Review of the revised manuscript “Inputs and processes affecting the distribution of particulate Fe in the North Atlantic along the GEOVIDE section” by Gourain, A. and co-authors.

First of all the manuscript has improved massively compared to the last version. The first half of the manuscript is mostly in good shape, but the second part lacks mainly a clear structure of paragraphs which makes it really hard to follow the stream of thoughts. So, especially the conclusion needs to be revisited and strengthened. There is a lot of text, but little information. I am also missing the highlighting of the biogenic fraction, there is hardly anything discussed. However, the data is interpreted and concluded correctly, but changes to the text that need to be done to improve the second part of the paper require between major and intermediate revision. I hope my comments below help to strengthen the text.

With best regards,

Christian Schlosser

Dear Dr Schlosser,

We would like to thank you for your time and effort in this review process.

Concerning the biogenic fraction, it is true that while we are mentioning it in our PMF analysis, we do not discuss it much further, as this is the focus of another paper currently under preparation (distribution between size fractions in the top 200m, completed with chemical leaches analyses). We wrote a specific sentence to mention this lines 358-359.

We reorganized most of the discussion, and simplified some of the wordy sentences.

We truly hope that you will now find this manuscript suitable for publication.

Our detailed answers are below.

Kind regards,

Arthur Gourain, on behalf of all coauthors.

Abstract

Line 35:replace “basins” by “basin” Done.

Line 36ff: Important sounds strange! I would use “high” instead. Please alos include “horizontal”, otherwise advection takes also place vertically. I would also include “advection of PFe containing water masses “ not PFe travels the water mass does this job. Done.

Line 40ff: This sentence is a bit lost, and out of context. We removed this sentence.

Method

Line 89: “briefly described in section 2.1” I cannot find a brief description of the complex circulation.
Indeed the circulation is described section 3.1. We changed 2.1 by 3.1 in the text.

Line 102; Remove “and the filters processed…” This is out of context here! Done.

Line 104: What find of filters you are talking about, these are not filters used for the Swinnex filtration right?
Yes, we are talking about the Swinnex filtration.

Line 133: Replace “filter” by “Filters” Done.

Line 137: You also removed the filter, right? Yes, this is now indicated.

Results

Line 180ff: I have not found any biological settings in this chapter… It is also very long, detailed, and to some extend hard to follow. It would be good to start with a sentence what you are doing and thenm characterize water masses basin after basin separated by different paragraphs. That would make it easier to follow. We removed the biological settings from the title, they were mentioned in the first version of the manuscript and we omit to remove them from the title. We also created more paragraphs to make it easier to follow.

Line 222: This sentence is really hard to understand, please rephrase. Please also shorten the title! We shortened the title as requested to “Open Ocean stations: from the Iberian Abyssal Plain to the Labrador Basin and add an introductory line to precise which stations are concerned by this paragraph. Line 254.

We modified the sentence as follow: “Particulate iron concentration profiles showed identical patterns at all of the open ocean stations encountered along the section.”

Line 229: I have not even watched Figure 3 and sup. Table 1and you introduce Figure 9b and sup. Table 2. We removed the citation.

Line 253: Include “in THE surface” Done.

Line 281: You refer here to 5 factors, figure 6 represents 4 factors. What is right, I presume the figure? Indeed 4 factors is the right one.

Line 286: change to “and remineralisation of biogenic material.” Done.

Line 300: Replace “material” by “ fraction”. Done.

Line 312: Replace “with consideration” by “carefully”. Done.

Line 320ff: with %PFe you mean the lithogenic fraction…, be careful and try to apply always the same abbreviation. Indeed there was a typo mistake. It’s been modified to $\%PFe_{litho.}$

Line 320-325: If keeping these sentence, please create a new paragraph. Please also rewrite sentences, they are really hard to understand and follow! Link the %PFe data to Salinity, that at least gives you some certainty that there is a change in water mass. We rewrote this paragraph and included salinity values to demonstrate the presence of the front and thus confirm the link between %PFelitho and salinity value. Lines 344 to 346.

