Associate Editor Decision: Publish subject to minor revisions (review by editor) (21 Jan 2019) by Zhongjun Jia Comments to the Author:

Dear Mr. Debany Fonseca-Batista

Thank you for your submission to BG. I have read your manuscript and found the major concerns have been addressed.

To ensure the reproducibility of N2 fixation and carbon uptake measurements, the methods need to be described in greater detail. However, I could not see the methodological details in section 3.3 as stated in L161 as stated. Please describe it as much as possible in the materials and method sections rather than in the result section.

We thank the Editor for pointing out this aspect as well as the following minor concerns. We have modified the methodological section to describe in more details the incubation experiments (lines 136 to 168). We have also listed in the method section the incubation that did not reveal any detectable N₂ fixation activity, as a result of an the insufficient or absent ¹⁵N-enrichment of the particles after incubation (lines 179 to 181).

Concerning the more specific comments please find the detailed modifications made below.

The language must be polished by a native English speaker before your next submission.

The manuscript has been read by a native English speaker, once all other requested revisions were made.

Some other minor concerns are the following. (1) L23. Delete "we report", and rephrased as "Substantial N2 fixation activity was observed at ...

The sentence was modified accordingly.

(2) L28-29. Along with the area-averaged Chl a concentrations, these results revealed that post-bloom prevailed at most sites....

The sentenced was adapted as follows (lines 27 to 29):

"In agreement with the area-averaged ChI a satellite data contemporaneous with our study period, our results revealed that post-bloom conditions prevailed at most sites, while at the northwesternmost station the bloom was still ongoing."

(3) L31. Delete "we find that"

The sentenced was adapted as follows (lines 29 to 31):

"When converted to carbon uptake using Redfield stoichiometry, N_2 fixation could support 1 to 3% of daily PP in the euphotic layer at most sites, except at the two most active sites where this contribution to daily PP could reach up to 25%."

- (4) L33. nifH sequences were assigned to
- (5) L34 that dominated nifH sequence.
- (6) L34 delete "recovered from DNA samples"

The sentenced was adapted as follows (lines 31 to 34):

"At the two sites where N_2 fixation activity was the highest, the prymnesiophyte-symbiont Candidatus Atelocyanobacterium thalassa (UCYN-A) dominated the nifH sequence pool, while the remaining recovered sequences belonged to non-cyanobacterial phylotypes."

- (7) L36 delete "where nifH sequences were recovered'
- (8) L36-37. Rephrased as: At all the other sites nifH gene sequences were phylogenetically exclusively related to non-cyanobacterial phylotypes.

The sentence was rephrased as follows (lines 34 and 35):

"At all the other sites however, the recovered nifH sequences were exclusively assigned phylogenetically to non-cyanobacterial phylotypes."

- (9) L36. Delete "We support that"
- (10) L37. ...were likely promoted....

We have deleted those three words, changed the sentence as suggested and it now reads as follows (lines 35 to 39):

"The intense N_2 fixation activities recorded at the time of our study were likely promoted by the availability of phytoplankton-derived organic matter produced during the spring bloom, as evidenced by the significant surface particulate organic carbon concentrations. Also, the presence of excess phosphorus signature in surface waters seemed to contribute to sustaining N_2 fixation, particularly at the sites with extreme activities."

(11) L40-41. These results provide a mechanistic understanding for the unexpected high N2 fixation in productive waters of the temperate North Atlantic, and highlight the importance of N2 fixation for future assessment of global N inventory.

We have deleted the sentence in lines 40-41 from the previous version and the above sentence was added instead.

(12) L493. Delete able

We have deleted that word.

(13) L497. We speculate

We have replaced the word "support" by "speculate" as suggested.

Regards Zhongjun Jia

Evidence of high N₂ fixation rates in the temperate Northeast Atlantic

- Abstract. Diazotrophic activity and primary production (PP) were investigated along two transects (Belgica BG2014/14 and GEOVIDE cruises) off the western Iberian Margin and the Bay of Biscay in May 2014. We report Substantial N₂ fixation activityies was observed at 8 of the 10 stations sampled, ranging overall between from 81 and to 384 μmol N m⁻² d⁻¹ (0.7 to 8.2 nmol N L⁻¹ d⁻¹), with two sites close to the Iberian Margin situated between
- 25 38.8° N and 40.7° N yielding rates reaching up to 1355 and 1533 μ mol N m⁻² d⁻¹. Primary production was relatively
- 26 lower along the Iberian Margin with rates ranging from 33 to 59 mmol C m⁻² d⁻¹, while it increased towards the
- 27 northwest away from the Peninsula, reaching as high as 135 mmol C m⁻² d⁻¹. Our observations in combination-In
- 28 agreement with the area-averaged Chl a satellite data, contemporaneous with our study period, our results revealed
- 29 that post-bloom conditions prevailed at most sites, while at the northwesternmost station the bloom was still ongoing.
- 30 When converted to carbon uptake using Redfield stoichiometry, we find that N₂ fixation rates could have supported 1
- 31 to 3% of euphotic layer daily PP in the euphotic layer at most sites, except at the two most active sites where this
- 32 contribution to daily PP could reached as high asup to 25%. At the two sites where N₂ fixation activity was the
- 33 highest, nifH sequences assigned to the prymnesiophyte-symbiont Candidatus Atelocyanobacterium thalassa
- 34 (UCYN-A) dominated the nifH sequence pool-recovered from DNA samples, while the remaining recovered
- 35 sequences belonged to non-cyanobacterial phylotypes. At all the other sites however, the recovered where nifH
- 36 sequences were recovered, these belonged exclusively assigned phylogenetically to non-cyanobacterial phylotypes.
- We support that $\underline{\mathbf{T}}$ the unexpectedly high intense N_2 fixation activities recorded at the time of our study were <u>likely</u>
- 38 promoted by the availability of phytoplankton-derived organic matter produced during the spring bloom, as
- 39 evidenced by the significant surface particulate organic carbon concentrations., and a Also, sustained by the presence
- 40 of excess phosphorus signature in surface waters seemed to contribute to sustaining N₂ fixation, particularly at the
- sites with extreme activities. These results provide a mechanistic understanding of the unexpectedly high N₂ fixation
- 42 in productive waters of the temperate North Atlantic, and highlight the importance of N₂ fixation for future
- 43 assessment of global N inventory. Our findings stress the need for a more detailed monitoring of oceanic N2 fixation

44 in productive waters of the temperate North Atlantic to better constrain nitrogen input to the Atlantic Ocean
45 inventory.

1 Introduction

46

47

83

Dinitrogen (N₂) fixation is the major pathway of nitrogen (N) input to the global ocean and thereby contributes to 48 49 sustaining oceanic primary productivity (Falkowski, 1997). The conversion by N₂-fixing micro-organisms (diazotrophs) of dissolved N₂ gas into bioavailable nitrogen also contributes to new production in the euphotic layer 50 51 and as such, to the subsequent sequestration of atmospheric carbon dioxide into the deep ocean (Gruber, 2008). Estimating the overall contribution of N₂ fixation to carbon sequestration in the ocean requires an assessment of the 52 53 global marine N₂ fixation. Until recently most studies of N₂ fixation have focused on the tropical and subtropical regions of the global ocean, 54 55 with few attempts to measure N₂ fixation at higher latitudes, with the exception of enclosed brackish seas 56 (Ohlendieck et al., 2000; Luo et al., 2012; Farnelid et al., 2013). The intense research efforts in the low latitude regions stem for the observable presence of cyanobacterial diazotrophs such as the diatom-diazotroph association 57 58 (DDA) and the colony-forming filamentous *Trichodesmium* (Capone, 1997; Capone et al., 2005; Foster et al., 2007). 59 Trichodesmium in particular, was long considered as the most active diazotroph in the global ocean, It has mostly 60 been reported in tropical and subtropical oligotrophic tropical and subtropical oceanic waters, which are thought to 61 represent the optimal environment for its growth and N₂-fixing activity (Dore et al., 2002; Breitbarth et al., 2007; 62 Montoya et al., 2007; Needoba et al., 2007; Moore et al., 2009; Fernández et al., 2010; Snow et al., 2015). In low 63 latitude regions, warm, stratified surface waters depleted in dissolved inorganic nitrogen (DIN), are assumed to give a 64 competitive advantage to diazotrophs over other phytoplankton since only they can draw N from the unlimited dissolved N₂ pool for their biosynthesis. As such, past estimates of global annual N₂ fixation were mainly based on 65 information gathered from tropical and subtropical regions, while higher latitude areas have been poorly explored for 66 67 diazotrophic activity (Luo et al., 2012). 68 Studies using genetic approaches targeting the *nifH* gene encoding the nitrogenase enzyme, essential for diazotrophy, 69 have shown the presence of diverse diazotrophs throughout the world's oceans, extending their ecological niche 70 (Farnelid et al., 2011; Cabello et al., 2015; Langlois et al., 2015). Small diazotrophs such as unicellular diazotrophic 71 cyanobacteria (UCYN classified in groups A, B and C) and non-cyanobacterial diazotrophs, mostly heterotrophic 72 bacteria (e.g. Alpha- and Gammaproteobacteria), have been observed over a wide range of depths and latitudes, 73 thereby expanding the potential for diazotrophy to a much broader geographic scale (Langlois et al., 2005, 2008; 74 Krupke et al., 2014; Cabello et al., 2015). The discovery of a methodological bias associated to the commonly used ¹⁵N₂ bubble-addition technique (Mohr et al., 2010) and the presence of an abundant diazotrophic community in high 75 latitude regions actively fixing N2 (Needoba et al., 2007; Rees et al., 2009; Blais et al., 2012; Mulholland et al., 2012; 76 77 Shiozaki et al., 2015), indicate that more efforts are needed to better constrain oceanic N₂ fixation and diazotrophic 78 diversity at higher latitudes. 79 In the Northeast Atlantic, the large input of iron-rich Saharan dust alleviating dissolved iron (dFe) limitation of the 80 nitrogenase activity (Fe being a co-factor of the N₂-fixing enzyme) (Raven, 1988; Howard & Rees, 1996; Mills et al., 81 2004; Snow et al., 2015) and the upwelling of subsurface waters with low DIN (dissolved inorganic nitrogen) to phosphate ratios, make this region highly favorable for N₂ fixation activity (Deutsch et al., 2007; Moore et al., 2009). 82

