 \text{ mmol m}^{-2} \text{ d}^{-1}$
315 and was relatively productive at Station 38 ($68 \text{ mmol m}^{-2} \text{ d}^{-1}$; Table 3 and Fig. 4 and 5).

316 POC concentrations and particulate ^{234}Th activities were relatively high, but unlike for the west European basin
317 the highest concentrations and activities were found in the SSF, reaching $5.8 \mu\text{mol L}^{-1}$ and 0.4 dpm L^{-1} , respectively
318 at Station 32 (Table S2). For surface waters of both stations, POC: ^{234}Th ratios in the SSF exceeded those in the
319 LSF (Fig. 3) but ratios were similar between the two size fractions at Eq depth (difference less than a factor of
320 1.1). The ratios extrapolated to Eq for the LSF were 3.6 and $4.2 \mu\text{mol dpm}^{-1}$ at Stations 32 and 38, respectively
321 and were in the median of the range along the transect (Table 3).

322 As for the west European basin, $^{234}\text{Th}/^{238}\text{U}$ ratios were low with station 38 having the lowest value for the whole
323 transect (0.50 in the surface; Fig. 2). Low ratios were also observed deeper in the water column and the combination
324 yielded the highest ^{234}Th export fluxes at Eq, reaching $2282 \pm 119 \text{ dpm m}^{-2} \text{ d}^{-1}$ at Station 32 (Table 1). While the
325 ^{234}Th scavenging flux was high at Station 32, reaching $3690 \text{ dpm m}^{-2} \text{ d}^{-1}$, it was much lower at Station 38 (1495
326 $\text{dpm m}^{-2} \text{ d}^{-1}$; Table 1). The export ratios (P/J) slightly exceeded the median value along the transect, reaching 0.62
327 and 0.76 at Stations 32 and 38, respectively. Despite similarities with the west European basin, the Icelandic basin
328 appeared more efficient to export ^{234}Th by sinking particles.

329 Below the Eq depth, there was no significant excess of ^{234}Th relative to ^{238}U , resulting in R100 values being close
330 or below uncertainty and indicating absence of significant shallow remineralisation.

331 One of the highest POC export fluxes along the transect was determined at Station 32, reaching $8.3 \text{ mmol m}^{-2} \text{ d}^{-1}$
332 while the POC flux at Station 38 was lower ($4.8 \text{ mmol m}^{-2} \text{ d}^{-1}$). Such POC export fluxes are lower than most values

333 reported in earlier studies, ranging from 6 to up to 52 mmol m⁻² d⁻¹ although Martin et al. (2011) reported a very
334 low value of 0.8 mmol m⁻² d⁻¹. (Ceballos-romero et al., 2016; Giering et al., 2016; Martin et al., 2011; Sanders et
335 al., 2010; Fig. 7).

336 3.4. The Irminger basin (Stations 44 and 51)

337 The ship crossed the Irminger basin one month after the beginning of the bloom and sampling occurred just 1 week
338 (Station 44) to 3 weeks (Station 51) after the peak of the bloom (Fig. 4). At sampling time, the *in-situ* PP was
339 amongst the highest observed along the whole section, reaching respectively 137 and 166 mmol m⁻² d⁻¹ at Stations
340 44 and 51. Such high values, in line with the satellite data, suggest that the bloom was still ongoing when visiting
341 these two stations (Table 3 and Fig. 4 and 5).

342 POC concentrations and particulate ²³⁴Th activities were overall highest at these two stations, reaching 17 μmol L⁻¹
343 and 1.2 dpm L⁻¹ for the SSF and 4.0 μmol L⁻¹ and 0.5 dpm L⁻¹ for the LSF at Station 44, respectively (Table S2).
344 POC:²³⁴Th ratios were moderate for both size fractions, reaching 14 μmol dpm⁻¹ for the SSF at Station 44 and 12
345 μmol dpm⁻¹ at Station 51 in the surface waters (Fig. 3). At the Eq depth, the extrapolated POC:²³⁴Th ratios were
346 similar between both size fractions at Station 51 but were 1.7 fold higher in the SSF at Station 44. The POC:²³⁴Th
347 ratio at Eq in the LSF at Station 44 fitted the median of the ranges determined along the transect, while the ratio at
348 Station 51 was relatively lower (2.9 μmol dpm⁻¹, Table 3).

349 The ²³⁴Th/²³⁸U ratios in the surface waters were higher than at other stations, reaching minima of 0.79 and 0.78 at
350 Stations 44 and 51, respectively. These low ²³⁴Th deficits were also restricted to the upper layer, especially at
351 Station 44 where the Eq depth was 40 m (Fig. 2). The particulate ²³⁴Th (sum of the SSF and LSF) contribution to
352 total ²³⁴Th ratios varied widely, from 27% at Station 51 (in the median of those observed elsewhere along the
353 transect) to 94% at Station 44. The extremely high fraction of particulate ²³⁴Th at Station 44 reflects an important
354 particle concentration in surface waters. On the other hand, this high particulate fraction in the upper layer did not
355 induce a high export flux, since Station 44 had the lowest ²³⁴Th export flux (321 ± 66 dpm m⁻² d⁻¹; Table 1) of all
356 stations. As a result, scavenging fluxes were much higher in this basin, reaching respectively 1802 and 2189 dpm
357 m⁻² d⁻¹ at Stations 44 and 51. This leads to very low P/J ratios in the Irminger basin (as low as 0.2 at Station 44),
358 suggesting that export of ²³⁴Th is particularly inefficient in this basin, in agreement with the low export flux and
359 the high particulate fraction in the upper layer.

360 Below the Eq depth, there was no significant excess of ²³⁴Th relative to ²³⁸U, reflecting no evidence for significant
361 shallow remineralisation, with R100 values being either negative or below uncertainty.