Line 335-340: Please rephrase the sentences, sorry hard to read! Especially the last sentence is formulated very vague! Done

Line 344ff: The following 3 paragraphs should have been included already in section 4.2.You are discussing your results and not discussing them. The structure of the following paragraphs needs to be changed as well, first you come with your hypothesis and then you explain why this is the case. Right now it is all turned around. Why are you coming up with the ratio Mn/Al now. It comes out of the blue. I would introduce this parameter earlier when you come up with %PFe for instance. We are now introducing %PFe litho and %PMn in the methods (section 2.6) as derived parameters. This way, the flow of the discussion is not altered by the explanation of these parameters and flows better. Furthermore, we deleted the subsection title “fingerprinting water masses” and merged the discussion of the water masses exhibiting a specific PFe/PAl with the PMF results and the %PFe litho (lines 380-381;).

Line 379: This paragraph is not explaining the differences of the Fe/Al ratio observed. What is the River doing? We deleted this paragraph. We were not discussing the PFe/PAl ratio from the water discharge due to the lack of data within the plume and the endmember. The differences of PFe/PAl ratio described line 472 are linked to the margin sediments resuspension.

Line 383:What do you mean with important! We replaced important by high.

Line 396ff: This sentence needs to come first. We reorganized this paragraph.

Line 399ff: Your paragraphs are really long. Anyway, you do not discuss why there are this two maxima. The last sentence "Therefore…" is the most important finding and should come first. And then switching between PFe and PMn, it is hard to follow your stream of thoughts. We reorganized this paragraph.

Line 423ff: What is the message of the paragraph. Buried in the text "Transfer of DFe to PFe. That needs to come in the beginning of the paragraph. We reorganized this paragraph.

Line 479ff: Good this is the most important paragraph, for the first time you put the finding into context and discuss them. It is very hard to go through the last 3 pages without a strong structured line of thoughts! Thanks, as previously explained, we rewrote the previous paragraph in light of your comments.

Line 494ff: The presented literature data needs to be put in context to your findings towards the end of the following paragraph. We reorganized this paragraph.

Line 526: Include the SEM picture in the sup material. Done.

Line 535ff: First: Barraqueta, Second: What do you mean with the following sentence. It is hard to follow. What has the concentration to do with the composition? We meant that surface waters along the section were not characterised by high concentration of trace metals. We removed to sentence about composition to make the discussion clearer.

Conclusion

This is not a conclusion, it is just a second abstract. We modified the conclusion.

Line 550: Maybe start the Sentence with: The Done.

Line 555: The river is not responsible or the PFe at 2500 m depth. Indeed. We modified the conclusion.

Figure 2 citation: Line 908: Replace "Stations" by "Station" Done.

Figure 3: Please increase the font size of the ODV graphs, it is almost impossible to read the depth and longitude on a print out. Done.

Figure 4 caption: Please include that the PFe scale changes within graphs. Done.

Abstract

The GEOVIDE cruise (May-June 2014, R/V *Pourquoi Pas?*) aimed to provide a better understanding on trace metal biogeochemical cycles in the North Atlantic. As particles play a key role in the global biogeochemical cycle of trace elements in the ocean, we discuss the distribution of particulate iron (PFe), in light of particulate aluminium (PAl), manganese (PMn) and phosphorus (PP) distributions. Overall, 32 full vertical profiles were collected for trace metal analyses, representing more than 500 samples. This resolution provides a solid basis for assessing concentration distributions, elemental ratios, size-fractionation, or adsorptive scavenging processes in key areas of the thermohaline circulation. Total particulate iron (PFe) concentrations ranged from as low as 9 pmol L^{-1} in surface Labrador Sea waters to 304 nmol L^{-1} near the Iberian margin, while median PFe concentrations of 1.15 nmol L^{-1} were measured over the sub-euphotic ocean interior.

