<u>"Evolution of 231Pa and 230Th in overflow waters of the North Atlantic"</u> by Feifei Deng et al.

Response to referees

We would like to thank all referees and the editor for their time reading the revised manuscript and giving constructive suggestions to further improve the paper. We are pleased that the referees appreciate our clarification and revision of the initial manuscript, and have accepted the manuscript for publication.

As we were preparing for the final production files, we made changes to the accepted manuscript to meet the requirements for publication as outlined below. The following page and line numbers refer to those in the accepted version of the revised manuscript.

- 1. We added data availability (and the reference: Deng, F., Henderson, G., Castrillejo, M., Browning, T.J.: GEOTRACES GA01 (cruise GEOVIDE) ²³¹Pa, ²³⁰Th and ²³²Th activities, British Oceanographic Data Centre Natural Environment Research Council, UK, doi:10/cws2, 2018.), author contributions, competing interests, and special issue statements.
- 2. p.2, line18, change 'ceased' to 'ceases'.
- 3. p.3, line 5, change 'suggested' to 'have suggested'.
- 4. p.6, line25, change 'west' to 'east'.
- 5. p.7, line 24, change '238/235U' to '238U/235U'.
- 6. p.11, line 13, change 'Use' to 'Using'.
- 7. We added the reviewers, editor and Jerry McManus who have helped greatly to improve the paper in the acknowledgement section.
- 8. We replotted Figure 9 so that major units of x-axis for all panels are the same. In the original figure of the accepted manuscript, the major units of x-axis for Fig. 9 (a) and (b) (being 5) do not match those of (c) and (d) (being 10).

Evolution of ²³¹Pa and ²³⁰Th in overflow waters of the North Atlantic

Abstract. Many paleoceanographic studies have sought to use the ²³¹Pa/²³⁰Th ratio as a proxy for deep ocean circulation rates in the North Atlantic. As yet, however, no study has fully assessed the concentration of, or controls on, ²³⁰Th and ²³¹Pa in waters immediately following ventilation at the start of Atlantic meridional overturning. To that end, full water-column ²³¹Pa and ²³⁰Th concentrations were measured along the GEOVIDE section, sampling a range of young North Atlantic deep waters. Th-230 and ²³¹Pa concentrations in the water column are lower than those observed further south in the Atlantic, ranging between 0.06 and 12.01 µBq/kg, and between 0.37 and 4.80 µBq/kg, respectively. Both ²³⁰Th and ²³¹Pa profiles generally increase with water depth from surface to deep water, followed by decrease near the seafloor, with this feature most pronounced in the Labrador Sea (LA Sea) and Irminger Sea (IR Sea). Assessing this dataset using Extended Optimum Multi-Parameter (eOMP) analysis and CFC-based water mass age indicates that the low values of 230Th and 231Pa in water near the seafloor of the LA Sea and IR Sea are related to the young waters present in those regions. The importance of water age is confirmed for ²³⁰Th by a strong correlation between ²³⁰Th and water mass age (though this relationship with age is less clear for ²³¹Pa and the ²³¹Pa/²³⁰Th ratio). Scavenged ²³¹Pa and ²³⁰Th were estimated and compared to their potential concentrations in the water column due to ingrowth. This calculation indicates that more ²³⁰Th is scavenged (~80%) than ²³¹Pa (~40%), consistent with the relatively higher particle-reactivity of 230 Th. Enhanced scavenging for both nuclides is demonstrated near the seafloor in young overflow waters. Calculation of meridional transport of ²³⁰Th and ²³¹Pa with this new GEOVIDE dataset enables a complete budget for ²³⁰Th and ²³¹Pa for the North Atlantic. Results suggest that net transport southward of ²³⁰Th and ²³¹Pa across GEOVIDE is smaller than transport further south in the Atlantic, and indicates that the flux to sediment in the North Atlantic is equivalent to 96% of the production of ²³⁰Th, and 74% of the production for ²³¹Pa. This result confirms a significantly higher advective loss of ²³¹Pa to the south relative to ²³⁰Th and supports the use of ²³¹Pa/²³⁰Th to assess meridional transport at a basin scale.

Key words. GEOTRACES; water-column ²³⁰Th and ²³¹Pa; water mass ageing; scavenging; meridional transport.

1 Introduction

Several paleoceanographic proxies have been proposed that rely on the ²³¹Pa/²³⁰Th ratio in marine sediments, one of which is that ²³¹Pa/²³⁰Th may record the rate of deep-water circulation, particularly in the North Atlantic. Both ²³¹Pa and ²³⁰Th are produced in seawater at a constant rate by decay of uranium, but have decay activities much lower than their parent uranium isotopes due to rapid removal by adsorption onto sinking marine particles. Both nuclides are also reversibly scavenged, leading to particularly low concentrations at the surface and increasing concentrations with depth (Nozaki et al., 1981). Advection of surface waters to depth transports water with low concentrations of ²³¹Pa and ²³⁰Th into the deep ocean, where their concentrations subsequently increase towards an equilibrium value at a rate dependant on the residence time of the nuclide. The longer residence time of ²³¹Pa relative to ²³⁰Th (~130 years versus ~20 years, Henderson and Anderson, 2003) means that the equilibrium concentration of ²³¹Pa is closer to that expected from uranium decay, and that the time taken to reach this equilibrium is longer.

This oceanic behaviour of ²³¹Pa and ²³⁰Th suggests that their measurement in marine sediments may reveal information about the past environment, with one common use being as a recorder of deep-water circulation, particularly in the North Atlantic (e.g. Gherardi et al., 2005, 2009; McManus et al., 2004; Roberts et al., 2014; Yu et al., 1996). The interpretation of sedimentary ²³¹Pa/²³⁰Th ratios for such past ocean circulation is based on two end-member conceptual models:

Basin-scale Advection: The longer residence time of ²³¹Pa than ²³⁰Th means that deep-water contains more ²³¹Pa than ²³⁰Th relative to production from decay. Advection of deep-waters out of the North Atlantic therefore removes more ²³¹Pa than ²³⁰Th, leaving sediments in the basin with a ²³¹Pa/²³⁰Th ratio below the production ratio. If deep-water ventilation ceases, ²³¹Pa removal from the North Atlantic also ceases, and sedimentary ²³¹Pa/²³⁰Th values reach their production ratio. This approach was first proposed by Yu et al. (1996) who measured ²³¹Pa/²³⁰Th in Holocene and Last Glacial Maximum (LGM) sediments from many core-top samples from the Atlantic and Southern Ocean. They found similar Holocene and LGM values at a basin scale, suggesting broadly similar overturning during the two periods. Subsequent application to sediments from Heinrich Stadial 1, initially in a single core (McManus et al., 2004) and progressively a geographical range of cores (Bradtmiller et al., 2014). revealed reduced advection of ²³¹Pa out of the basin at that time, suggesting decreased overturning.