362 The Irminger basin was characterized by low POC export fluxes (1.4 and 2.7 mmol m⁻² d⁻¹ at Stations 44 and 51,
363 respectively). In the literature, a relatively large range of POC export fluxes has been reported for this basin.
364 Puigcorbé et al. (2017) observed POC export fluxes ranging from 1.5 to 43 mmol m⁻² d⁻¹. Ceballos-Romero et al.
365 (2016) also determined much higher POC fluxes compared to those observed in the present study, with differences
366 reaching factors of 27 and 19 for the month before and after our sampling, respectively (Fig. 7).

367 3.5. The Labrador basin (Stations 64, 69 and 77)

368 Stations of the Labrador basin were sampled approximatively one month after the beginning of the bloom. Station
369 64 was sampled just after a second peak of the bloom while Stations 69 and 77 were sampled one week after this
370 peak (Fig. 4). At sampling time, the *in-situ* PP was low in the Labrador basin, ranging from 27 to 80 mmol m⁻² d⁻¹

371 ¹ at Stations 69 and 77, respectively (Table 3). In agreement with the satellite data shown in Fig. 4, this indicates
372 that the decline of the bloom was ongoing in the Labrador basin.
373 POC concentrations and particulate ²³⁴Th activities were moderate to low, except at Station 77 where values were
374 higher in the surface, reaching 11 μmol L⁻¹ and 0.45 dpm L⁻¹ for the SSF, and, 3.0 μmol L⁻¹ and 0.20 dpm L⁻¹ for
375 the LSF, respectively. Moderate POC:²³⁴Th ratios were observed in both size fractions, except in the upper layer
376 at station 77 where SSF POC:²³⁴Th ratios were high (Fig. 3). At the Eq depth, POC:²³⁴Th ratios were similar in the
377 two size fractions and reached 9.2, 14 and 8.8 μmol dpm⁻¹ at Stations 64, 69 and 77, respectively. Interestingly,
378 these ratios are higher than the median ratio determined along the transect.
379 The surface ²³⁴Th/²³⁸U ratios were in the median of those observed along the transect (0.74 ± 0.06, n=8) with
380 minima of 0.78, 0.66 and 0.73 at Stations 64, 69 and 77, respectively. These ²³⁴Th deficits were nevertheless
381 observed in a relatively shallow layer (Eq depths between 40 and 80 m in this basin; Fig. 2). Stations 64 and 69
382 were also characterized by a low particulate ²³⁴Th activity (combined LSF and SSF) accounting for 10 and 15%
383 of the total ²³⁴Th activity in agreement with relatively low POC concentrations observed at these stations. The
384 ²³⁴Th export flux at Station 64 was slightly greater than those of Stations 69 and 77 but, in general, the ²³⁴Th export
385 fluxes of the Labrador basin were moderate, averaging 758 dpm m⁻² d⁻¹ (Table 1). ²³⁴Th scavenging fluxes were
386 also generally low in the Labrador basin, but with again, a slightly lower scavenging flux at Station 64 (Table 1).
387 A higher export ratio was thus estimated at Station 64 (P/J ratio = 0.75), suggesting a more efficient export close
388 to the Greenland margin compared to Stations 69 and 77 (Fig. 6).
389 Below Eq, there was a significant excess of ²³⁴Th relative to ²³⁸U at Stations 69 and 77, reaching respectively 1.08
390 and 1.11. Evidence for shallow remineralisation was also clear from the R100 values exceeding uncertainties
391 (Station 69, R100=401 ± 159 dpm m⁻² d⁻¹ and Station 77, R100=252 ± 165 dpm m⁻² d⁻¹, Table 1). The flux
392 reductions due to remineralisation below Eq were 50 and 40% of the fluxes at Eq, respectively.
393 High POC exports were observed within the Labrador basin and in particular at Station 69 where POC export flux
394 reached 10 mmol m⁻² d⁻¹. As for the Irminger basin, Puigcorbé et al. (2017) determined a low POC export (0.7
395 mmol m⁻² d⁻¹) in May, one month before our sampling period, while Moran et al. (2003) observed higher fluxes
396 reaching 47 mmol m⁻² d⁻¹ in July, one month after our sampling period (Fig. 7).

397 4. Discussion

398 In the following section, we first discuss the potential impact of the physics and the non-steady state conditions on
399 the ²³⁴Th export flux estimations. Then, temporal and regional variations of the carbon export fluxes are discussed
400 with respect to the intensity and stage of the bloom, the phytoplankton size structure and the phytoplankton
401 community. Finally, we examine carbon export and transfer efficiencies along the transect.

402 4.1. Validity of the export estimations

403 4.1.1. ²³⁴Th export fluxes under the potential influence of physical conditions

404 The GEOVIDE section sampled a diversity of dynamic regimes (Zunino et al., 2017) including continental margins
405 affected by strong zonal surface currents (LC, WGC and EGC; Mercier et al., 2015; Reverdin et al., 2003), local
406 and seasonal upwelling (close to the Iberian Margin), as well as deep convection zone in the Labrador Sea. In such
407 conditions, Eq. 3, which assumes negligible lateral and vertical advective and diffusive fluxes, may not always be

408 appropriate (Savoie et al., 2006). Whenever possible, we explore quantitatively or qualitatively, the potential
409 errors arising from neglecting physical transport in our calculation.