Within the Iberian Abyssal Plain, ratio of PFe over ~~particulate aluminium (~~PAl~~)~~ is identical to the continental crust ratio (0.21), indicating the important influence of crustal particles in the water column. Overall, the

Formatted: Font: Italic

lithogenic component explained more than 87% of PFe variance along the section. Within the Irminger and Labrador basinss, the formation of biogenic particles led to an increase of the PFe/PAl ratio (up to 0.7 mol mol-1) compared to the continental crust ratio (0.21 mol mol^{-1}). Margins provide ~~important~~ high quantities of particulate trace elements (up to 10 nmol L^{-1} of PFe) to the open ocean, and in the case of the Iberian margin, horizontal advection of PFe was visible more than 250km away from the margin. Additionally, several benthic nepheloid layers spreading over 200m above the seafloor were encountered along the transect, especially in the Icelandic, Irminger and Labrador basins, delivering particles with high PFe content, up to 89 nmol L^{-1} ~~of PFe~~. ~~Finally, remineralisation processes are also discussed, and showed different patterns among basins and elements.~~

1. Introduction

Particles play a key role in the ocean where they drive the residence time of most elements (Jeandel and Oelkers~~et al.~~, 2015), and strongly influence the global biogeochemistry of macro and micro-nutrients including iron (Milne et al., 2017). In the surface ocean, biological activity produces biogenic suspended matter through planktonic organisms, while atmospheric deposition (Baker et al., 2013; Jickells et al., 2005), riverine discharge (Aguilar-Islas et al., 2013; Berger et al., 2008; Ussher et al., 2004) or ice-melting (Hawkings et al., 2014; Lannuzel et al., 2011, 2014) bring mostly lithogenic derived particles to surface waters. These particulate inputs highly vary, both spatially and seasonally, around the world's oceans. At depth, benthic and shelf sediment resuspension (e.g. Aguilar-Islas et al., 2013; Cullen et al., 2009; Elrod et al., 2004; Fitzwater et al., 2000; Hwang et al., 2010; Lam et al., 2015; Lam and Bishop, 2008; McCave and Hall, 2002), and hydrothermal activity (Elderfield and Schultz, 1996; Lam et al., 2012; Tagliabue et al., 2010, 2017; Trefry et al., 1985), provides important amounts of particles to the water column. Moreover, authigenic particles can be produced *in-situ* by aggregation of colloids (Bergquist et al., 2007) or oxidation processes (Bishop and Fleisher, 1987; Collier and Edmond, 1984). Thus, oceanic particles result from a complex combination of these different sources and processes (Lam et al., 2015).

Particles represent the main part of the total iron pool in the upper water column (Radic et al., 2011), and strongly interact with the dissolved pool (e.g. Ellwood et al., 2014). Indeed, dissolved iron can be scavenged onto particles (Gerringa et al., 2015; Rijkenberg et al., 2014), incorporated into biogenic particles (Berger et al., 2008) or produced by remineralisation of particles (Dehairs et al., 2008; Sarthou et al., 2008). Interestingly, the concept of "reversible scavenging" (i.e. release at depth of dissolved iron previously scavenged onto particles) has been advocated recently (Dutay et al., 2015; Jeandel and Oelkers, 2015; Labatut et al., 2014), while other studies reveal distinct dissolution processes (e.g. Oelkers et al., 2012; Cheize et al., ~~submitted to Chemical Geology~~2018). Slow dissolution of particulate iron at margins has also been evoked as a continuous fertilizer of primary production and should be considered as a source of dissolved iron (e.g. Jeandel et al., 2011; Jeandel and Oelkers, 2015; Lam and Bishop, 2008). Within or below the mixed layer, the rates of regeneration processes can also impact the bioavailable pool of iron, among other trace metals (e.g. Ellwood et al., 2014; Nuester et al., 2014). However, the rates of these processes are not yet fully constrained. The study of particulate iron is thus essential to better constrain ~~the global~~ its marine biogeochemical cycle ~~of iron in the ocean~~. This subject received a growing interest over the last 10 years in particular (e.g. Bishop and Biscaye, 1982; Collier and Edmond, 1984; Frew et al., 2006; Lam et al., 2012; Milne et al., 2017; Planquette et al., 2011, 2013; Sherrell et

al., 1998) and, to our knowledge, only two have been performed at an ocean-wide scale and published so far: the GA03 GEOTRACES North Atlantic Zonal Transect (Lam et al., 2015; Ohnemus and Lam, 2015) and the GP16 GEOTRACES Pacific Transect (Lam et al., 2017; Lee et al., 2017).