Water-mass Evolution: The longer residence time of ²³¹Pa means that, following ventilation, it takes longer for deep-water ²³¹Pa concentrations to reach equilibrium with respect to scavenging than is the case for ²³⁰Th. This leads to a systematic evolution of ²³¹Pa/²³⁰Th with age of the water. Sediments capture this ratio (with a fractionation due to different scavenging coefficients for the two nuclides), so capture information about the age of the water. Simple models suggest an increase of ²³¹Pa/²³⁰Th with age over about 400 years (e.g. several residence times of ²³¹Pa). This approach to interpreting sedimentary ²³¹Pa/²³⁰Th allows for the possibility of calculating flow rates for a single water mass and from a single core rather than at a basin scale. It has been pursued by (Negre et al., 2010) to assess deep-water flow in both southerly and northerly directions by comparing sediments in the North and South Atlantic, and allowed these authors to apply a simple model (Thomas et al., 2007) to calculate flow rates.

Deleted: ceased

Recent water-column measurements of ²³¹Pa and ²³⁰Th on GEOTRACES cruises shed new light on the chemical behaviour and controls on these isotopes in seawater and provided evidence to assess the validity of the models underlying the use of sedimentary ²³¹Pa/²³⁰Th as a proxy for deep-water circulation. These measurements have indicated that there is considerably more net advection of ²³¹Pa than ²³⁰Th out of the North Atlantic (Deng et al., 2014), supporting the Basin-scale Advection model for ²³¹Pa/²³⁰Th. But these measurements also have suggested that there is no simple relationship between increasing ²³¹Pa/²³⁰Th and age of water, as would be expected for the Water-mass Evolution model (e.g. Deng et al., 2014). Studies using 2-D and 3-D ocean models (e.g. Marchal et al., 2010; Siddall et al., 2007) have also supported the use of sedimentary ²³¹Pa/²³⁰Th to constrain deep-water circulation at a basin scale, and suggested that the relationship between ²³¹Pa/²³⁰Th and water mass age is more complex than assumed in earlier studies (e.g. Luo et al., 2010).

Observations and model studies of ²³¹Pa and ²³⁰Th have also suggested that other controls complicate ²³¹Pa/²³⁰Th as a dynamic tracer of deep-water circulation, such as the effect of boundary scavenging at seafloor and ocean margins (e.g. Anderson et al., 1994; Deng et al., 2014; Rempfer et al., 2017) and the influence of particle flux and composition (e.g. Chase et al., 2002; Hayes et al., 2014; Siddall et al., 2005).

To fully assess the behaviour of ²³¹Pa/²³⁰Th, and its potential as a dynamic tracer of deep-water circulation, knowledge of the concentrations and variations of these isotopes as deep waters form and enter the deep Atlantic is required. Some measurements have placed initial constraints on ²³¹Pa and ²³⁰Th values in young North Atlantic deep waters (e.g. Moran et al., 1997, 2002; Rutgers van der Loeff and Berger, 1993), but there has not yet been a systematic study of the composition of waters in the far north Atlantic. The GEOVIDE cruise allowed waters to be collected for such a study, along a line where significant other data are available, both from that cruise and previous occupations of OVIDE. GEOVIDE provided an ideal opportunity to understand ²³¹Pa and ²³⁰Th at the start of the ocean meridional overturning circulation, and to assess the hypotheses underlying the use of ²³¹Pa/²³⁰Th as a paleo-proxy for the rate of deep-water circulation.

2 Sampling strategies and analytical methods

as part of GEOTRACES Section GA01. The cruise sampled four regions in the North Atlantic between 40°-60°N: Labrador Sea (LA Sea), Irminger Sea (IR Sea), Iceland Basin (IC Basin), and Western European Basin (WE Basin) (Fig. 1). Full-depth water-column ²³¹Pa and ²³⁰Th for this study were collected from 11 stations (Fig. 1). Sampling followed the procedure suggested by GEOTRACES intercalibration work (Anderson et al., 2012). Briefly, seawater samples of 5 Litres were directly filtered from Niskin bottles mounted on the Stainless Steel CTD Rosette through AcroPakTM capsules with Supor® Membrane (0.45 µm pore size). Filtered seawater samples were collected into acid cleaned HDPE plastic bottles, and sealed with a screw cap and Parafilm to reduce evaporation and contamination. Samples were then double bagged for storage in boxes for transport back to the shore-based lab for analysis.

Seawater samples were collected during the GEOVIDE cruise aboard the R/V Pourquoi Pas? from 15 May to 30 June, 2014

Deleted: suggest

Once returned to the laboratory in Oxford, samples were weighed and then acidified with quartz distilled concentrated HCl to pH ~1.7, shaken and left for at least four days to ensure that Pa and Th was desorbed from the walls of the bottle. A mixed ²²⁹Th-²³⁶U spike and a ²³³Pa spike were then added to each sample to allow measurement of Th, U (for another study), and Pa by isotope dilution MC-ICP-MS (Multi Collector-Inductively Coupled Plasma-Mass Spectrometry). The ²³³Pa spike was freshly made by milking from ²³⁷Np (following Regelous et al., 2004) and calibrated against a known ²³⁶U solution after complete decay of ²³³Pa to ²³³U, i.e. four to five half-lives of ²³³Pa (tu/2=26.98 days, Usman and MacMahon, 2000) after spike production (Robinson et al., 2004). 50 mg of pure Fe as a chloride solution was also added to each water sample. Samples were left overnight to allow for spike equilibrium after which the pH was raised to ~8.5 using distilled NH₄OH to co-precipitate the actinides with insoluble Fe-oxyhydroxides. At least 48 hours were allowed for scavenging of the actinides onto Fe-oxyhydroxides. The precipitate was centrifuged and rinsed, and Th, Pa and U were separated using anion exchange chromatography following Thomas et al. (2006).

After chemical separation, Pa and Th were measured on a Nu instrument MC-ICP-MS at the University of Oxford. Mass discrimination and ion-counter gain were assessed with the measurement of a U standard, CRM-145 U, before each sample measurement. Use of a U standard for this purpose minimises memory problems that might be caused by use of a Th or Pa standard (Thomas et al., 2006). Measurements were also made 0.5 mass units either side of masses of interest to allow accurate correction for the effect of abundance sensitivity on small ²³¹Pa and ²³⁰Th beams, and a correction for a small ²³²ThH interference on the ²³³Pa beam is made from assessment of the hydride formation rate on a ²³²Th standard. Concentrations of ²³¹Pa, ²³⁰Th together with ²³²Th were obtained from the precise MC-ICP-MS measurement of ²³¹Pa/²³³Pa, ²³⁰Th/²²⁹Th, and ²³²Th/²³⁹Th ratios together with well-calibrated concentrations of ²³³Pa, and ²²⁹Th-²³⁶U spikes.