410 Lateral processes associated with high velocity currents and intense mesoscale activity are known to affect the
411 ^{234}Th distribution (Benitez-Nelson et al., 2000; Resplandy et al., 2012; Roca-Marti et al., 2016b; Savoie et al.,
412 2006). In our case, this may concern several stations located at or close to margins such as Stations 51 and 64,
413 which were respectively subject to the powerful East and West Greenland Currents at the Greenland Margin,
414 Station 77 under the influence of the LC on the Newfoundland Margin and Station 1 under influence of the Portugal
415 Current at the Iberian Margin (Fig. 1). However, the impact of lateral advection cannot be quantified from our
416 dataset, as the possible horizontal gradients of ^{234}Th cannot be resolved at sufficient resolution. As an alternative,
417 we compare stations close to each other such as Stations 44 and 51, both located in the Irminger Basin where
418 surface currents are strong. The Irminger basin in spring is a really patchy and dynamic area (Ceballos-romero et
419 al., 2016; Le Moigne et al., 2012; Puigcorbé et al., 2017) but the relatively high variability of the ^{234}Th fluxes
420 found at these two stations (321 and 922 dpm $\text{m}^{-2} \text{d}^{-1}$, respectively) may also indicate a potential influence of lateral
421 advection. The higher export flux at Station 51 could reflect an input of ^{234}Th depleted waters originating from the
422 Arctic and/or the Greenland shelf. However, Arctic (Cai et al., 2010; Roca-Marti et al., 2016a) and Greenland shelf
423 waters (Station 53, see Table S1) reveal very limited depletions of ^{234}Th relative to ^{238}U . Thus, it is reasonable to
424 consider that the ^{234}Th deficit at Station 51 was essentially driven by vertical rather than horizontal processes.

425 Hydrodynamic processes could also impact open ocean sites, such as stations within the west European and
426 Icelandic basins (Stations 26 and 32) which are subjected to mesoscale activity. An inverse modeling study carried
427 out for the Porcupine Abyssal Plain located in the same region, suggests that the vertical transport of ^{234}Th
428 associated with small-scale structures could represent up to 20% of the estimated vertical export flux (Resplandy
429 et al., 2012). This error is larger than our analytical uncertainty and should be kept in mind when considering the
430 export flux data in this area.

431 In upwelling systems, the contribution of vertical advection on the ^{234}Th distribution has been shown to be
432 important (Buesseler, 1998; Buesseler et al., 1995). Near the Portuguese coast, the intensity of the upwelling is
433 seasonally dependent (Costa Goela et al., 2016; Zúñiga et al., 2016) and was rather inactive at the time of the
434 GEOVIDE cruise (<http://marine.copernicus.eu/>). Therefore, the input of ^{234}Th -rich deep waters to the surface is
435 likely to be limited, as already observed in the northern Iberian margin in early summer (Hall et al., 2000).

436 Downwelling systems, such as the intense convection that occurred in the Labrador basin during the winter prior
437 to our sampling (Kieke and Yashayaev, 2015), are also likely to impact the ^{234}Th distribution. However, a strong
438 vertical advection would homogenize the ^{234}Th activities in the water column, which is not the case during our
439 study (Fig. 2). Moreover, this convection ended more than two months before our sampling, a time lag that largely
440 exceeds the ^{234}Th half-life thereby erasing any potential impact on the ^{234}Th signal. Therefore, the influence of
441 vertical advection on ^{234}Th export fluxes was neglected.

442 Finally, the contribution of the vertical diffusion was estimated using the vertical gradients of total ^{234}Th activity
443 in upper waters and a K_z value ranging between 10^{-4} and $10^{-5} \text{m}^2 \text{s}^{-1}$, as observed in the upper 1000 m between
444 Portugal and Greenland along the OVIDE transect (Ferron et al., 2014). The highest vertical diffusive flux was
445 determined at Station 69 and reached 181 dpm $\text{m}^{-2} \text{d}^{-1}$, which is in the range of the ^{234}Th flux uncertainties.
446 Therefore, the impact of the vertical diffusion has not been considered further.

447 In conclusion, hydrodynamic processes are likely to have at most a limited impact on the measured ^{234}Th export
448 fluxes.

449 4.1.2. Accounting for non-steady state conditions

450 As the cruise sampling scheme did not allow to collect samples through a time series, it was necessary to assume
451 steady state conditions (i.e., no variation of ^{234}Th activity with time). However, as documented in previous studies
452 in the west European and Icelandic basins (Buesseler et al., 1992; Martin et al., 2011), this assumption can be
453 questioned as large variations of ^{234}Th activity were observed at a time scale of one to three weeks along with the
454 onset of the seasonal biological productivity. As a consequence, the SS model was shown to poorly describe the
455 magnitude of the ^{234}Th export flux, leading to differences with the NSS model up to a factor of 3 (Buesseler et al.,
456 1992; Martin et al., 2011).

457 During the weeks preceding GEOVIDE, large changes in satellite-derived PP were observed (Fig. 4). In order to
458 evaluate the potential error introduced by the SS approach, we attempted to apply a NSS model (see section 2.3;
459 Eq. 4).

460 The west European and Icelandic basins had the highest NSS ^{234}Th fluxes ($3540 \text{ dpm m}^{-2} \text{ d}^{-1}$ at Station 32) while
461 the Irminger basin had the lowest ($516 \text{ dpm m}^{-2} \text{ d}^{-1}$ at Station 44; Table 1). The NSS ^{234}Th fluxes were either larger
462 or similar to those obtained using the SS model. This results from the fact that the NSS approach used here assumes
463 the observed ^{234}Th activity changes to only reflect a linear decrease from an initial ^{234}Th activity in secular
464 equilibrium with ^{238}U , over the time elapsed since the onset of the bloom (Δt , see section 2.3). For stations sampled
465 shortly after the start of the bloom such as in the Irminger, Icelandic and Labrador basins (Δt ranges from 23 to 43
466 days), the fluxes predicted by the NSS model are from 1.4 to 2.1 fold higher than to the SS fluxes. In the west
467 European and Iberian basins, this difference is reduced (NSS fluxes are from 1.1 to 1.3 fold higher) due to a larger
468 Δt , ranging from 48 to 78 days.

469 As a conclusion, the SS export fluxes may have underestimated ^{234}Th export fluxes at some stations by a maximum
470 factor of 2 such as in the Icelandic basin. Yet, we need to keep in mind that this NSS approach has limitations by
471 assuming the equilibrium between ^{234}Th and ^{238}U at the bloom start and by considering only an increasing deficit
472 of ^{234}Th activity over a given time period (Δt).