In addition, the northeast eastern North Atlantic has been observed to harbour a highly active and particularly diverse

84 diazotrophic community (Langlois et al., 2008; Moore et al., 2009; Großkopf et al., 2012; Ratten et al., 2015; 85 Fonseca-Batista et al., 2017) not only in the tropical and subtropical regions but also in the temperate Iberian region 86 which was reported to be a hotspot of for the globally important prymnesiophyte-UCYN-A symbiotic associations at 87 the global ocean scale (Cabello et al., 2015). Earlier studies in the Iberian open waters investigated the diazotrophic 88 activity either during under stratified water column conditions of boreal summer and autumn (Moore et al., 2009; 89 Benavides et al., 2011; Snow et al., 2015; Fonseca-Batista et al., 2017) or during the winter convection period 90 (Rijkenberg et al., 2011; Agawin et al., 2014). Here, we present N₂ fixation rate measurements and the taxonomic 91 affiliation of the diazotrophic community from two consecutive missions campaigns carried out in the Northeast 92 sector of the Atlantic Ocean in May 2014, during and after the spring bloom.

2 Material and Methods

122123

2.1 Site description and sample collection

Field experiments were conducted during two nearly simultaneous cruises in May 2014. The Belgica BG2014/14 95 cruise (21-30 May 2014, R/V Belgica), investigated the Bay of Biscay and the western Iberian Margin. In parallel, 96 97 the GEOVIDE expedition in the framework of the international GEOTRACES program (GA01 section, May 16 to June 29 2014, R/V Pourquoi pas?) sailed from the Portuguese shelf area towards Greenland and ended in 98 99 Newfoundland, Canada (http://dx.doi.org/10.17600/14000200). N₂ fixation activities were determined at ten stations 100 within the Iberian Basin, among which four sites were investigated during the GEOVIDE cruise (stations Geo-1, 101 Geo-2, Geo-13 and Geo-21) and six sites during the BG2014/14 cruise (stations Bel-3, Bel-5, Bel-7, Bel-9, Bel-11 102 and Bel-13; Fig. 1). For the latter expedition, only four stations within the Iberian Basin investigated for N₂-fixation 103 activity (stations Geo 1, 2, 13 and 21) are considered in this paper and the measurements are compared with those 104 conducted at the six sites studied during the BG2014/14 cruise (stations Bel 3, 5, 7, 9, 11 and 13; Fig. 1). 105 All sampling sites were located within the Iberian Basin Portugal Current System (PCS) (Ambar and Fiúza, 1994) 106 which is influenced by highly fluctuating wind stresses (Frouin et al., 1990). The predominant upper layer water mass 107 in this basin is the Eastern North Atlantic Central Water (ENACW), a winter_mode water, which according to Fiúza 108 (1984) consists of two components (see θ/S diagrams in Supporting Information Fig. S1): (i) the lighter, relatively warm (> 14°C) and salty (salinity > 35.6) ENACWst formed in the subtropical Azores Front region (~35° N) when 109 110 Azores Mode Water is subducted as a result of strong evaporation and winter cooling; and (ii) the colder and less 111 saline ENACWsp, underlying the ENACWst, and formed in the subpolar eastern North Atlantic (north of 43° N) 112 through winter cooling and deep convection (McCartney and Talley, 1982). The spatial distribution of these Central 113 Waters allowed the categorizationing of the sampling sites into 2 groups: (i) ENACWsp stations north of 43° N (Bel-114 3, Bel-5, Bel-7, and Geo-21) only affected by the ENACWsp (Fig. S1a, b) and (ii) ENACWst stations, south of 43° 115 N, characterized by the an upper layer being influenced by the ENACWst and the an subsurface layer, by the 116 ENACWsp (Fig. S1a, b). Most of these ENACWst stations were open ocean sites (Bel-9, Bel-11, Bel-13, and Geo-117 13) while two stations were in proximity of the Iberian shelf (Geo-1 and Geo-2) (Tonnard et al., 2018). 118 Temperature, salinity and photosynthetically active radiation (PAR) profiles down to 1500 m depth were obtained 119 using a conductivity-temperature-depth (CTD) sensor (SBE 09 and SBE 911+, during the BG2014/14 and GEOVIDE 120 cruises, respectively) fitted to the rosette frames. For all biogeochemical measurements, seawater samples were 121 collected from with Niskin bottles attached to the rosette and triggered closed at specific depths in the upper 200 m. In particular, for stable isotope incubation experiments seawater was collected in 4.5 L acid-cleaned polycarbonate

(PC) bottles from four depths corresponding to 54%, 13%, 3% and 0.2% of surface PAR at stations Bel-3, Bel-5, Bel-

7, <u>Bel-9</u>, <u>Bel-11</u>, and Geo-2. At stations Geo-1, <u>Geo-</u>13 and <u>Geo-</u>21, two additional depths corresponding to 25% and 125 1% of surface PAR were also sampled for the same purpose.

126

127

2.2 Nutrient measurements

- 128 Surface water concentrations of A ammonium (NH₄+) concentrations were measured on board during both cruises,
- 129 <u>while</u> were measured on board as well as nitrate + nitrite (NO₃⁻ + NO₂⁻) concentrations were measured on board only
- during the GEOVIDE expedition. During the BG2014/14 cruise, samples for NO₃⁻ + NO₂⁻ and phosphate (PO₄³⁻)
- measurements were filtered (0.2 μ m) and stored at -20° C until analysis at the home-based laboratory. PO₄³⁻ data are
- 132 not available for the GEOVIDE cruise.
- Nutrient concentrations were determined using the conventional fluorometric (for NH₄⁺) (Holmes et al., 1999) and
- 134 colorimetric methods (for the other nutrients) (Grasshoff et al., 1983) with detection limits (DL) of 64 nmol L⁻¹
- 135 (NH_4^+) , 90 nmol L^{-1} $(NO_3^- + NO_2^-)$ and 60 nmol L^{-1} (PO_4^{3-}) . For the BG2014/14 cruise, chlorophyll a (Chl a)
- concentrations were determined according to Yentsch and Menzel (1963). Briefly, by filtering 250 mL of seawater
- 137 was filteredsample onto Whatman GF/F glass microfiber filters (0.7 µm nominal pore size), followed by pigment
- 138 extraction in 90% acetone, centrifugation and fluorescence measurement using a Shimadzu RF-150 fluorometer. For
- the GEOVIDE cruise, Chl a concentrations were measured as described in Ras et al. (2008). Briefly, filters samples
- 140 were extracted in 100% methanol, disrupted by sonification, and clarified by vacuum filtration through Whatman
- 141 GF/F filters. The extracts were analysed by high-performance liquid chromatography (HPLC Agilent Technologies
- 142 1200).