Chemistry blanks were assessed by conducting the complete chemical procedure on ~100 ml of Milli-Q water with each batch of samples. Based on six blank measurements, the average blanks for dissolved ²³¹Pa, ²³⁰Th and ²³²Th are 0.21±0.14 fg, 1.59±0.60 fg and 5.13±1.47 pg, respectively (uncertainties are 2 standard errors). Blank contributions account for 2-22%, 2-26%, and 0.2-16% of the dissolved ²³¹Pa, ²³⁰Th and ²³²Th respectively (with the higher values being for surface samples due to their low concentrations).

25 3 Results

Measured ²³⁰Th and ²³¹Pa concentrations were corrected for blanks, ingrowth from U in seawater since the time of sample collection, and detrital U-supported ²³⁰Th and ²³¹Pa concentrations. Measured and corrected concentrations of ²³⁰Th, ²³¹Pa, and ²³²Th, along with details of corrections, are provided in the Supplemental Information S1. Although analysis was conducted in terms of fg/kg, results are converted to the SI units adopted by GEOTRACES data product, i.e., μBq/kg for ²³⁰Th and ²³¹Pa, and pmol/kg for ²³²Th. This conversion uses half-lives for ²³¹Pa, ²³⁰Th and ²³²Th of 32,760 yr, 75,584 yr and 1.405×10¹⁰ yr, respectively (Cheng et al., 2013; Holden, 1990; Robert et al., 1969). Uncertainties were propagated, including the contribution from sample weighing, spike calibration, impurities in the spikes, blank corrections, and mass spectrometric measurement,

and are reported as 2 standard errors (2 s.e.). Average total uncertainties for 231 Pa, 230 Th and 232 Th are $\pm 0.17~\mu$ Bq/kg, $\pm 0.17~\mu$ Bq/kg, and $\pm 0.0032~\mu$ Bq/kg, respectively. Vertical profiles showing the results of corrected 230 Th and 231 Pa concentrations in the water column are plotted by region in Fig. 2.

Th-230 concentrations in the water column range between 0.06 and 12.01 μ Bq/kg, and initially generally increase with water depth from surface to deep water. Towards the seafloor, six of the eleven stations show a prominent decrease of ²³⁰Th, with this feature most pronounced in the LA and IR Seas.

Pa-231 concentrations in the water column range between 0.37 and 4.80 μ Bq/kg and also increase with water depth, but less rapidly than ²³⁰Th. ²³¹Pa profiles also often exhibit a decrease near the seafloor at stations showing a ²³⁰Th decrease. Station 38 at the Reykjanes Ridge distinguishes itself from other ²³¹Pa profiles in that an increase in ²³¹Pa concentrations from low concentrations at 1000 m is observed, continuing towards the bottom.

Observed ²³⁰Th and ²³¹Pa values at GEOVIDE are lower than those observed in inter-calibrated GEOTRACES data from further south in the Atlantic. Figure 3 compares average depth profiles for ²³⁰Th and ²³¹Pa in the west Atlantic, covering high-latitude Northwest Atlantic (from GEOVIDE, west of the Mid-Atlantic Ridge), mid-latitude Northwest Atlantic (GEOTRACES section GA03_w, Hayes et al., 2015) and Southwest Atlantic (GEOTRACES section GA02, Deng et al., 2014).

15 A southward increase of both ²³⁰Th and ²³¹Pa concentrations is observed below 1000 m.

4 Discussion

Early studies of water-column ²³⁰Th and ²³¹Pa reported a linear increase of both nuclides with water depth (e.g., Anderson et al., 1983b; Nozaki et al., 1981), and introduced a reversible scavenging model with exchange of both nuclides between their dissolved and particulate phases. Later studies observed a deviation of ²³⁰Th and ²³¹Pa profiles from this reversible scavenging model, with the expected increase with depth often inverting near the seafloor (e.g., Anderson et al., 1983a; Bacon and Anderson, 1982). This feature has been further investigated in more recent studies. Rutgers van der Loeff and Berger (1993) observed that ²³⁰Th concentrations decrease in the bottom water in the South Atlantic south of the Antarctic Polar Front and interpreted this as the influence of relatively young bottom water in the region. Okubo et al. (2012) also found decreasing ²³⁰Th values near the seafloor in the North Pacific and, in the absence of ventilation in the area, interpreted these as due to bottom scavenging. Deng et al. (2014) observed low concentrations of both ²³⁰Th and ²³¹Pa in near-bottom water coinciding with the presence of the nepheloid layer, and interpreted the low values as a result of enhanced scavenging by resuspended particles in the nepheloid layer.

In this study, recently ventilated overflow waters are sampled at depth, particularly in the Labrador and Irminger Seas. Low values of ²³⁰Th and ²³¹Pa near the seafloor might be expected to relate to these young waters, but the effects of scavenging must also be considered.

4.1 Water mass distribution and influence

The presence of multiple water masses sampled by the GEOVIDE Section allows the influence of water mass (and age) on ²³⁰Th and ²³¹Pa to be assessed. Extended Optimum Multi-Parameter (eOMP) Analysis (García-Ibáñez et al., 2018) for the GEOVIDE section maps the presence of 10 water-mass end-members in the section (Fig. 4), including three recently ventilated waters in the GEOVIDE section:

- 5 i. Labrador Sea Water (LSW), which is formed by deep convection (Talley and McCartney, 1982), is the dominant deep water along the section, extending from 1000 to 2500 m depth in the east and from surface to 3500 m in the west of the section.
 - *ii.* Iceland–Scotland Overflow Water (ISOW), which is formed in the Norwegian Sea and subsequently entrains overlying warmer and more salty waters. This water mass initially flows along the eastern flank of the Reykjanes Ridge before spreading back northwards, after crossing the Charlie-Gibbs Fracture Zone, into the Irminger and Labrador Seas (Dickson and Brown,
- 1994; Saunders, 2001). A pronounced layer of this water mass is observed immediately below the LSW, and extends as deep as 4000 m west of 20°W.
 - iii. Denmark Strait Overflow Water (DSOW), which is formed after the Nordic Seas deep waters overflow and entrains Atlantic waters (SPMW and LSW) (Yashayaev and Dickson, 2008) with dense Greenland shelf water cascading down to the DSOW layer in the Irminger Sea (Falina et al., 2012; Olsson et al., 2005; Tanhua et al., 2005). This water occupies the deepest
- 15 part of the IR and LA Seas.
 - In the east of the section, deep waters consist of the much older Lower North East Atlantic Deep Water ($NEADW_L$) which is formed with a significant southern component from Antarctic Bottom Water. A number of other water masses are also observed at shallow depths, including Mediterranean Water, and various mode waters.
 - Some control of water mass on ²³⁰Th and ²³¹Pa concentration is evident in nuclide section plots (Fig. 5), particularly relatively low ²³⁰Th and ²³¹Pa concentrations in DSOW and high values in the old NEADW. In other places, the impact of water mass is less apparent. The challenge with these nuclides is that they are not conservative tracers of water mass, but evolve significantly during transport and water aging. On the GEOVIDE Section we can analyse this evolution because the ages of the water-masses can be assessed from CFC data.
- CFC measurements are not available from the GEOVIDE cruise itself. de la Paz et al. (2017), however, measured CFC concentrations along the east of the same section (covering WE Basin, IC Basin, and IR Sea) in 2012 (OVIDE/CATARINA cruise). This allowed the computing of CFC-based age with the Transit Time Distribution (TTD) method. Using the water mass distribution along GEOVIDE given by García-Ibáñez et al. (2018) and the distribution for the same water masses in 2012 (García-Ibáñez et al., 2015), we derived CFC-based ages for GEOVIDE waters (Fig. 6; further details in Supplemental Information S2). Uncertainties (1 standard error) associated with CFC-based age calculated with this approach range between 11-40%.

CFC-based water-mass ages range from \approx 10 years, observed in DSOW at the bottom of the LA Sea, to \approx 800 years, observed for NEADW at the bottom of the WE Basin. Because this study focuses on understanding controls on 231 Pa and 230 Th in recently ventilated waters, we omit detailed consideration of the upper 1km in subsequent discussion, and restrict our analysis to water sampled west of 35°W of the section where young waters (<50 years) dominate. A rescaled version of the CFC age

Deleted: west

section indicates the variation in age of ventilated waters (Fig. 6b). DSOW, occupying the deepest LA and IR Seas, is the youngest water mass in this region, with an average age of \sim 19 years. ISOW and LSW are slightly older, with ages ranging from 26 to 45 years and 32 to 40 years respectively.

4.2 Evolution of ²³⁰Th and ²³¹Pa with water age

20

- The presence of recently ventilated deep-waters with constrained CFC ages allows analysis of the rates at which ²³⁰Th and ²³¹Pa concentrations increase during transport, and the rates of scavenging of these nuclides. To conduct this analysis, we define five components in the budget of ²³⁰Th and ²³¹Pa:
- i. Preformed component: The 230 Th or 231 Pa transported from the surface into the interior. For this analysis, in the absence of measurements for the exact location of deep-water formation during winter convection, we assume the same preformed value for all water masses and set this as the average of concentrations measured in surface waters <100 m depth along GEOVIDE section. This gives preformed concentrations of 1.66 μ Bq/kg for 230 Th and 1.31 μ Bq/kg for 231 Pa. We recognise that true preformed values may differ from these values and between water masses, and discuss the implications of uncertainty in preformed values in the following section. Preformed 230 Th and 231 Pa will decrease due to radioactive decay during transport. Although we take this decay into account in the following analysis, it is insignificant given the ages of waters involved and the much longer half-lives of 230 Th and 231 Pa.
- *ii.* Ingrown component: The ingrown ²³⁰Th or ²³¹Pa from radioactive decay of U since the water was last in contact with the surface. This component increases as the water mass ages. The concentration of this component in a water mass of age t can be calculated as:

$$^{230}Th_{ln\,arown} = ^{234}U \times (1 - e^{-\lambda_{230}t})$$
 (4.1)

$$^{231}Pa_{lnarown} = ^{235}U \times (1 - e^{-\lambda_{231}t})$$
 (4.2)

where $^{230}\text{Th}_{\text{Ingrown}}$ and $^{231}\text{Pa}_{\text{Ingrown}}$ are the ^{230}Th and ^{231}Pa ingrown from their U parents, respectively; ^{234}U and ^{235}U are activities of ^{234}U , and ^{235}U in seawater (45551.2 µBq/kg (2801.4 dpm/1000l) and 1823.8 µBq/kg (112.2 dpm/1000l), respectively, assuming a constant seawater ^{238}U activity of 39609.8 µBq/kg (2436 dpm/1000l) at salinity 35 psu, and seawater $^{234}\text{U}/^{238}\text{U}$ activity ratio of 1.15 and natural $^{238}\text{U}/^{235}\text{U}$, abundance ratio of 137.88); λ_{230} and λ_{231} are decay constants of ^{230}Th and ^{231}Pa (9.17 ×10.6 yr $^{-1}$ and 2.12×10.5 yr $^{-1}$, respectively).

iii. Potential Total component: The ²³⁰Th and ²³¹Pa expected in the water due to the combination of preformed and ingrown components, if there were no removal by scavenging.

iv. Observed component: The ²³⁰Th and ²³¹Pa observed in the water column, i.e. dissolved ²³⁰Th and ²³¹Pa measured in this study (after correction for detritus and ingrowth from U since sample collection).

Formatted: Superscript

Formatted: Superscript

Deleted: 238/235U

v. Scavenged component: The net ²³⁰Th or ²³¹Pa removed from the water since it left the surface due to scavenging. For each depth, this component is the net of nuclide added from above by desorption from settling particles, and the removal downwards by scavenging.

These components are related to each other as follows:

5

30

$$Preformed + Ingrown = Potential\ Total\ ^{230}Th\left(or\ ^{231}Pa\right) = \ Observed + Scavenged \tag{4.3}$$

The difference between the Potential Total and the Observed concentration of ²³⁰Th (or ²³¹Pa), therefore provides a measure of the amount of nuclide scavenged since the water left the surface (Fig. 7).

We examine the evolution of both the observed and scavenged components of ²³⁰Th and ²³¹Pa with water mass age (Fig. 8). Both ²³⁰Th and ²³¹Pa show an increase in observed concentration with age of water, with the increase for ²³⁰Th much more regular than for ²³¹Pa. This strong ²³⁰Th relationship, regardless of depth of the sample (Fig. 8a), indicates a primary control of water-mass age on the increase of ²³⁰Th in these younger waters.