473 **4.2. Influence of the intensity and stage of the bloom on POC exports**

474 The GEOVIDE cruise was carried out in late spring (May-June), a period during which the productivity and the
475 carbon export can be important (Sanders et al., 2014). The ^{234}Th proxy integrates the activity deficits over a
476 timescale of several weeks preceding the sampling and it appears thus essential to compare the sampling time in
477 light of the bloom development.

478 Apart from Stations 1 and 13, which were sampled after the bloom, the different basins were sampled during the
479 spring bloom, but at different stages. One of the lowest POC export flux was determined at Station 13 in the Iberian
480 basin, where the intensity of the bloom remained rather low along the season (seasonal VGPM-PP=81 mmol m^{-2}
481 d^{-1} , Fig. 5) due to oligotrophic conditions (depleted nutrients; Fonseca-Batista et al., 2018). In contrast, the highest
482 POC export flux was determined at Station 1, also in the Iberian basin. Station 1 was sampled after the bloom
483 period and satellite-data showed this station was relatively productive in the early spring ($185 \text{ mmol m}^{-2} \text{ d}^{-1}$ in
484 March, Fig. 4). This greater POC export observed when the bloom had already declined may be caused by an

485 ecosystem change, as already described in the Southern Ocean with the emergence of silicified diatoms because
486 of nutrient stress (e.g., Baines et al., 2010; Claquin et al., 2002).

487 High POC export fluxes were also observed for the west European and Icelandic basins sampled during the bloom.
488 PP appeared maximal just before the sampling in the west European basin (Fig. 4 and 5) and could have promoted
489 these high POC exports. Within the Icelandic basin, both stations were sampled during the productive period,
490 although the peak of the bloom was not yet reached (Fig. 4), suggesting that the export maximum might have
491 occurred later in the season. Both basins have previously been characterized by the presence of fast-sinking
492 particles during the bloom (data from cruises in Spring 2012 and Summer 2009; Villa-Alfageme et al., 2016)
493 promoting the high POC export fluxes.

494 The Irminger basin was sampled close to the bloom maximum, but unlike the west European and Icelandic basins
495 the POC export flux was low there, probably reflecting accumulation of biomass preceding export. Indeed, this
496 area had the highest *in-situ* PP, a high proportion of particulate ^{234}Th in surface waters (reaching 94% of the total
497 ^{234}Th activity at Station 44) and a very low P/J ratio, indicating that ^{234}Th was retained in the upper waters rather
498 than being exported (Fig. 6; Table 1).

499 The Labrador Sea basin was sampled just shortly after the peak of PP and was characterized by low *in-situ* PP,
500 low nutrient concentrations, indicating the beginning of the decline of the bloom. The combination of the important
501 PP a few weeks before our sampling (Fig. 4 and 5) and the decline of the bloom likely triggered the high POC
502 export fluxes, as observed elsewhere (Martin et al., 2011; Roca-Marti et al., 2016b; Stange et al., 2016).

503 Overall, the magnitude of the POC export appears to depend on the degree of progress of the bloom. Indeed, the
504 negative relationship found between the POC export fluxes and the *in-situ* PP relative to the maximal VGPM-PP
505 along the season, representing the bloom stage, highlights that highest export occurs in post bloom periods (Fig.
506 8), as also evidenced from deep sediment trap studies (Lampitt et al., 2010), and is driven by large and rapidly
507 sinking aggregates (Lampitt et al., 2001; Turner and Millward, 2002).

508 **4.3. Influence of the phytoplankton size and community structure on POC exports**

509 In the North Atlantic, the phytoplankton composition varies significantly, depending on the stage of the bloom and
510 on the evolution of environmental parameters such as micro- and macro-nutrient concentrations or stratification
511 depth (Moore et al., 2005). Spatial variations in phytoplankton size structure are known to exert a control on the
512 magnitude of the POC export flux (Boyd and Newton, 1999) and high POC exports are usually related to a greater
513 size of the sinking phytoplankton cells (Aldredge and Silver, 1988; Guidi et al., 2009).

514 Within the Iberian basin, the highest abundance of pico-phytoplankton was observed at Station 13 (Tonnard et al.,
515 in prep.). These conditions are typical of the subtropical and oligotrophic waters (Dortch and Packard, 1989).
516 Villa-Alfageme et al. (2016) highlighted that small cells are usually slow-sinking particles that can be easily
517 remineralised in the upper layers. A small sinking velocity ($<100 \text{ m d}^{-1}$) allows time for bacteria and zooplankton
518 to degrade such particles, thus reducing the export flux. For the same area, Owens et al. (2014) also report a low
519 flux later in October, confirming a lower carbon export in general in this oligotrophic area. However, Station 1
520 was characterized by a greater POC export that could be related to the mixed proportion of micro-, nano- and pico-
521 phytoplankton and thus to the greater proportion of larger cells such as diatoms or haptophytes, increasing the
522 particle sinking velocity. The greater POC export there may also be related to the proximity to the margin, where
523 particle dynamics are intense and lithogenic particles are numerous (Gourain et al., 2018).

524 At higher latitudes, particle sinking velocity has been reported to be high ($>100 \text{ m d}^{-1}$; Villa-Alfageme et al., 2016),
525 as cells generally are of a larger size. Micro-phytoplankton, with dominance of diatoms, represented an important
526 fraction of the phytoplankton community in the west European, Irminger and Labrador basins and the dense
527 frustules of diatoms have been reported to act as ballast for the sinking organic matter (Klaas and Archer, 2002).
528 Fast-sinking particles could have promoted the relatively high POC export fluxes in those basins. However, in the
529 Icelandic basin, the dominance of nano-phytoplankton coincided with relatively high POC export. Both stations
530 in the Icelandic basin were dominated by haptophytes, including coccolithophorids (Tonnard et al., in prep.).
531 Despite their smaller size, the dense calcium carbonate shells of the latter could promote the export of POC
532 (Francois et al., 2002; Lam et al., 2011).
533 Our results suggest that high POC export fluxes can be mediated through either micro- or nano-phytoplankton
534 species, suggesting that sinking velocity is influenced by other parameters than the size, likely their composition
535 and density (Fig. 8).