143 2.3 ¹⁵N₂ fixation and ¹³C-HCO₃ uptake rates

N₂ fixation and primary production (PP) were determined simultaneously from the same incubation sample at each 144 145 depth in duplicate, using the ¹⁵N-N₂ dissolution method (Großkopf et al., 2012) and ¹³C-NaHCO₃ tracer addition technique (Hama et al., 1983) techniques, respectively. Details concerning the applied ¹⁵N₂ dissolution method can be 146 147 found in Fonseca-Batista et al. (2017). Briefly, ¹⁵N₂-enriched seawater was prepared by degassing prefiltered (0.2 148 μm) low nutrient seawater, under acid-clean conditions using a peristaltic pump slowly circulating (100 mL min⁻¹) 149 the seawater through two degassing membrane contactor systems (MiniModule, Liqui-Cel) in series, held under high vacuum (50 mbar). The degassed water was directly transferred into , thereafter stored in-2 L gastight Tedlar bags 150 151 (Sigma-Aldrich) fitted with a septum through which 30 mL of pure ¹⁵N₂ gas (98 ¹⁵N atom%, Eurisotop, lot number 23/051301) was subsequently injected with 30 mL of pure ¹⁵N₂ gas (98 ¹⁵N atom%, Eurisotop, lot number 152 153 23/051301) and before the bags were left shaken 24 hours forto tracer equilibratione. This 15N2 gas batch (Eurisotop) 154 whas previously been shown to be free of ¹⁵N-labelled contaminants such as nitrate, nitrite, ammonium and nitrous 155 oxide (Fonseca-Batista et al., 2017). Each PC incubation bottle was partially filled with sampled seawater, then 156 amended with 250 mL of ¹⁵N₂-enriched seawater and, spiked with 3 mL of ¹³C-labelled dissolved inorganic carbon (DIC; 200 mmol L⁻¹ solution of a-NaH¹³CO₃ solution (200 mmol L⁻¹, 99%, Eurisotop). The ¹³C-DIC added to a 4.5 L 157 158 incubation bottle results in a ~6.5% increment of the initial DIC content, considered equal to the average oceanic DIC concentration (~2000 µmol kg-1; Zeebe and Wolf-Gladrow, 2003). This allows sufficient tracer enrichment for a 159 160 sensitive detection in the particulate organic carbon (POC) pool as a result of incorporation (Hama et al., 1983). 161 Finally, each incubation bottle was and topped off with the original seawater sample. Samples were then incubated 162 for 24 hours in on-deck incubators circulated with surface seawater and wrapped with neutral density screens (Rosco) 163 simulating the in situ irradiance conditions. After incubation, water was transferred under helium pressure from each

164 PC bottle into triplicate 12 mL gastight Exetainer vials (Labco) poisoned (100 µL of saturated HgCl₂ solution) and pre-flushed with helium for the determination of the ¹⁵N and ¹³C atom% enrichments of the dissolved N₂ (in 165 166 duplicate) and DIC pools. The remaining incubated samples wasere filtered onto pre-combusted MGF filters (glass 167 microfiber filters, 0.7 µm nominal pore size, Sartorius), which were subsequently dried at 60_°C and stored at room 168 temperature. The natural concentration and isotopic composition of particulate organic carbonPOC and particulate nitrogen (POC and PN) were assessed by filtering immediately after sampling an additional 4.5 L of non-spiked 169 170 seawater from each depth. All samples were measured for POC and PN concentrations and isotopic compositions 171 using an elemental analyser (EuroVector Euro EA 3000) coupled to an isotope ratio mass spectrometer (Delta V Plus, 172 Thermo Scientific) and calibrated against international certified reference materials (CRM): IAEA-N1 and IAEA-305B for N and IAEA-CH6 and IAEA-309B for C. The isotopic composition of the DIC and dissolved № pools was 173 174 determined using a gas bench system coupled to an IRMS (Nu Instruments Perspective). Exetainers vials were first 175 injected with He to create a 4 mL headspace and then equilibrated on a rotatory shaker: for 12 hours after phosphoric 176 acid addition (100 µL, 99%, Sigma-Aldrich) for DIC analyses and only for an hour without acid addition for N₂ 177 analyses. DIC measurements were corrected according to Miyajima et al. (1995) and ¹⁵N₂ enrichments were 178 calibrated with atmospheric N₂. N₂ fixation and carbon uptake volumetric rates were computed as shown in Equation 179 1:

180
$$N_2$$
 or HCO $_3^-$ uptake $rate$ (nmol $L^{-1}d^{-1}$ or $\mu mol \ m^{-3}d^{-1}$) = $\frac{A_{PN\,or\,POC}^{final} - A_{PN\,or\,POC}^{t=0}}{A_{N_2\,or\,DIC} - A_{PN\,or\,POC}^{t=0}} \times \frac{[PN\,or\,POC]}{\Delta t}$ (1)

where $A_{PN \text{ or } POC}$ A represents the ¹⁵N or ¹³C atom% excess of PN or POC, respectively, at the beginning (t =0) and 181 end (final) of the incubation, while $A_{N_2 \text{ or DIC}}$ represents the ¹⁵N or ¹³C atom% excess of or of the dissolved inorganic 182 183 pool (N_2 or dissolved inorganic carbon, DIC); and Δt represents the incubation period. 184 Depth-integrated rates were calculated by non-uniform gridding trapezoidal integration for each station. The DL, 185 defined as the m4inimal detectable uptake rates were determined as detailed in Fonseca-Batista et al. (2017). To do 186 so, the minimal acceptable ¹⁵N or ¹³C enrichment of PN or POC after incubation (Montoya et al., 1996) is considered 187 to be equal to the natural isotopic composition, specific to each sampled depth, increased byplus three times the 188 uncertainty obtained for N and C isotopic analysis of CRM. All remaining experiment-specific terms are then used to 189 recalculate the minimum detectable uptake. Carbon uptake rates were always above their specific DL, while N₂ 190 fixation was not undetectable for some incubations at any of the four depths of stations Bel-3 and Bel-5, nor at Bel-9 191 120 m, Bel-11 45 m and Geo-21 18 m (-see Supporting Information Table S1details in section 3.3).

2.4 DNA sampling and nifH diversity analysis

192

193

194 During the BG2014/14 and GEOVIDE cruises, water samples were also collected for DNA extraction and nifH 195 sequencing at the stations where N₂ fixation rate measurements were carried out, prior to incubation. Two liters2 L 196 volumes of seawater samples were vacuum filtered (20 to 30 kPa) through sterile 0.2 μm 47 mm sterile-membrane 197 filters eellulose acetate filters (cellulose acetate 47 mm Sartorius type 111 for BG2014/14; Millipore's Isopore -198 GTTP04700 for GEOVIDE) subsequently placed in cryovials directly flash deep frozen in liquid nitrogen. At the 199 land-based laboratory samples were transferred to a -80 °C freezer until nucleic acid extraction. 200 For the BG2014/14 samples, DNA was extracted from the samples using the Power Water DNA Isolation kit 201 (MOBIO) and checked for integrity by agarose gel electrophoresis. The amplification of nifH sequences was 202

performed on 3-50 ng μL⁻¹ environmental DNA samples using one unit of Taq polymerase (5PRIME), by nested

PCR according to Zani et al. (2000) and Langlois et al. (2005). Amplicons of the predicted 359-bp size observed by 203

gel electrophoresis were cloned using the PGEM T Easy cloning kit (PROMEGA) according to the manufacturer's instructions. A total of 103 clones were sequenced by the Sanger technique (GATC, Marseille).