For ²³⁰Th, the rate of increase with age (i.e. slope in Fig. 8a) indicates that about one quarter of the ²³⁰Th formed from U decay remains in the water, with the other three quarters being removed by scavenging. This ratio is consistent with the average ²³⁰Th for these waters, which requires that about three times more ²³⁰Th than remains in water has been removed by scavenging (Fig. 8a, 8b). The scatter between ²³¹Pa and age (Fig. 8c) precludes the use of the slope to assess the relative proportion of scavenged ²³¹Pa, but the average values (Fig. 8c, 8d) indicate that about half of the ²³¹Pa remains in the water, while half is removed by scavenging. The relative behaviour of ²³⁰Th and ²³¹Pa is consistent with previous expectations, with a higher fraction of scavenging of ²³⁰Th than ²³¹Pa.

The hypothesis that ²³¹Pa/²³⁰Th ratios increase monotonically as water mass ages forms the foundation of the Water-mass Evolution model for interpretation of sedimentary ²³¹Pa/²³⁰Th in terms of the rate of deep water circulation. For these young waters, however, there is no clear relationship between observed ²³¹Pa/²³⁰Th and age (Fig. 8e), nor between the ²³¹Pa/²³⁰Th value scavenged to the sediment and age (Fig. 8f), calling the Water-mass Evolution model into question.

4.3 The importance of preformed ²³⁰Th and ²³¹Pa in young waters

To assess the controls on ²³⁰Th, ²³¹Pa, and particularly the resulting ²³¹Pa/²³⁰Th ratio, we apply a simple scavenging-mixing model following Moran et al. (1997). This model was first created to assess the evolution of ²³⁰Th in a 1D water column as it ages following ventilation. Here we adopt it by modelling the nuclide evolution with age for each depth, and by also modelling ²³¹Pa. This assumes that waters have remained at the same depth since ventilation which, though not correct in detail, still allows the model to provide insights about controls on these nuclides.

Following Moran et al. (1997), dissolved concentration of ²³⁰Th and ²³¹Pa is given by,

$$c_{d} = \frac{c_{pre,t} + P \quad \tau_{w}}{(K_{d} \ SPM + 1)} \times \left[1 - \exp\left(-\frac{(K_{d} \ SPM + 1)}{SK_{d} \quad \tau_{w} SPM} \times z\right)\right] \quad (4.4)$$

where C_d is the dissolved concentration of the nuclide; P is the production rate of 230 Th and 231 Pa, $0.42~\mu$ Bq/kg/yr ($2.57~\times~10^{-2}~dpm/1000l/yr$) and $0.039~\mu$ Bq/kg/yr ($2.37~\times~10^{-3}~dpm/1000l/yr$), respectively; K_d is the distribution coefficient of the nuclide; λ is the decay constant of the nuclide; $C_{pre,t}$ is the preformed total concentration of 230 Th (or 231 Pa); SPM is the suspended particle concentration; and S is the particle settling speed, which represents the net effect of particle sinking, disaggregation and aggregation; τ_W is water mass age; z is the water depth.

The model requires values for four parameters: particle settling speed (S), suspended particle concentration (SPM), and distribution coefficients for 230 Th (K_d^{Th}) and 231 Pa (K_d^{Pa}). We select these parameters to give a good fit to the 230 Th and 231 Pa observations at an open ocean station, Station 13, on the east of the section (i.e. a station sampling older waters, which are close to equilibrium) and use these values to interpret the younger waters to the west. Best fits to Station 13 suggested S = 800 m/yr; SPM = 25 μ g/l; K_d^{Th} =1.1×10⁷ ml/g; and K_d^{Pa} = 1.4×10⁶ ml/g (the first three of these are close to those of Moran et al. (1997)). A fuller description of the model is given in Supplemental Information S3.

We show two sets of output from the model, one with a preformed component (C_{pre}) equal to the nuclide concentrations observed in the upper 100 m of the GEOVIDE section (as in 4.2 above), and one with the preformed component set to zero for both nuclides. For both cases, the modelled evolution of nuclide concentrations with age between 0-50 years at 2000 m and 3500 m water depths is plotted in Fig. 9, and compared to data. As expected, modeled 230 Th and 231 Pa concentrations increase with age, with deeper waters having higher concentrations and 230 Th increasing more rapidly initially (Fig. 9), but the preformed concentration is seen to be important in setting total nuclide concentration for several decades after ventilation. The fit of the model to observations in young waters from GEOVIDE is improved in the model run with zero preformed nuclide, particularly for 230 Th. This is surprising, given that surface-water 230 Th and 231 Pa values are generally non-zero, and typically close to the value observed in the GEOVIDE surface waters. For 230 Th in young deep waters, even the model with zero preformed nuclide overestimates the observed value, possibly indicating additional scavenging from these waters close to the seafloor, or as a result of differing biological productivity and particle fluxes between stations.

The most striking effect of changing the assumed preformed values in the model is on ²³¹Pa/²³⁰Th (Fig. 9c). When preformed values are set at zero, ²³¹Pa/²³⁰Th ratios always increase with water age, but when set at the average surface value from GEOVIDE, ²³¹Pa/²³⁰Th ratios initially decrease before increasing. The impact of preformed concentrations has a long-lasting impact on water-column and scavenged ²³¹Pa/-Th, lasting for hundreds of years following ventilation (Supplementary Information Figure S2 (c), (d)). This indicates that knowledge of the nuclide concentration at the site of deep-water formation is critical to understanding the early evolution of ²³¹Pa/²³⁰Th in waters and their underlying sediments.

4.4 Scavenging of ²³⁰Th and ²³¹Pa

Knowledge of the CFC ages of the waters analysed on the GEOVIDE cruise allow an assessment of the scavenging rates of ²³⁰Th and ²³¹Pa. To do so, we compare the Scavenged component to the Potential Total component (as defined in Section 4.2).

The percentage of the Scavenged component relative to the Potential Total component is higher for ²³⁰Th, at an average of 80%, than for ²³¹Pa at an average of 40% (Fig. 10), consistent with the relatively higher particle-reactivity of ²³⁰Th. For both nuclides, there is a higher fraction of scavenging in samples from near the seafloor, particularly those from DSOW in the deepest LA Sea. Bottom scavenging has been indicated in previous studies (e.g. Bacon and Anderson, 1982; Deng et al., 2014; Okubo et al., 2012), but this study indicates that this enhanced nuclide scavenging occurs even in the very young overflow waters at the start of the meridional circulation.

4.5 Uncertainty analysis of the assessment of the scavenging of ²³⁰Th and ²³¹Pa

Uncertainty in both CFC-based ages and in preformed values of ²³⁰Th and ²³¹Pa contribute to uncertainty when calculating the scavenging of ²³⁰Th and ²³¹Pa. Uncertainties associated with CFC-based age range between 11-40% (1 standard error). This uncertainty leads to an average uncertainty of 23% and 13% in potential total ²³⁰Th and ²³¹Pa respectively, corresponding to an average uncertainty of 30% in the scavenged component of ²³⁰Th and 40% in the scavenged component of ²³¹Pa.