536 **4.4. Export and transfer efficiencies of POC**

537 In order to characterize the strength of the biological carbon pump, we used two parameters: the export efficiency
538 (ThE), which is the ratio of the POC export flux at Eq over the PP (Buesseler, 1998) and the transfer efficiency
539 (T100) which is the ratio of the POC export flux at 100 m below Eq over the POC export flux at Eq (Fig. 9). Note
540 that the POC export flux at Eq+100 (Table 3) was calculated by multiplying the ^{234}Th flux at Eq+100 by the POC
541 to ^{234}Th ratio of large particles for the same depth. The POC: ^{234}Th ratio at Eq+100 was deduced from a power law
542 fit (Fig. 3).

543 Based on *in-situ* PP values (Table 3), ThE ranged from 1 (Station 44) to 38% (Station 69) with a median value of
544 7% along the transect. The highest export efficiencies were determined at Stations 1 and 69 with values reaching
545 35 and 38%, respectively. Other stations were characterized by $\text{ThE} \leq 14\%$ with highest values (7 – 14%) at
546 Stations 32, 38, 64 and 77. Export efficiencies around 10% are common in the open ocean (Buesseler, 1998). A
547 lower export efficiency can be related to important microbial and zooplankton grazing activities or to biomass
548 accumulation in surface waters (Planchon et al., 2013, 2015). A high ThE can result from many factors such as the
549 presence of large and/or dense and fast sinking particles, low surface remineralisation, active zooplankton
550 migration or nutrient stress (Ceballos-romero et al., 2016; Le Moigne et al., 2016; Planchon et al., 2013).
551 Interestingly, stations with the highest ThE were also characterized by the lowest PP (Stations 1 and 69) while
552 stations with the lowest ThE were characterized by the highest PP (Stations 44 and 51). This inverse relationship
553 between PP and ThE was significant for all stations of the GEOVIDE cruise (regression slope: -0.20; $r^2=0.58$;
554 $p<0.01$; $n=11$; Fig. S2) and has been explained in the Southern Ocean by the temporal decoupling between PP and
555 export due to biomass accumulation in surface waters (Henson et al., 2015; Planchon et al., 2013) as well as by
556 other processes such as zooplankton grazing and bacterial activity (Maiti et al., 2013; Le Moigne et al., 2016;
557 Roca-Marti et al., 2016a). Such particle recycling has also been observed in the North Atlantic (Collins et al.,
558 2015; Giering et al., 2014; Marsay et al., 2015) limiting POC export to the deep ocean. A recent study in the
559 Icelandic and Irminger basins highlights the impact of the bloom dynamics on the particle export efficiency
560 resulting in strong seasonal variability of the ThE (Ceballos-Romero et al., 2016). Our estimates are generally in
561 the lower range of export efficiencies reported by others for the North Atlantic with values ranging from 1 to 42%
562 in the western European basin (Buesseler et al., 1992; Lampitt et al., 2008; Thomalla et al., 2008), from 5 to 8%

563 in the Icelandic basin (Ceballos-romero et al., 2016), from 4 to 16% in the Irminger basin (Ceballos-romero et al.,
564 2016) and from 4 to > 100% in the Labrador basin (Moran et al., 2003). This wide range confirms that export
565 efficiencies are highly variable in the North Atlantic in late spring. The overall low export efficiency of the North
566 Atlantic is characteristic of highly productive areas of the world ocean.

567 However, it should be kept in mind that the ThE calculation is based on two parameters that are integrating
568 processes over different time scales: 24 h for *in-situ* PP and several weeks for export. Strong variability of PP
569 during this longer period would highly impact the ThE ratio. Therefore, ThE ratios were also estimated using the
570 VGPM-derived 8-day, 32-day and seasonal PP (Table 3). As seen in Section 2.7, there are no significant
571 differences between the VGPM-PP estimates regardless of the integrations times, and thus no significant
572 differences between the corresponding ThE values. Stations 1 and 69 are exceptions with ThE values decreasing
573 from 35 to 12% and from 38 to 8%, respectively, due to unusually low *in-situ* PP during our study which led to
574 over-estimated ThE.

575 Carbon transfer efficiencies (T100) ranged from 30 (Station 69) to 78% (Station 32). Generally, the fluxes at these
576 greater depths were characterized by greater error bars (see Fig. 9) due to the increasing uncertainty of the ²³⁴Th
577 fluxes with increasing depth. The highest T100 were observed within the Icelandic basin with values reaching 78
578 and 74% at Stations 32 and 38 respectively. On the contrary, the lowest T100 values were observed at Stations 1,
579 13, 21 and 69 (between 30 and 49%) highlighting greater carbon remineralisation between Eq and Eq+100 m at
580 these latter stations, as well as confirming important regional variability of the transfer efficiency as reported also
581 by others (Lam et al., 2011; Lutz et al., 2002). The low T100 (and high R100) values observed in the eastern part
582 of the transect (Stations 1, 13 and, to a lesser extent Station 21) likely reflect an important bacterial activity in
583 these warmer waters (>13°C in the upper 100 m; Iversen and Ploug, 2013; Marsay et al., 2015; Rivkin and
584 Legendre, 2001), efficiently degrading the probably slow-sinking particles. Such recycling is characteristic for
585 regeneration-based microbial food webs in oligotrophic regimes (Karl, 1999; Thomalla et al., 2006). In the
586 Icelandic basin, the high T100 may be related to the large abundance of coccolithophorids (Tonnard et al., in prep.)
587 known to enhance the POC transfer due to their ballasting effect (Francois et al., 2002; Lam et al., 2011). Indeed,
588 Bach et al. (2016) found that a bloom of coccolithophorids can increase the transfer efficiency through the
589 mesopelagic layer by 14-24%. Finally, the Labrador and Irminger basins exhibit relatively similar T100 (between
590 50 and 69%), except at Station 69 where the lowest T100 was observed. This is also in agreement with the highest
591 R100 and carbon remineralisation flux determined with the Ba_{xs} proxy (Lemaitre et al., 2018). The central
592 Labrador basin, in proximity of Station 69, was characterized by strong subduction of the LSW during the winter
593 preceding the GEOVIDE cruise. This downwelling could have promoted an important organic matter export
594 leading to important prokaryotic heterotrophic activity in mesopelagic waters. This enhanced remineralisation was
595 still observed during GEOVIDE as traced by a large mesopelagic Ba_{xs} content (Lemaitre et al., 2018).