206 For the GEOVIDE samples, DNA was extracted using the QIAGEN DNeasy Plant Mini Kit as directed instructed by the manufacture, with a modified step to improve cell lysis. This step consisted of an incubation at 52 °C on an 207 208 orbital shaker for 1 hour (300 rpm) with 50 μL of lysozyme solution (5 mg mL⁻¹ in TE buffer), 45 μL of Proteinase K 209 solution (20 mg mL⁻¹ in MilliO PCR grade water) and 400 μL of AP1 lysis buffer from the OIAGEN DNeasy Plant 210 Mini Kit. DNA concentration and purity were assessed with NanoDrop 2000 and then stored at -80 °C. The DNA 211 samples were screened for the presence of the nifH gene as described in Langlois et al. (2005). Samples that tested 212 positive were further prepared for next generation sequencing on an Illumina MiSeq platform using primers that 213 included the nifH1/2 primers (Langlois et al., 2005; Ratten, 2017) attached to Illumina adaptors and barcodes for 214 multiplexing in the Illumina MiSeq instrument. Next generation sequencing was carried out at the Integrated 215 Microbiome Resource (IMR) of the Centre for Comparative and Evolutionary Biology (CGEB) at Dalhousie University (Halifax, Canada). Raw Illumina paired-end reads of nifH were preprocessed using the QIIME pipeline 216 217 (Quantitative Insights Into Microbial Ecology; Caporaso et al., 2010) using following the IMR workflow 218 (https://github.com/mlangill/microbiome_helper/wiki/16S-standard-operating-procedure; Comeau et al., 2017). The 219 28 OTUs for the nifH genes presented in this study were assembled based on 96% identity of sequence reads. 220 DNA alignments were performed using the Molecular Evolutionary Genetics Analysis software (MEGA 7.0) (Kumar 221 et al., 2016) and nifH operational taxonomic units (nifH-OTUs) were defined with a maximum 5% divergence cut-222 off. DNA sequences were translated into amino acid sequences, then nifH evolutionary distances which are 223 considered as the number of amino acid substitutions per site, were computed using the Poisson correction method 224 (Nei, 1987). All positions containing gaps and missing data were eliminated (see phylogenetic tree in Fig. 6). One 225 representative sequence of each nifH-OTU was deposited in GenBank under the accession numbers referenced from 226 KY579322 to KY579337, for the Belgica DNA samples and referenced from MH974781 to MH974795 for the 227 GEOVIDE Iberian samples.

229

2.5 Statistical analysis

230 In order to examine $\underline{\mathbf{T}}$ the relationship between N_2 fixation activities and ambient physical and chemical properties 231 was examined, using SigmaPlot (Systat Software, San Jose, CA) by we-computinged Spearman rank correlation 232 coefficients linking depth-integrated rates and volumetric rates of N₂ fixation and primary production to environmental variables. These ambient variables were either averaged or integrated over the euphotic layer, or 233 234 measured considered in as discrete measurements anner, respectively. These variables include temperature, salinity, Chl a, NH_4^+ , $NO_3^- + NO_2^-$, phosphorus excess ($P^* = [PO_4^{3-}] - [NO_3^- + NO_2^-] / 16$) derived from in situ nutrient 235 measurements and climatological data (Garcia et al., 2013), dissolved iron concentrations determined for the 236 GEOVIDE cruise (Tonnard et al., 2018) and satellite-derived dust deposition fluxes at the time of our study 237 238 (Giovanni online data system). When nutrient concentrations were below the DL we used the DL value to run the 239 correlation test. In addition, we also ran a principal component analysis (PCA); using XLSTAT 2017 (Addinsoft, Paris, France, 2017) to get an overview of the interconnection between all the latter key variables with N₂ fixation at 240 241 the time of our study. The output of the PCA are discussed in section 4.3.

3 Results

242

243

3.1 Ambient environmental settings

- 244 Surface waters of all the ENACWst stations showed a relatively strong stratification resulting from the progressive
- spring heating, with sea surface temperature (SST) ranging from 15.3 (Geo-13) to 17.2°C (Bel-13). At the surface,
- 246 nNutrients were depleted at the surface ($NO_3^- + NO_2^- < 0.09 \mu M$ in the upper 20 m; Fig. 2c, f) and surface Chl a
- concentrations were low ($< 0.25 \,\mu g \, L^{-1}$; Fig. 2a, d) but showed a subsurface maximum (between 0.5 and 0.75 $\,\mu g \, L^{-1}$
- 248 at approximately 50 m), a common feature for oligotrophic open ocean waters. Amongst the ENACWst stations,
- station Geo-13 had a slightly higher nutrient content ($NO_3^- + NO_2^- = 0.7 \mu M$) in the lower mixed layer depth, (MLD)
- 250 and a higher Chl a concentration (> 0.5 μ g L⁻¹ in the upper 35 m).
- 251 Surface waters at ENACWsp stations were less stratified (SST between 14.0 and 14.5_°C), were nutrient replete
- 252 (surface $NO_3^- + NO_2^-$ ranging from 0.3 to 0.8 μ M) and had a higher phytoplankton biomass (Chl a between 0.7 to 1.2
- μ g L⁻¹ in the upper 30 m except for station Bel-5). Highest Chl a values were observed at station Bel-7 (44.6° N, 9.3°
- W), which appeared to be located within an anticyclonic mesoscale eddy, as evidenced by the downwelling structure
- detected in the Chl a and $NO_3^- + NO_2^-$ profiles (Fig. 2a, c) at this location (as well as T and S sections, data not
- 256 shown).

257

273

258 3.2 Primary production and satellite-based Cehl a observations

- 259 Primary production (PP), estimated through the incorporation of enriched bicarbonate (13C-NaHCO₃) into the
- 260 particulate organic carbon (POC) pool, illustrated volumetric rates ranging from 7 to 3500 μmol C m⁻³ d⁻¹ (see
- 261 Supporting Information Table S1) and euphotic layer integrated rates ranging from 32 to 137 mmol C m⁻² d⁻¹ (Fig.
- 3a, b, and Supporting Information Table S2). PP was relatively homogenous in the Bay of Biscay (stations Bel-3,
- 263 Bel-5 and Bel-7) and along the Iberian Margin (Bel-9, Bel-11, Bel-13 and Geo-1) with average rates ranging from 33
- 264 to 43 mmol C m⁻² d⁻¹, except at for station Bel-7 where it was slightly higher (52 mmol C m⁻² d⁻¹; Fig. 3a, b, and
- 265 Table S2), likely due to the presence of an anticyclonic mesoscale structure at this location. PP increased westwards
- 266 away from the Iberian Peninsula, reaching highest values at stations Geo-13 and Geo-21 (79 and 135 mmol C m⁻²
- 267 d⁻¹, respectively; Fig. 3b), as well as but also slightly higher eloser toon the Portuguese shelf (reaching 59 mmol C
- 268 m⁻² d⁻¹ at Geo-2). These results are in the range of past measurements in this region for the same period of the year,
- 269 ranging from 19 to 103 mmol C m⁻² d⁻¹ (Marañón et al., 2000; Fernández et al., 2005; Poulton et al., 2006; Fonseca-
- 270 Batista et al., 2017). Area-averaged Chl a derived from satellite imagery for a time-period overlapping with ours
- 271 (Giovanni online data system; Fig. 4a, b) revealed that post-bloom conditions prevailed at most sites (Bel-3 to Bel-13
- and Geo-1 to Geo-13) while bloom conditions were still found ongoing at station Geo-21 at the time of our study.

274 3.3 N₂ fixation and dominant diazotrophs at the sampling sites

- 275 Volumetric N₂ fixation rates were above the detection limitDL at 8 of the 10 stations sampled in this study (excluding
- 276 Bel-3 and Bel-5 where rates were being below the detection limitDL) and ranged from 0.7 to 65.4 nmol N L⁻¹ d⁻¹ (see
- Table S1), with areal rates ranging between 81 and 1533 μmol N m⁻² d⁻¹ (Fig. 3c, d, and Table S2).
- We observed intense N₂ fixation activities at the two sites (Bel-11 and Bel-13) most affected by ENACWst waters of
- 279 subtropical origin (Fig. S1). At stations Bel-11 and Bel-13, volumetric rates of N₂ fixation ranged from 2.4 to 65.4
- 280 nmol N L⁻¹ d⁻¹, with highest rates found at surface level (65.4 and 45.0 nmol N L⁻¹ d⁻¹, respectively), while areal rates