A two-fold increase in preformed values results in an increase by a factor of 1.2 and 1.6 in the total potential ²³⁰Th and ²³¹Pa, respectively, leading to an increase by a factor of 1.2 in the scavenged component of ²³⁰Th and of 2.6 in the scavenged component of ²³¹Pa. The impact of preformed uncertainty is less significant when comparing the scavenging to the potential total components. The ratio of scavenged/potential total increases by a factor of 1.1 and 1.4 for ²³⁰Th and ²³¹Pa, respectively. This sensitivity analysis indicates that a better knowledge of preformed values will benefit the assessment of the scavenging of both nuclides.

4.6 Meridional transport of ²³⁰Th and ²³¹Pa in the North Atlantic

Previous calculations have indicated removal of ²³⁰Th and ²³¹Pa from the North Atlantic by meridional transport southward. Deng et al. (2014) calculated net southward transport of 6% of the ²³⁰Th and 33% of ²³¹Pa, relative to production of these nuclides in the water column. That calculation, however, did not provide a complete budget for ²³⁰Th and ²³¹Pa for the North Atlantic because observations at the time did not constrain input of these nuclides from the north. Data in this study allow this calculation, and therefore a more complete budget for the modern North Atlantic.

García-Ibáñez et al. (2018) calculated volume transports for the Portugal to Greenland section of the GEOVIDE section by combining the water mass fractions from eOMP analysis with the absolute geostrophic velocity field calculated using inverse model constrained by Doppler current profiler velocity measurements (Zunino et al., 2017). They separated northward flowing upper, and southward flowing lower limbs of the AMOC at isopycnal σ_1 (potential density referenced to 1000 dbar) = 32.15 kg/m³, with +18.7 ± 2.4 Sv and -17.6 ± 3.0 Sv flow across the section above and below this value (positive value indicates northward transport). With average 230 Th and 231 Pa concentrations in the upper limb ($\sigma_1 < 32.15 \text{ kg/m}^3$) of 1.60 and 1.32 uBq/kg respectively, northward transport of 230 Th is 3.07×10^{10} and of 231 Pa is 2.53×10^{10} uBq/s. Average 230 Th and 231 Pa

concentrations in the lower limb ($\sigma_1 > 32.15 \text{ kg/m}^3$) are 3.44 and 2.07 $\mu\text{Bq/kg}$, respectively, indicating transports of ²³⁰Th and ²³¹Pa are -6.22 \times 10¹⁰ and -3.74 \times 10¹⁰ $\mu\text{Bq/s}$, respectively.

Net transport of 230 Th and 231 Pa across GEOVIDE is therefore to the south, and supplies $3.15 \times 10^{10} \, \mu Bq/s$ 230 Th and $1.21 \times 10^{10} \, \mu Bq/s$ 231 Pa to the North Atlantic (Fig. 11). This is a smaller net transport than further south in the Atlantic (Fig. 11), due to the lower 230 Th and 231 Pa concentrations in the water column close of the site of deep-water formation.

The budget for these nuclides for the North Atlantic consists of: production in the water column; addition by advection from the North; loss by advection to the South and removal to the sediment. The data from this study allows this budget to be fully assessed, and indicates that the flux to the sediment is equivalent to 96% of the production of ²³⁰Th, and 74% of the production for ²³¹Pa (Supplemental Information Table S4). For both nuclides, these fluxes are higher than in previous calculations (Deng et al., 2014) which ignored advective fluxes from the North. There is, however, still a significantly higher advective loss of ²³¹Pa relative to ²³⁰Th. At a basin scale, therefore, ²³¹Pa/²³⁰Th in the sediment must be lower than the production ratio. This lower value is generated by the meridional transport of the North Atlantic, and likely to be sensitive to changes in this transport. Using the Basin-scale Advection model to interpret sedimentary ²³¹Pa/²³⁰Th to assess meridional transport, as initially proposed by Yu et al. (1996), is therefore still supported by a full modern North Atlantic budget for these nuclides.

5 Conclusion

15

Measurement of ²³⁰Th and ²³¹Pa in waters from GEOVIDE show some control of water mass on ²³⁰Th and ²³¹Pa concentrations, particularly low concentrations in DSOW and high values in the old NEADW. There is, however, no close mapping of nuclide concentration to water mass.

With the availability of CFC-based ages on this section, the evolution of ²³⁰Th and ²³¹Pa concentration with age is possible. A systematic increase of ²³⁰Th concentration is observed over the first 50 years following ventilation, and a similar though more scattered relationship seen for ²³¹Pa. There is no clear relationship between the ²³¹Pa/²³⁰Th ratio and age for these young waters. The long-term evolution of ²³¹Pa/²³⁰Th is found from a simple model to be highly dependent on the preformed concentrations for these nuclides. These results complicate the interpretation of sedimentary ²³¹Pa/²³⁰Th as a paleo-proxy for deep water circulation based on systematic evolution of water ²³¹Pa/²³⁰Th with age, and point to the importance of a better knowledge of preformed ²³⁰Th and ²³¹Pa concentrations to improve interpretation. This analysis of the ²³⁰Th and ²³¹Pa concentration relative to the age of the water not only demonstrates the influence of water mass aging on ²³¹Pa and ²³⁰Th, but also points to the influence of scavenging. Scavenged ²³⁰Th is much more extensive than ²³¹Pa, as expected, and enhanced removal of both nuclides is seen immediately above the seafloor, particularly for young waters.

Calculation of meridional transport of ²³⁰Th and ²³¹Pa indicates a southward net transport of both nuclides across the GEOVIDE section. This advection is smaller than that further south in the Atlantic as a result of lower ²³⁰Th and ²³¹Pa concentrations at GEOVIDE. Calculation of the flux across GEOVIDE allows a more complete budget for the North Atlantic to be constructed and demonstrates a significantly higher advective loss of ²³¹Pa to the south relative to ²³⁰Th, with 26% of the

Deleted: Use

²³¹Pa produced advected southward (relative to only 4% for ²³⁰Th). This calculation supports the interpretation of sedimentary ²³¹Pa/²³⁰Th measurements as a proxy for overturning circulation, when based on advective loss of ²³¹Pa at a basin scale.

Data availability, GEOVIDE ²³Pa, ²³⁰Th and ²³²Th data are available at British Oceanographic Data Centre - Natural-Environment Research Council, UK, http://doi.org/10.5285/7a150d33-956b-0fec-e053-6c86abc0b35c (Deng et al., 2018).