596 5. Conclusion

597 Overall, POC export varied by a factor of ~ 9 along the transect highlighting an important spatial variation. POC
598 flux results obtained from other studies in the North Atlantic range from similar to up to 27 times larger values,
599 with rapid changes over a month duration, confirming the large temporal variability of the POC export fluxes.

600 The magnitude of the POC export seems to be associated with the state of the bloom. Accumulation of biomass in
601 surface waters during the bloom may induce a limitation of the POC export flux while during the post bloom
602 period increasing numbers of rapidly sinking particles increases POC export.
603 The magnitude of the fluxes seems also related to the phytoplankton size and community structure. One of the
604 lowest POC export fluxes was found at the stations where pico-phytoplankton dominated the community. In
605 contrast, the areas composed by micro- and nano-phytoplankton were characterized by high POC export fluxes.
606 These areas were dominated by diatoms or coccolithophorids, known to strongly ballast the POC export fluxes.
607 This suggests that the size as well as the composition and density of the particles likely play an important role on
608 the particulate sinking velocities and thus on the magnitude of the POC export fluxes.
609 For most stations, the fraction of primary production that is exported from the surface zone (export efficiency) was
610 $\leq 14\%$, which is in agreement with the global ocean export efficiency ($\sim 10\%$; Buesseler, 1998). Export efficiency
611 was also inversely related to primary production, indicating that the North Atlantic during our study behaved like
612 most of the highly productive areas of the world's ocean, with a low export efficiency. Finally, the fraction of POC
613 that is not remineralised in the mesopelagic zone (transfer efficiency) fits within the range of measured transfer
614 efficiencies reported elsewhere (e.g., Black et al., 2017; Buesseler and Boyd, 2009). The highest transfer
615 efficiencies were determined at the stations where coccolithophorids dominated.

616 **Acknowledgements**

617 We would like to thank the captain and the crew of the R/V Pourquoi Pas?, the chief scientists Pascale Lherminier
618 and Géraldine Sarthou, as well as Fabien Perault and Emmanuel De Saint Léger (CNRS DT-INSU), Pierre
619 Branellec, Michel Hamon, Catherine Kermabon, Philippe Le Bot, Stéphane Leizour and Olivier Ménage
620 (Laboratoire d'Océanographie Physique et Spatiale) for their technical expertise during ISP and CTD deployments
621 and Catherine Schmechtig for the GEOVIDE database management. We also acknowledge Emilie Grossteffan,
622 Manon Le Goff, Morgane Galinari and Paul Tréguer for the analysis of nutrients. Special thanks to Maxi Castrillejo
623 (UAB, Spain), Catherine Jeandel (LEGOS, France), Virginie Sanial (WHOI, USA), Raphaëlle Sauzède (LOV,
624 France) and Lorna Foliot (LSCE, France) for their help at sea and for the ISP coordination. We would also like to
625 thank Phoebe Lam for providing two modified McLane ISP. Laurence Monin (MRAC, Belgium), David
626 Verstraeten, Claire Mourgues and Martine Leermarkers (VUB, Belgium) greatly helped during sample processing
627 and element analysis by ICP-MS and EA-IRMS. Audrey Plante (ULB, Belgium) and Emilie Le Roy (LEGOS,
628 France) assisted with the counting of the residual Thorium-234 activities. Satellite primary production data and
629 visualizations used in this study were produced with the Ocean Productivity website at Oregon State University.

925 **Table 1:** Summary of the ^{234}Th export and scavenging fluxes using steady state (SS) and non-steady state (NSS) models. The
 926 ^{234}Th export fluxes using the SS model are calculated at the depths corresponding to the bottom of the primary production
 927 zone (PPZ), the equilibrium (Eq) depth and 100 m below Eq (Eq+100); the latter being used to estimate a remineralisation
 928 flux of ^{234}Th (R100). Negative R100 values indicate an increase of the export flux between Eq and Eq+100. Note that the
 929 depth was fixed to 100 m at Station 26 because of the lower sampling vertical resolution. Consequently, the export flux at
 930 Eq+100 and the R100 were not determined at Station 26.

Basin	Station		Export depth m	Th export (SS) dpm m ⁻² d ⁻¹	Th export (NSS) dpm m ⁻² d ⁻¹	Th scavenging (SS) dpm m ⁻² d ⁻¹

941
 942 **Figure 1:** Simplified schematic of the surface circulation in the North Atlantic (adapted from Daniault et al., 2016)
 943 superimposed with the GEOVIDE cruise track (thick grey line) and stations (colored diamonds). Main surface currents are
 944 indicated: East Greenland Current (EGC), West Greenland Current (WGC), Labrador Current (LC), Eastern Reykjanes
 945 Ridge Current (ERRC), North Atlantic Current (NAC). The Sub-Arctic Front (SAF) and the Labrador Seawater (LSW)
 946 when in surface (i.e. within the Labrador basin) are also represented. The color codes for sampled stations are also used in
 947 the following figures.