averaged 1533 and 1355 µmol N m⁻² d⁻¹, respectively. N₂ fixation was detected at all four GEOVIDE stations. Shelf-281 282 influenced (Geo-1 and Geo-2) and open ocean (Geo-13) ENACWst sites, geographically close to Bel-11 and Bel-13, 283 also displayed high N₂ fixation activities with volumetric rates ranging between-from 1.0 and to 7.1 nmol N L⁻¹ d⁻¹ (Table S1) while depth-integrated rates averaged 141, 262 and 384 µmol N m⁻² d⁻¹, respectively (Fig. 3c, d, and Table 284 285 S2). Significant N₂ fixation rates were also measured at stations that overall exhibited the highest primary production 286 rates, including Bel-7, Geo-13 and Geo-21 (Fig. 3). We computed the relative contribution of N₂ fixation to PP by 287 converting N₂ fixation rates to carbon uptake using either thea Redfield ratio of 6.6 or the determined median 288 POC/PN ratio for natural particles (equivalent to the mean value of 6.3 ± 1.1 , \pm SD, n = 46; Table 1). N_2 fixation 289 contributed to less than 2% of PP at the ENACWsp sites Bel-7 and Geo-21 and between 3 to 28% of PP at the 290 ENACWst sites, except at for station Bel-9 where it supported about 1% of PP. 291 Screening of the nifH genes from DNA samples collected during the BG2014/14 cruise, returned positive nifH 292 presence at stations Bel-11 and Bel-13 that displayed the largest areal N₂ fixation rates. Cloning of the nifH 293 amplicons found in surface waters (54% PAR level where volumetric rates of N₂ fixation were the highest) yielded 294 103 nifH sequences. No successful nifH amplifications were obtained at the other Belgica stations or depths where 295 diazotrophic activities were lower or undetectable. All $\frac{1}{1}$ of the clones (n = 41) recovered from station Bel-11 were 296 taxonomically regrouped assigned toin a single OTU that had 99% similarity identity at the nucleotide level and 297 100% similarity at the amino acid level with the symbiotic diazotrophic cyanobacteria UCYN-A1 or Candidatus 298 Atelocyanobacterium thalassa, first characterized from station ALOHA in the North Pacific (Fig. 5a and 6) 299 (Thompson et al., 2012). While the UCYN-A OTU also dominated the clones recovered from station Bel-13, fourteen 300 additional nifH phylotypes affiliated with non-cyanobacterial diazotrophs were also recovered at that station (Fig. 5a 301 and 6). Among these 15 OTUs, represented by a total of 62 sequenced clones, 45.2% of the sequences were affiliated 302 to UCYN-A1 (identical to those found at Bel-11), and the rest to heterotrophic bacteria with 25.8% affiliated to 303 Bacteroidetes, 19.3% to Firmicutes and 9.7% to Proteobacteria (Gamma-, Epsilon- and Delta-proteobacteria; Fig. 5a 304 and 6). For the GEOVIDE cruise, nifH screening returned positive nifH presence at stations Geo-2, Geo-13 and Geo-305 21. Next generation sequencing of these amplicons yielded in total 21001 reads, with a range of 170 to 9239 nifH 306 amplicons per sample, belonging exclusively to non-cyanobacterial diazotrophs, with the major affiliation to 307 Verrucomicrobia, and Gamma-, Delta- and Alpha-proteobacteria, representing 54, 28, 15 and 1% of total nifH 308 amplicons, respectively (Fig. 5b and 6). Members of a clade that has recently been recently characterized from the 309 TARA expedition through metagenome reconstructed assembled genomes of marine heterotrophic diazotrophs 310 (Delmont et al., 2018), were found among the Gammaproteobacteria OTU types that dominated the community at 311 station Geo-21.

3.4 Relationship between N₂ fixation rates and environmental variables

312

313

N₂ fixation activities were measured in surface waters characterized by relatively low SST (12.5–17.3 $^{\circ}$ C) and a wide range of dissolved inorganic nitrogen (DIN) concentrations (NO₃ $^{-}$ + NO₂ $^{-}$ from < 0.1 to 7.6 μ M). Water column integrated N₂ fixation tended to increase with the average surface water salinity (n = 10, p < 0.05, Table S3) but was inversely correlated to satellite-based dust deposition in May 2014, the month during which our sampling took place (n = 10, p < 0.01). Volumetric rates of N₂ fixation tended to increase with temperature (n = 46, p < 0.01, Table S4) and excess phosphorus concentration (only available for Belgica studied sites, n = 24, p < 0.01) while being negatively correlated to nitrate plus nitrite concentration (n = 46, p < 0.01).

4 Discussion

321

During two quasi-simultaneous expeditions to the Iberian Basin and the Bay of Biscay in May 2014 (38.8-46.5° N), 322 323 we observed N₂ fixation activity in surface waters of most visited stations (except at-for the two northernmost sites in 324 the Bay of Biscay). Our results are in support of other recent studies, that have observed diazotrophic communities 325 and significant N₂ fixation rates in marine environments that departing from the previously established belief that diazotrophs are preferentially associated with warm oceanic water and low fixed-nitrogen concentrations (Needoba et 326 327 al., 2007; Rees et al., 2009; Blais et al., 2012; Mulholland et al., 2012; Shiozaki et al., 2015). Although there is 328 growing evidence that diazotrophs and their activity can extend geographically to temperate coastal and shelf-329 influenced regions, there are still exist very few rate measurements at higher latitudes, especially in open waters. In 330 the following sections we shall (1) we discuss the significance of N_2 fixation in the Iberian Basin, as well as its relation to primary productivity pattern and extend our view to the whole Atlantic Ocean, (2) we provide information 331 332 on the taxonomic affiliation of diazotrophs that were present at the time of our study, and (3) we explore potential 333 environmental conditions that may have supported this unexpectedly high diazotrophic activity in the Iberian Basin.

334

335

360361

4.1 Significance of N₂ fixation in the temperate ocean

336 In the present study, we found surprisingly high N₂ fixation activities at most of the studied sites. Rates were 337 exceptionally elevated at two open ocean sites stations located between 38.8 and 40.7° N at about 11° W (averaging 1533 and 1355 μmol N m⁻² d⁻¹ at stations Bel-11 and Bel-13, respectively; Fig. 3c, d, and Tables S1 and S2). 338 Although N₂ fixation was not detected in the central Bay of Biscay (stations Bel-3 and Bel-5), rates recorded at all the 339 other sites were relatively high, not only in shelf-influenced areas (141 and 262 µmol N m⁻² d⁻¹ at stations Geo-1 and 340 Geo-2, respectively) but also in the open ocean (average activities between 81 and 384 µmol N m⁻² d⁻¹ at stations 341 342 Bel-7, Bel-9, Geo-13 and Geo-21). By fuelling the bioavailable nitrogen pool, N₂ fixation may support marine primary production (PP), but the extent of 343 344 this contribution needs to be established for areas outside tropical and subtropical regions. PP rates measured here are 345 of similar range if not slightly higher than those reported in earlier investigations in the Northeast Atlantic from works for subtropical to temperate waters of the northeast Atlantic (32 to 137 mmol C m⁻² d⁻¹ relative to 19 to 103 346 347 mmol C m⁻² d⁻¹) (Marañón et al., 2000; Fernández et al., 2005; Poulton et al., 2006; Fonseca-Batista et al., 2017). 348 However, the contribution of N₂ fixation contributions to PP in the present work (1–28% of PP) reached values twice 349 as high as those reported in other studies for the tropical and subtropical northeast Atlantic (contributions to PP ranging from < 1% to 12%) (Voss et al., 2004; Rijkenberg et al., 2011; Fonseca-Batista et al., 2017). This observation 350 351 further questions the general ideaaccepted premise that oligotrophic surface waters of tropical and subtropical regions 352 are the key environment where diazotrophic activity significantly supports marine primary productivity is 353 significantly supported by diazotrophic activity (Capone et al., 2005; Luo et al., 2014). Nevertheless, it is important 354 to keep in mind that our computation relies on the assumption that only photoautotrophic diazotrophs contribute to 355 bulk N₂ fixation, which is may not always be the case, particularly in the present study, where mostly heterotrophic 356 diazotrophs were observed. However, it is likely that all the recently fixed-nitrogen ultimately becomes available for 357 the whole marine autotrophic community. 358 Previous studies in the open waters of the Iberian Basin (35–50° N, east of 25° W) reported relatively lower N₂ fixation rates (from < 0.1 to 140 μmol N m⁻² d⁻¹), regardless of whether the bubble-addition method (Montoya et al., 359

1996) or the dissolution method (Mohr et al., 2010; Großkopf et al., 2012) were was used. However, these studies

were carried out largely outside the bloom period, either during the late growingth season (summer and autumn)