5 Author contributions. GMH conceptualized and acquired funding for the research. MC collected seawater samples for ²³¹Pa, ²³⁰Th and ²³²Th at sea and provided expertise about other measurements on the cruise. FD conducted the chemical analysis and MC-ICP-MS measurement of ²³¹Pa, ²³⁰Th and ²³²Th. FFP and RS conducted the analysis, calculation and interpretation of CFC ages. FD conducted the interpretation and analysis of ²³¹Pa, ²³⁰Th and ²³²Th data, with extensive contribution from GMH. FD wrote the paper and prepared all figures, with GMH contributing extensively and contributions from other co-authors.

10 Competing interests. The authors declare that they have no conflict of interest.

Special issue statement. This article is part of the special issue "GEOVIDE, an international GEOTRACES study along the OVIDE section in the North Atlantic and in the Labrador Sea (GA01)". It is not associated with a conference.

Acknowledgements

Géraldine Sarthou and Pascale Lherminier are thanked for leading the GEOVIDE cruise, along with the captain, Gilles Ferrand, and crew of the R/V Pourquoi Pas?. We would like to give a special thanks to Pierre Branellec, Floriane Desprez de Gésincourt, Michel Hamon, Catherine Kermabon, Philippe Le Bot, Stéphane Leizour, Olivier Ménage, Fabien Pérault and Emmanuel de Saint Léger for their technical expertise and to Catherine Schmechtig for the GEOVIDE database management. This work was supported by the French National Research Agency (ANR-13-BS06-0014, ANR-12-PDOC-0025-01), the French National Centre for Scientific Research (CNRS-LEFE-CYBER), the LabexMER (ANR-10-LABX-19), and Ifremer. It was supported for the logistic by DT-INSU and GENAVIR. Thank you also to Yi Tang who helped with sampling during the cruise. We are grateful to Mercedes de la Paz Arandiga, and Pascale Lherminier for providing valuable input during analysis of water masses and ages, and to Maribel García-Ibáñez for early provision of the eOMP analysis presented elsewhere in this volume. We also thank Yves Plancherel and Jerry McManus for valuable insight during discussion of the results presented We thank Roger Francois, and two anonymous reviewers, and the editor Gilles Reverdin, for their constructive comments on the manuscript.

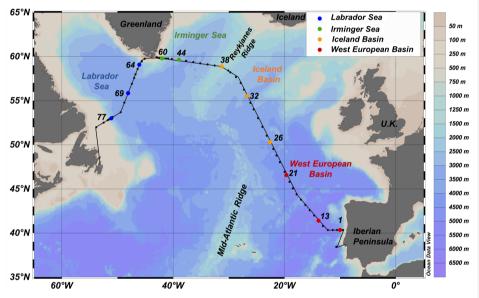

Figure 1: Map showing GEOVIDE cruise track (black line) and station locations (black dots). Colour bars indicate water depth. Sampling locations for water-column ²³¹Pa and ²³⁰Th in this study are shown by coloured dots, with colours representing the ocean regions they are located in.

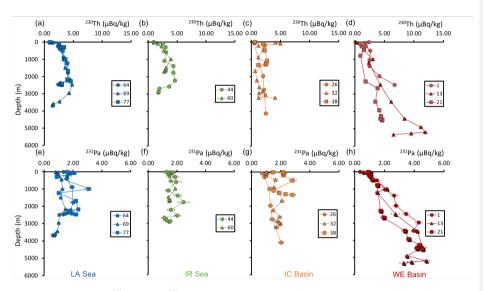

Figure 2: Vertical profiles of ²³⁰Th (a-d) and ²³¹Pa (e-h) in the water column along the GEOVIDE section. Colours corresponds to the region (as in Fig. 1). LA = Labrador, IR = Irminger, IC = Iceland, WE = West European). Uncertainties represent 2 standard error (2 s.e.).

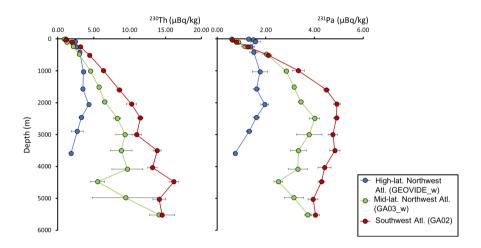

Figure 3: Vertical profiles of ²³⁰Th and ²³¹Pa from high-latitude Northwest Atlantic (west section of GEOVIDE), mid-latitude Northwest Atlantic (GA03_w), and Southwest Atlantic (GA02. Data from all stations were sorted by water depth and averages for depth and ²³⁰Th and ²³¹Pa concentrations were taken for surface, 25 m,100 m, 250 m, 500 m, and every 500 m interval below. Error bars on ²³⁰Th and ²³¹Pa concentrations averages reflect standard deviation of the mean of measurements.

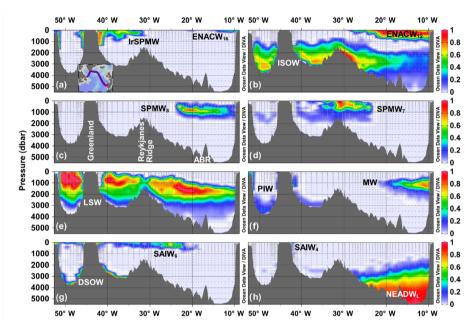

Figure 4: Results of Extended Optimum MultiParameter (eOMP) analysis for the GEOVIDE section (García-Ibáñez et al., 2018). Colours reflect the fraction of water at each location assigned to the water mass shown in that panel: ENACW₁₆ and ENACW₁₂ = East North Atlantic Central Water of 16° C and 12° C; SPMW₈, SPMW₇, IrSPMW = Subpolar Mode Water of 8° C, 7° C and of the Irminger Sea; SAIW₆ and SAIW₄ = Subarctic Intermediate Water of 6° C and 4° C; MW = Mediterranean Water; PIW = Polar Intermediate Water; ISOW=Iceland–Scotland Overflow Water; LSW=Labrador Sea Water; DSOW: Denmark Strait Overflow Waters; and NEADW_L: Lower North East Atlantic Deep Water; ABR= Azores-Biscay Rise.