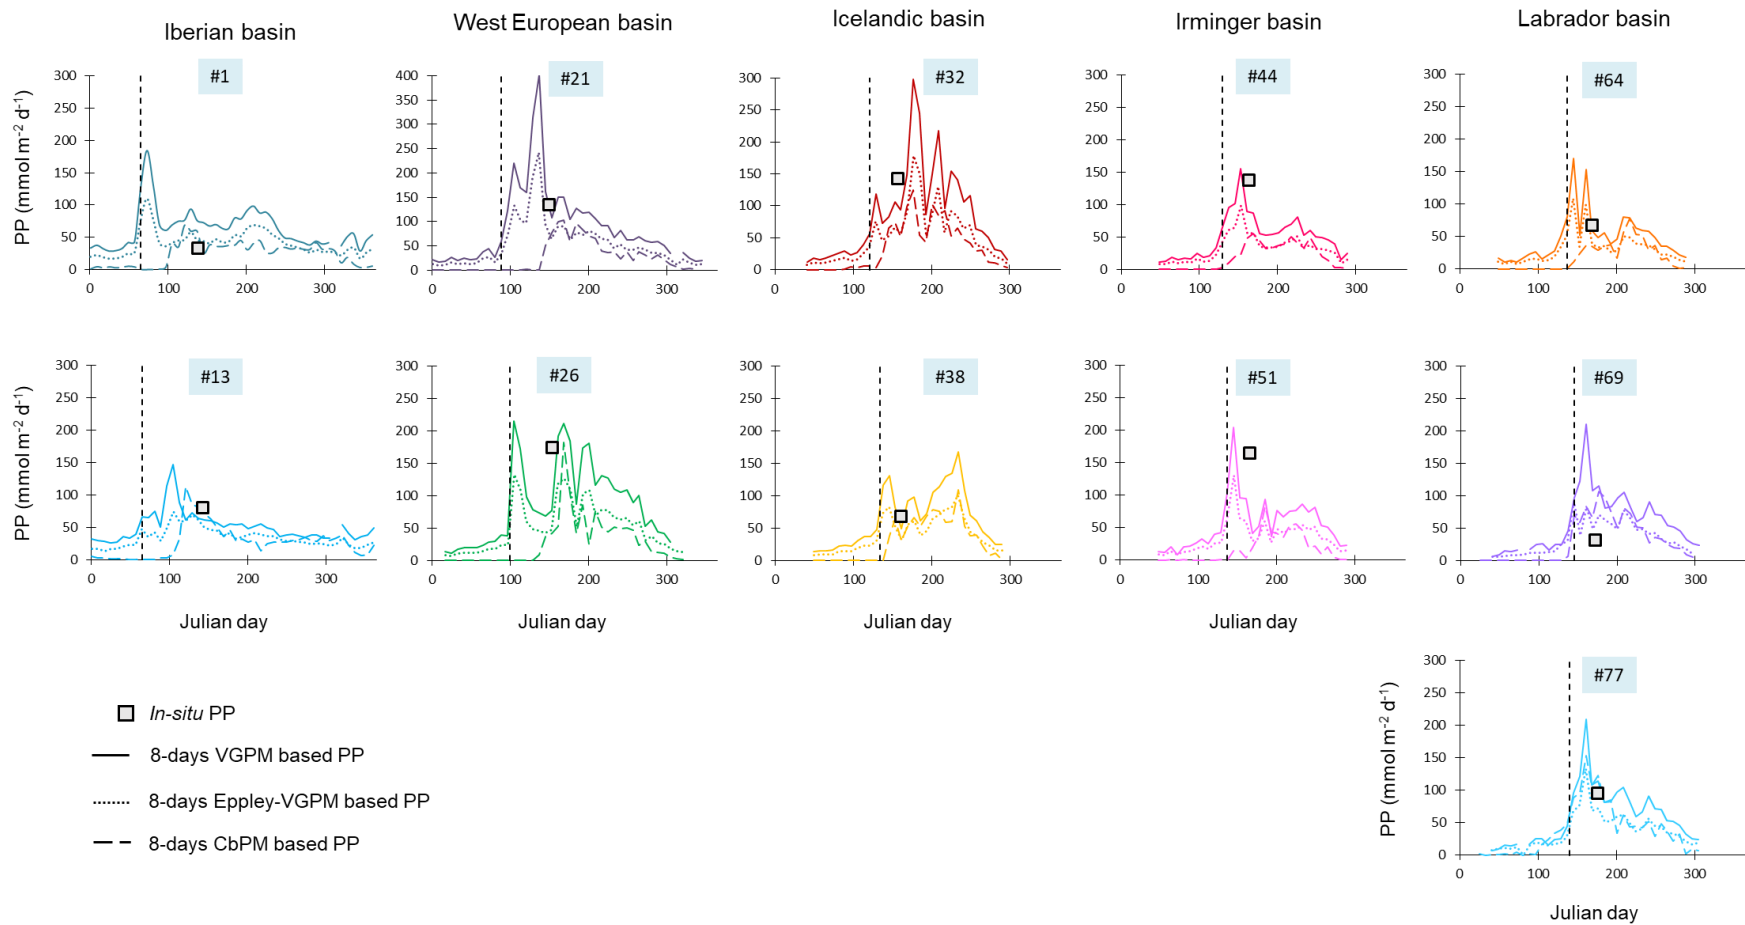

948

949 **Figure 2:** Profiles of the total ²³⁴Th (closed circles), total ²³⁸U (black dotted vertical line) and particulate ²³⁴Th activities for
 950 the small size fraction (SSF; 1-53 μm; open diamonds) and for the large size fraction (LSF; >53 μm; closed triangles). All
 951 activities are expressed in dpm L⁻¹. The horizontal black line is the Eq depth (depth where ²³⁴Th returns to equilibrium with
 952 ²³⁸U), and the horizontal green line is the depth of the PPZ (primary production zone). Error bars are plotted but may be
 953 smaller than the size of the symbols. Note that the Eq depth at Station 26 is fixed at 100 m because of the lower sampling
 954 vertical resolution.