362 (Moore et al., 2009; Benavides et al., 2011; Snow et al., 2015; Riou et al., 2016; Fonseca-Batista et al., 2017) or 363 during winter (Rijkenberg et al., 2011; Agawin et al., 2014). In contrast, the present study took place in spring, during or just at the end of the vernal phytoplankton bloom. Differences in timing of these various studies and to a lesser 364 365 extent, different in methodologies (bubble-addition versus dissolution method) may explain the discrepancies in 366 diazotrophic activity observed between our study and earlier works. Yet, the 20 months survey by Moreira-Coello et al. (2017) in nitrogen-rich temperate coastal waters in the southern Bay of Biscay, covering the seasonal spring 367 bloom and upwelling pulses, did not revealed significant N₂ fixation activities: from 0.1 to 1.6 μmol N m⁻² d⁻¹ (up to 368 369 3 orders of magnitude lower than those reported here). However, unlike our study, this work was carried out not only 370 using the bubble-addition method but also in an inner coastal system, as opposed to the mainly open waters studied 371 investigated here, making it difficult to predict which variable or combination of variables caused the difference in 372 observedations between both the two studies. 373 Our maximal values recorded at stations Bel-11 and Bel-13 are one order of magnitude higher than maximal N₂ 374 fixation rates reported further south for the eastern tropical and subtropical North Atlantic (reaching up to 360-424 375 μmol N m⁻² d⁻¹) (Großkopf et al., 2012; Subramaniam et al., 2013; Fonseca-Batista et al., 2017). Besides these two 376 highly active sites, N₂ fixation rates at the other studied locations (ranging between 81 and -384 µmol N m⁻² d⁻¹) were 377 still in the upper range of values reported for the whole eastern Atlantic region. Yet, conditions favouring N2 fixation 378 are commonly believed to be met in tropical and subtropical regions where highest activities have mostly been 379 measured, particularly in the eastern North Atlantic (e.g., higher seawater temperature, DIN limiting concentrations, 380 excess phosphorus supply through eastern boundary upwelling systems) (Capone et al., 2005; Deutsch et al., 2007; 381 Luo et al., 2014; Fonseca-Batista et al., 2017). In the Atlantic Ocean, very high N₂ fixation rates up to ~1000 μmol N m⁻² d⁻¹ as observed here, have only been 382 reported for temperate coastal waters of the Northwest Atlantic (up to 838 µmol N m⁻² d⁻¹) (Mulholland et al., 2012) 383 384 and for tropical shelf-influenced and mesohaline waters of the Caribbean and Amazon River plume (maximal rates ranging between 898 and 1600 μmol N m⁻² d⁻¹) (Capone et al., 2005; Montoya et al., 2007; Subramaniam et al., 385 386 2008). Shelf and mesohaline areas have indeed been shown to harbour considerable N₂ fixation activity, not only in 387 tropical regions (Montoya et al., 2007; Subramaniam et al. 2008) but also in areas-waters extending from temperate to 388 polar regions areas (Rees et al., 2009; Blais et al., 2012; Mulholland et al., 2012; Shiozaki et al., 2015). Yet, the 389 environmental conditions that leading to the high N₂ fixation rates in theose regions are currently not well 390 understood. For tropical mesohaline systems, the conditions proposed to drive such an intense diazotrophic activity 391 include the occurrence of highly competitive diatom-diazotrophs associations and the influence of excess phosphorus 392 input (i.e., excess relative to the canonical Redfield P/N ratio; expressed as P*) from the Amazon River 393 (Subramaniam et al., 2008). However, such conditions of excess P were not observed in previous studies carried out 394 in high latitude shelf regions with elevated N₂ fixation activities (Blais et al., 2012; Mulholland et al., 2012; Shiozaki 395 et al., 2015), nor was it distinctly apparent in the present study (see section 4.3). In addition, while tropical 396 mesohaline regions are characterized by the predominance of diatom-diazotroph associations (and filamentous 397 Trichodesmium spp.), in temperate shelf areas the diazotrophic community is reported to be essentially dominated by UCYN-A and heterotrophic bacteria (Rees et al., 2009; Blais et al., 2012; Mulholland et al., 2012; Agawin et al., 398 2014; Shiozaki et al., 2015; Moreira-Coello et al., 2017). 399

401 4.2 Features of the diazotrophic community composition in the temperate North Atlantic

402 Our qualitative assessment of nifH diversity revealed a predominance of UCYN-A symbionts, only at the two stations with the highest recorded surface N2 fixation rates (up to 65.4 and 45.0 nmol N L-1 d-1 at Bel-11 and Bel-13, 403 404 respectively; Table S1) while the remaining nifH sequences recovered belonged to heterotrophic diazotrophs, at Bel-405 13 and also as well as at all the other sites where nifH genes could be detected. No Trichodesmium nifH sequences 406 were recovered from either BG2014/14 or GEOVIDE DNA samples, and the absence of the filamentous 407 cyanobacteria was also confirmed by thea CHEMTAX analysis of phytoplankton pigments (M. Tonnard, personal 408 communication, January 2018). Previous work in temperate regions of the global ocean, including the Iberian Margin 409 also reported that highest N₂ fixation activities were predominantly related to the presence of UCYN-A symbionts, 410 followed by heterotrophic bacteria, while Trichodesmium filaments were low or undetectable (Needoba et al., 2007; 411 Rees et al., 2009; Mulholland et al., 2012; Agawin et al., 2014; Shiozaki et al., 2015; Moreira-Coello et al., 2017). 412 UCYN-A (in particular from the UCYN-A1 clade) were shown to live in symbioses with single-celled 413 prymnesiophyte algae (Thompson et al., 2012). This symbiotic association, considered obligate, has been reported to 414 be particularly abundant in the central and eastern basin of the North Atlantic (Rees et al., 2009; Krupke et al., 2014; 415 Cabello et al., 2015; Martínez-Pérez et al., 2016). 416 Besides UCYN-A, all the remaining *nifH* sequences recovered from both cruises, although obtained through different 417 approaches, belonged to non-cyanobacterial diazotrophs. The phylogenetic tree (Fig. 6) showed that the non-418 cyanobacterial diazotrophs clustered with (1) Verrucomicrobia, a phylum yet poorly known that includes aerobic to 419 microaerophilice methanotrophs groups, found in a variety of environments (Khadem et al., 2010; Wertz et al., 2012), 420 (2) anaerobic bacteria, obligate or facultative, mostly affiliated to Cluster III phylotypes of functional nitrogenase 421 (e.g., Bacteriodetes, Firmicutes, Proteobacteria) and finally lastly (3) phylotypes from Clusters I, II, and IV (e.g., 422 Proteobacteria and Firmicutes). Among the Cluster III phylotypes, Bacteroidetes are commonly encountered in the 423 marine environment, and are known as specialized degraders of organic matter that preferably grow attached to 424 particles or algal cells (Fernández-Gómez et al., 2013). N₂ fixation activity has previously been reported in five 425 Bacteroidetes strains including Bacteroides graminisolvens, Paludibacter propionicigenes and Dysgonomonas gadei 426 (Inoue et al., 2015) which are the closest cultured relatives of the nifH-OTUs detected at station Bel-13 (Fig. 6). 427 Anaerobic Cluster III phylotypes have been previously recovered from different ocean basins (Church et al., 2005; 428 Langlois et al., 2005, 2008; Man-Aharonovich et al., 2007; Rees et al., 2009; Halm et al., 2012; Mulholland et al., 429 2012). These diazotrophs were suggested to benefit from anoxic microzones found within marine snow particles or 430 zooplankton guts to fix N₂ thereby avoiding oxygenic inhibition of their nitrogenase enzyme (Braun et al., 1999; 431 Church et al., 2005; Scavotto et al., 2015). Therefore, the bloom to early post-bloom conditions, prevailing during our 432 study, were likely beneficial to-for the development of diazotrophic groups that depend on the availability of detrital 433 organic matter or on the association with grazing zooplankton. In contrast, at the northern-most Geo-21 station, we 434 observed a dominance of Gammaproteobacteria phylotypes belonging to a recently identified clade of marine 435 diazotrophs within the Oceanospirillales (Delmont et al., 2018). 436 These observations tend to strengthen the idea of a substantial role playedthat not only by UCYN-A (Cabello et al., 437 2015; Martínez-Pérez et al., 2016) but also by-non-cyanobacterial diazotrophs (Halm et al., 2012; Shiozaki et al., 438 2014; Langlois et al., 2015) play a substantial role in oceanic N₂ fixation. Although it is possible to assign a broad 439 taxonomic affiliation to classify the nifH genes, we know very little is known with respect to their physiology, their 440 role in the ecosystem and the factors that controlling their distribution, largely due to the lack of representative whole 441 genome sequences and environmentally relevant strains available for experimentation (Bombar et al., 2016). While

studies have been reporting on the widespread distribution of UCYN-A and heterotrophic non-cyanobacterial diazotrophs has been reported, their contribution to in situ activity remains until now poorly quantified.