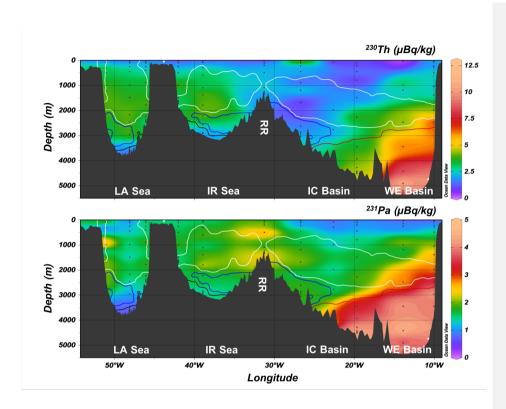

Figure 5: Distribution of 230 Ph and 231 Pa along the GEOVIDE section. Water masses were indicated by contours (black: DSOW; blue: ISOW; white: LSW; red: NEADW.) based on 50% level percentage composition of source water types from eOMP analysis.

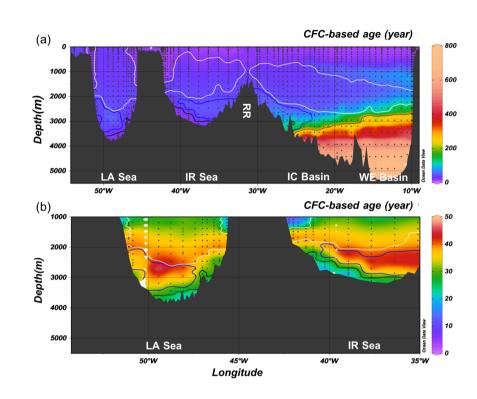

Figure 6: Water mass age based on CFC data along the GEOVIDE section. (a) Full water-column data for the entire section, showing waters from 10 to 800 years in age; (b) A rescaled version of (a) omitting the upper 1000m and the older waters east of 35°W to show age variation in recently ventilated deep-waters. Water masses were indicated by contours (black: DSOW; blue: ISOW; white: LSW; red: NEADW.) based on 50% level percentage composition of source water types from eOMP analysis.

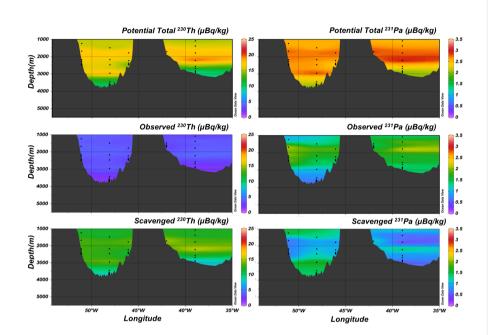

Figure 7: Potential Total, Observed, and Scavenged components of ²³⁰Th and ²³¹Pa in waters >1000 m water depth and west of 35°W.

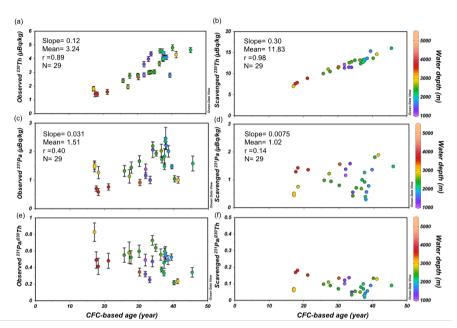

Figure 8: Relationship between water mass age and the Observed and Scavenged components of ²³⁰Th, ²³¹Pa and ²³¹Pa/²³⁰Th (colour coded by water depth). Least square fitting statistics were also given, i.e. slope and correlation coefficient r of the least square line, mean value and number of the data points. Note the increase of observed concentrations for both nuclides with age. Comparison of average values indicates that about three quarters of ²³⁰Th produced by decay is scavenged, compared with about half of the ²³¹Pa.

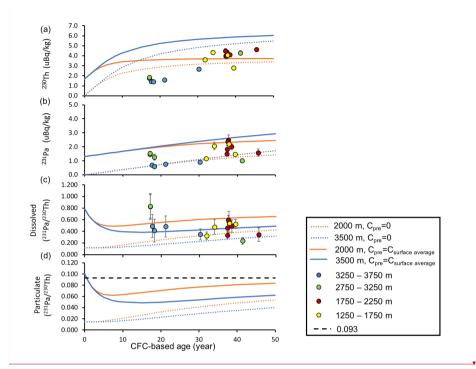

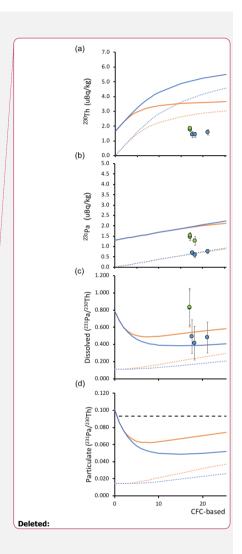

Figure 9: Results from a scavenging-mixing model of 230 Th, 231 Pa, Dissolved 231 Pa/ 230 Th and particulate 231 Pa/ 230 Th compared to observations. Preformed concentration (C_{pre}) were set at 0 (dashed line) and at the average surface concentration ($C_{surface average}$) from GEOVIDE section (solid line), i.e. 230 Th= 1.66 μ Bq/kg, 231 Pa= 1.31 μ Bq/kg. A version of this figure extending to older waters is available in the Supplemental Information Figure S2.

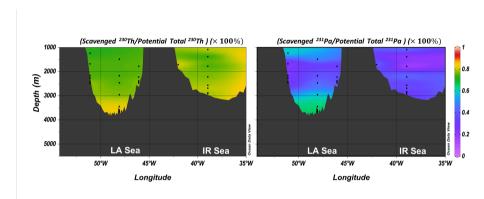

Figure 10: Ratio of Scavenged component to Potential Total component for 230 Th and 231 Pa, providing an assessment of the relative importance of scavenging for the two nuclides, and of the location of scavenging.

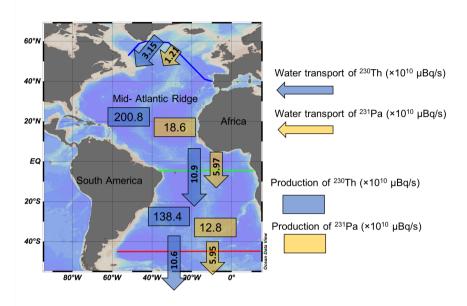

Figure 11: Fluxes of ²³⁰Th (blue arrow) and ²³¹Pa (yellow arrow) across the GEOVIDE section (blue solid line), 4.5°S (green solid line) and 45°S (red solid line). Also shown are production of ²³⁰Th (blue box) and ²³¹Pa (yellow box) in the North Atlantic (between GEOVIDE section and 4.5°S) and in the South Atlantic (between 4.5°S and 45°S), based on calculation in Deng et al. (2014). These fluxes indicate that 4% of the ²³⁰Th produced in the North Atlantic is exported southward by ocean circulation, and 26% of the ²³¹Pa.