955

956 **Figure 3:** Profiles of the POC:²³⁴Th ratios (μmol dpm⁻¹) in the SSF (open symbols) and LSF (closed symbols). The Eq depth,
 957 where ²³⁴Th is back to equilibrium with ²³⁸U, is indicated with the grey horizontal line. The thin black line represents the
 958 power law fit (POC:²³⁴Th=a×Z^{-b}) of the LSF. The median percentage errors on POC:²³⁴Th ratios are respectively
 959 representing 5 and 6% of the value for the SSF and the LSF. Error bars are plotted but may be smaller than the size of the
 960 symbols.

961

962 **Figure 4:** *In-situ* (squares) and satellite VGPM-derived (continuous lines), VGPM-Eppley-derived (dotted lines) and CbPM-derived (dashed lines) primary production (PP;
 963 in $\text{mmol m}^{-2} \text{d}^{-1}$) data at the time of our sampling and along the year 2014. The start of the bloom, defined by a PP increase of 30% above the winter value, is indicated
 964 with the black vertical dashed line.

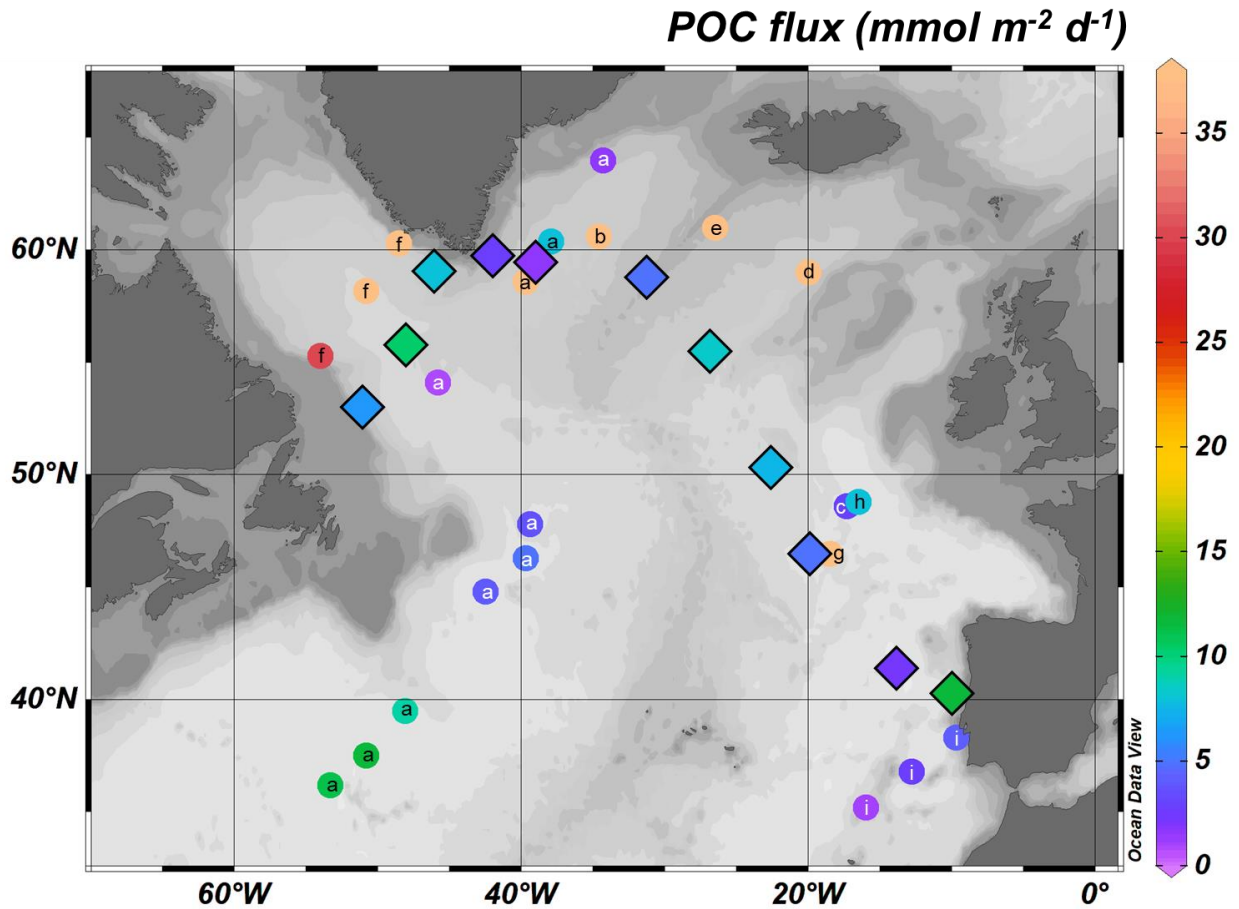

965
966
967

Figure 5: Comparison of *in-situ* and satellite VGPM (8-days, 32-days and seasonal averages) primary productivities (mmol m⁻² d⁻¹) along the GEOVIDE transect. The median of the four values is also indicated (black line).

968

969 **Figure 6:** Variability of the ^{234}Th export ratio (i.e., the ratio of the ^{234}Th export flux over the ^{234}Th scavenged flux; P/J ratio)
 970 along the GEOVIDE section.

971
 972 **Figure 7:** Comparison of the POC export fluxes from this study (diamonds with black borders) with other ^{234}Th -derived
 973 estimates of POC exports in the North Atlantic (a: Puigcorbé et al., 2017; b: Ceballos-Romero et al., 2016; c: Thomalla et
 974 al., 2008; d: Sanders et al., 2010; e: Martin et al., 2011; f: Moran et al., 2003; g: Buesseler et al., 1992; h: Le Moigne et al.,
 975 2013; i: Owens et al., 2015).