444

445

482

4.3 Key environmental drivers of N₂ fixation

446 Environmental conditions that promote autotrophic and heterotrophic N₂ fixation activity in the ocean are currently not well understood (Luo et al, 2014). While heterotrophic diazotrophs would not be directly affected by the 447 commonly recognized environmental controls of autotrophic diazotrophy such as solar radiation, seawater 448 449 temperature and DIN, as they possess fundamentally different ecologies, the molecular and cellular processes for 450 sustaining N₂ fixation activity would nevertheless require a supply of dFe and P (Raven, 1988; Howard & Rees, 451 1996; Mills et al., 2004; Snow et al., 2015). Besides the need for these critical inorganic nutrients, heterotrophic N₂ fixation was also recently shown to be highly dependent on the availability of organic matter (Bonnet et al., 2013; 452 453 Rahav et al., 2013, 2016; Loescher et al., 2014). 454 Findings from the GEOVIDE cruise tend to support the hypothesis of a stimulating effect of organic matter 455 availability on N_2 fixation activity at the time of our study. Lemaitre et al. (2018) report that the surface upper 100 456 120 m-waters (upper 100-120 m) of the Iberian Basin (stations Geo-1 and Geo-13) and the West European Basin 457 (Geo-21) carried significant particulate organic carbon POC loads (POC of 166, 171 and 411 mmol C m⁻², 458 respectively) with a dominant fraction of small size POC (the 1-53 µm size fraction; 75%, 92% and 64% of the total 459 POC, respectively). Smaller cells, usually being slow-sinking particles, are more easily remineralized in surface 460 waters (Villa-Alfageme et al., 2016). This is confirmed by the very low export efficiency (only 3 to 4% of euphotic 461 layer integrated PP) observed at stations Geo-13 and Geo-21, evidencing suggesting an efficient shallow 462 remineralisation (only 3 to 4% of euphotic layer integrated PP reaching the depth of export at these stations; 463 (Lemaitre et al., 2018). This availability of organic matter in the upper layers likely contributed to supplying 464 remineralized P (organic P being generally more labile than other organic nutrients; Vidal et al., 1999, 2003) and to 465 enhancing the residence time of dFe originating from atmospheric deposition due to the formation of organic ligands (Jickells, 1999; de Baar and de Jong, 2001; Sarthou et al., 2003). 466 P* values from the BG2014/14 cruise (Table S1) and the climatological P* data for the Iberian Basin (Garcia et al., 467 2013) do not exhibit a clear PO₄³⁻ excess in the region (P* ranging between from -0.1 and to 0.1 μmol L⁻¹; Fig. 1 and 468 469 Tables S1 and S2). Nevertheless, Spearman rank correlations indicate that volumetric N2 fixation rates were 470 significantly correlated with the BG2014/14 shipboard P* values (n = 24, p < 0.01, Table S4), with stations Bel-11 471 and Bel-13 weighing heavily in this correlation. Without the data from these two sites (data not shown), the correlation between in situ P* and N₂ fixation rates is no longer significant (n= 16, p=0.163), with while P* 472 becomesing highly correlated with PP and Chl a (n = 16, p = 0.0257 and 0.016, respectively). This suggests that 473 474 the P* effect of P* on N₂ fixation, although not clearly evident from absolute values, was most important at stations 475 Bel-11 and Bel-13 but nonetheless existent at the other sites (Bel-7 and Bel-9). The impact-occurrence of N₂ fixation 476 in oligotrophic waters displaying of weak P* values, in oligotrophic waters depleted in DIN and PO₄3- but replete in 477 dFe might in fact reflect the direct use by diazotrophs of dissolved organic phosphorus (DOP). Indeed, according to 478 Landolfi et al. (2015) diazotrophy ensures the supply of additional N and energy for the enzymatic mineralization of 479 DOP (synthesis of extracellular alkaline phosphatase). Therefore, a likely enhanced DOP release towards the end of 480 the spring bloom may have contributed to sustaining N₂ fixation in the studied region. Such DOP utilization has 481 indeed been reported for various marine organisms, particularly diazotrophic cyanobacteria (Dyhrman et al., 2006;

Dyhrman & Haley, 2006) and bacterial communities (Luo et al., 2009).

483 Supply routes of dFe to the surface waters of the investigated area relied on lateral advection from the continental 484 shelf (stations Geo-1 and Geo-2) (Tonnard et al., 2018), vertical mixing due to post-winter convection (Thuróczy et 485 al., 2010; Rijkenberg et al., 2012; García-Ibáñez et al., 2015), and/or atmospheric dust deposition (dry + wet). In the 486 following we discuss that A atmospheric deposition may have been particularly important for the area of stations Bel-487 11 and Bel-13 receiving warm and saline surface waters from the subtropics. 488 Atmospheric aerosol deposition determined during the GEOVIDE cruise (Shelley et al., 2017), as well as the 489 satellite-based dust deposition (dry + wet) averaged over the month of May 2014 (Fig. S3b; Giovanni online satellite 490 data system, NASA Goddard Earth Sciences Data and Information Services Center), reveal rather weak dust loadings 491 over the investigated region, resulting in areal N₂ fixation rates being actually inversely correlated to the satellite-492 based average dust input (p < 0.01, Table S3). In contrast, satellite-based dust deposition (dry + wet) averaged over 493 the month of April 2014 (i.e. preceding the timing of sampling) indicates high values fluxes over the subtropical 494 waters located south of the studied region (Fig. S3a;). The θ /S diagrams at stations Bel-11 and Bel-13 (and to a lesser 495 extent at Geo-13; Fig. S1) illustrate the presence of very warm and saline waters, which were advected from the 496 subtropics as suggested by the and satellite SST images suggest these were advected from the subtropics (Fig. S2). 497 We thus argue that advection of surface waters from south of the study area represented a source of atmospherically 498 derived dFe and contributed to driving the high N2 fixation activity recorded at stations Bel-11 and Bel-13. This resulted in N_2 fixation rates there being positively (although weakly) correlated (p = 0.45, Table S3) with the April 499 500 average dust input. 501 For the central Bay of Biscay, where N₂ fixation was below the DL detection limit (stations Bel-3 and Bel-5), dust 502 deposition in April 2014 was also the lowest, suggesting that N₂ fixation there might have been limited by dFe 503 availability. Indeed, at stations Bel-3 and Bel-5 diazotrophic activity in surface waters was boosted following dFe amendments (> 25 nmol N L-1 d-1; Li et al., 2018). 504 505 Thus, the enhanced N₂ fixation activity at stations Bel-11 and Bel-13, as compared to the other sites, was likely stimulated by the combined effects of the presence of highly competitive prymnesiophyte-UCYN-A symbionts, 506 organic matter as a source of DOP, positive P* signatures, and advection of subtropical surface waters enriched in 507 508 dFe. 509 These statements are further supported by the outcome of a multivariate statistical analysis, providing a 510 comprehensive view of the environmental features influencing N₂ fixation. A principal component analysis (PCA; 511 Fig. 7 and Tables S2 and S5) generated two components (or axes) explaining 68% of the system's variability. Axis 1 512 illustrates the productivity of the system, or more precisely the oligotrophic state towards which it was evolving. Axis 513 1 is defined by a strong positive relation with surface temperature (reflecting the onset of stratification, particularly 514 for stations Bel-11 and Bel-13; Fig. 7) and an inverse relation with PP and associated variables (Chl a, NH₄⁺, NO₃⁻ + NO₂-), which reflects the prevailing post-bloom conditions of the system. Sites characterized by a moderate (Bel-3 515 516 and Bel-5) to high (Bel-7, Geo-21 and to a lesser extent Geo-13) PP appear indeed tightly linked to these PP-517 associated variables as illustrated in Fig. 7. Axis 2 is defined by the positive relation with surface salinity and P* (Fig. 518 7) and reflects the advection of surface waters of subtropical origin, for stations Bel-11, Bel-13 and Geo-13. For 519 stations Geo-1 and Geo-2, the inverse relation with surface salinity (Fig. 7) is interpreted to reflect fluvial inputs

13

(Tonnard et al., 2018). Finally, this statistical analysis indicates that N_2 fixation activity was likely influenced by the

two PCA components, tentatively identified as productivity (axis 1) and surface water advection (axis 2) from the

520521

522

shelf and the subtropical region.

5 Conclusions

523

524 The present work highlights the occurrence of elevated N₂ fixation activities (81–1533 µmol N m⁻² d⁻¹) in spring 2014 525 in open waters of the temperate eastern North Atlantic, off the Iberian Peninsula. These rates exceed those reported 526 by others for the Iberian Basin, but which were largely obtained outside the bloom period (from < 0.1 to 140 µmol N 527 m⁻² d⁻¹). In contrast, we did not detect any N₂ fixation activity in the central Bay of Biscay. At sites where significant 528 N₂ fixation activity was detected measured, rates were similar to or up to an order of magnitude larger compared 529 tothan values reported for the eastern tropical and subtropical North Atlantic, regions commonly believed to represent 530 the main areas harbouring of oceanic N_2 fixation for the eastern Atlantic. Assuming that the carbon versus nitrogen 531 requirements by these N₂ fixers obeyed the Redfield stoichiometry, N₂ fixation was found able-to contribute 1-3% of 532 the euphotic layer daily PP and even up to 23-25% at the sites where N_2 fixation activities $\frac{1}{2}$ wereas the highest. The 533 pPrymnesiophyte-symbiont Candidatus Atelocyanobacterium thalassa (UCYN-A) contributed the most to the nifH 534 sequences recovered at the two sites where N₂ fixation activity were theas highest, while the remaining sequences 535 belonged exclusively to heterotrophic bacteria. We support speculate that the unexpectedly high N₂ fixation activity 536 recorded at the time of our study was sustained by (i) organic matter availability in these open waters, resulting from 537 the prevailing vernal bloom to post-bloom conditions, in combination with (ii) excess phosphorus signatures which 538 appeared to be tightly related to diazotrophic activity particularly at the two most active sites. Yet these observations 539 and hypotheses rely on the availability of dFe with evidence for input from shelf waters and pulsed atmospheric dust 540 deposition being a significant source of iron. Further studies are required to investigate this possible link between N2 541 fixation activity and phytoplankton bloom under iron-replete conditions in the studied region and similar 542 areasenvironments, as these would require to be considered in future assessment of global N₂ fixation.

Acknowledgements. We thank the Captains and the crews of R/V Belgica and R/V Pourquoi pas? for their skilful logistic support. A very special thank goes to the chief scientists G. Sarthou and P. Lherminier of the GEOVIDE expedition for the great work experience and wonderful support on board. We would like to give special thanks to Pierre Branellec, Michel Hamon, Catherine Kermabon, Philippe Le Bot, Stéphane Leizour, Olivier Ménage (Laboratoire d'Océanographie Physique et Spatiale), Fabien Pérault and Emmanuel de Saint Léger (Division Technique de l'INSU, Plouzané, France) for their technical expertise during clean CTD deployments. We thank A. Roukaerts and D. Verstraeten for their assistance with laboratory analyses at the Vrije Universiteit Brussel. We acknowledge Ryan Barkhouse for the collection of the DNA samples during the GEOVIDE cruise, Jennifer Tolman and Jenni-Marie Ratten for the nifH amplification and Tag sequencing. P. Lherminer, P. Tréguer, E. Grossteffan, and M. Le Goff are gratefully acknowledged for providing us with the shipboard physico-chemical data including CTD and nitrate plus nitrite data from the GEOVIDE expedition. Shiptime for the Belgica BG2014/14 cruise was granted by Operational Directorate 'Natural Environment' (OD Nature) of the Royal Institute of Natural Sciences, Belgium. OD Nature (Ostend) is also acknowledged for their assistance in CTD operations and data acquisition on board the

Figure legends

respectively. (Schlitzer, R., Ocean Data View).

Figure 1: Location of sampling stations during the Belgica BG2014/14 (black labels) and GEOVIDE (white labels) cruises (May 2014) superimposed on a map of the seasonal average phosphate excess (P* = [PO₄³⁻] – [NO₃⁻] / 16) at 20 m (April to June for the period from 1955 to 2012; World Ocean Atlas 2013; Garcia et al., 2013). Areas of dominance of the Eastern North Atlantic Central Waters of subpolar (ENACWsp) and subtropical (ENACWst) origin are separated by a horizontal dashed line. Black dashed and solid contour lines illustrate 500 m and 1500 m isobaths,

871 872

865

Figure 2: Spatial distribution of Chl *a* (**a, d**), NH₄⁺ (**b, e**) and NO₃⁻ + NO₂⁻ (**c, f**) concentrations along the Belgica BG2014/14 (**upper panels**) and GEOVIDE (**lower panels**) cruise tracks. Station numbers are indicated above the sections. The vertical black line represents the boundary between areas with dominance of Eastern North Atlantic Waters of subpolar (ENACWsp) and subtropical (ENACWst) origin. Mixed layer depth (MLD, black lines connecting diamonds) was estimated using a temperature threshold criterion of 0.2_°C relative to the temperature at 10 m (de Boyer Montégut et al., 2004). (Schlitzer, R., Ocean Data View).

879

Figure 3: Spatial distribution (± SD) of depth-integrated rates of primary production (**a, b**) (duplicates are in light and dark green bars with the corresponding values in mmol C m⁻² d⁻¹); N₂ fixation (**c, d**) (duplicates are in light and dark blue bars with the corresponding values in μmol N m⁻² d⁻¹) determined during the Belgica BG2014/14 (**a, c**) and GEOVIDE (**b, d**) cruises. Error bars represent the propagated measurement uncertainty of all parameters used to compute volumetric uptake rates.

885

Figure 4: Time series of area-averaged chlorophyll a concentration (mg m⁻³) registered by Aqua MODIS satellite (Giovanni online satellite data system) between December 2013 and December 2014 for the 0.5° x 0.5° grid surrounding the different stations during the (a) Belgica BG2014/14 and (b) GEOVIDE cruises. The dashed box highlights the sampling period for both cruises (May 2014).

890

893

Figure 5: Diversity of *nifH* sequences during (a) the Belgica BG2014/14 cruise (successfully recovered only at stations Bel-11 and Bel-13, 5 m) and (b) the GEOVIDE cruise (stations Geo-2, 100 m; Geo-13, 35 m and Geo-21, 15 and 70 m. The total numbers of recovered sequences are indicated on top of the bars, and the exact percentage represented by each group is shown inside the bars.

Figure 6: Phylogenetic tree of nifH predicted amino acid sequences generated using the Maximum Likelihood 896 897 method of the Kimura 2-parameter model (Kimura, 1980) via the Molecular Evolutionary Genetics Analysis software 898 (MEGA 7.0) (Kumar et al., 2016). Initial tree(s) for the heuristic search were obtained automatically by applying 899 Neighbor-Join and BioNJ algorithms to a matrix of pairwise distances estimated using the Maximum Composite 900 Likelihood (MCL) approach, and then selecting the topology with superior log likelihood value. A discrete Gamma 901 distribution was used to model evolutionary rate differences among sites (5 categories (+G, parameter = 0.4038)). All 902 sequences recovered from DNA samples, including those previously identified and the newly recovered ones (with \geq 95% similarity at the nucleotide level with representative clones) are highlighted in blue. For the nifH sequences 903 904 recovered from the GEOVIDE cruise, only those contributing to the cumulative 98% of recovered sequences were 905 included in this tree. Bootstrap support values (≥ 50%) for 100 replications are shown at nodes. The scale bar

indicates the number of sequence substitutions per site. The archaean *Methanobrevibacter smithii* was used as an outgroup. Accession numbers for published sequences used to construct the phylogenetic tree are given.

Figure 7: Euclidean distance biplot illustrating the axis loadings for the two main PCA components based on the Spearman rank correlation matrix shown in Table S3. Variables taken into account include depth-integrated rates of N₂ fixation and primary production (PP), average phosphate excess at 20 m depth surrounding each sampled site recovered from World Ocean Atlas 2013 climatology data between April and June from 1955 to 2012 (Garcia et al., 2013); satellite average dust deposition (dry + wet) derived during April 2014 (Giovanni online data system, NASA Goddard Earth Sciences Data and Information Services Center) and ambient variables (temperature, salinity, and nutrient data). Coloured dots in the biplot represent the projection of the different stations. Axis 1 has high negative loadings for PP, Chl *a*, NH₄⁺ and NO₃⁻ + NO₂⁻, and high positive loadings for temperature and N₂ fixation rates, with values of -0.812, -0.768, -0.936, -0.783, 0.942 and 0.506, respectively (see Table S5). Axis 2 has high positive loadings of 0.584, 0.943 and 0.602 for climatological P*, salinity and N₂ fixation rates, respectively. PCA analysis was run in XLSTAT 2017 (Addinsoft, Paris, France, 2017).