In this context, this paper presents the particulate iron distribution in the North Atlantic Ocean, along the GEOTRACES GA01 section (GEOVIDE), and discusses the various sources and processes affecting its distribution, using particulate aluminium, phosphorus or manganese.

2. Methods

2.1. Study area

Particulate samples were collected at 32 stations during the GEOVIDE (GEOTRACES GA01 section) cruise between May and June 2014 aboard the R/V *Pourquoi Pas?* in the North Atlantic (Sarthou et al., 2018). The sampling spanned several biogeochemical provinces (Figure 1) that first comprised the Iberian margin (IM, Stations 2, ~~1~~4 and 14), the Iberian Abyssal Plain (IAP, Stations 11 to 17), the Western European Basin (WEB, Station 19 to Station 29) and the Icelandic Basin (IcB, Stations 32 to 36). Then, samples were collected above the Reykjanes Ridge (RR, Station 38), in the Irminger Basin (IrB, Stations 40 to 60), close to the Greenland shelf (GS, Stations 53, 56 and 61), the Labrador Basin (LB, Stations 63 to 77) and finally close the Newfoundland shelf (NS, Station 78) (Figure 1). The North Atlantic is characterized by a complex circulation (briefly described in section ~~2~~3.1 and in detail by Zunino et al. (2017) and García-Ibáñez et al. (2015) and is one of the most productive regions of the global ocean (Martin et al., 1993; Sanders et al., 2014), with a complex phytoplankton community structure composed of diverse taxa (Tonnard et al., in prep.).

2.2. Sampling

Samples were collected using the French GEOTRACES clean rosette, equipped with twenty-two 12L GO-FLO bottles (two bottles were leaking and were never deployed during the cruise). GO-FLO bottles (General Oceanics) were initially cleaned in the home laboratory (LEMAR) following the GEOTRACES procedures (Cutter and Bruland, 2012). The rosette was deployed on a 14mm Kevlar cable with a dedicated, custom-designed clean winch. Immediately after recovery, the GO-FLO bottles were individually covered at each end with plastic bags to minimize contamination. They were then transferred into a clean container (class-100) for sampling ~~and the filters processed under a laminar flow unit~~. On each cast, nutrient and/or salinity samples were taken to check potential leakage of the GO-FLO bottles.

Filters were cleaned following the GEOTRACES protocols (http://www.geotraces.org/images/Cookbook.pdf) and kept in acid-cleaned 1 L LDPE bottles (Nalgene) filled with ultrapure water (Milli-Q, resistivity of 18.2 MΩ cm) until use. All filters were 25 mm diameter in order to optimize signal over the filter blank except at the surface depth where 47 mm diameter filters mounted on acid-cleaned polysulfone filter holders (Nalgene™) were used. Prior to filtration, the GO-FLO bottles were shaken three times, as recommended in the GEOTRACES cookbook to avoid settling of particles in the lower part of the bottle. GO-FLO bottles were pressurized to <8 psi with 0.2 µm filtered dinitrogen (N_2, Air Liquide). Seawater was then filtered directly through paired filters (Pall Gelman Supor™ 0.45 µm polyetersulfone, and Millipore mixed ester cellulose MF 5

µm) mounted in Swinnex polypropylene filter holders (Millipore), following Planquette and Sherrell (2012) inside the clean container. Filtration was operated until the bottle was empty or until the filter clogged; volume filtered ranged from 2 liters for surface samples to 11L within the water column. After filtration, filter holders were disconnected from the GO-FLO bottles and a gentle vacuum was applied using a syringe in order to remove any residual water under a laminar flow hood. Filters were then removed from the filter holders with plastic tweezers that were rinsed with Milli-Q between samples. Most of the remaining seawater was 'sipped' by capillary action, when placing the non-sampled side of the filter onto a clean 47 mm supor filter. Then, each filter pair was placed in an acid-cleaned polystyrene PetriSlides (Millipore), double bagged, and finally stored at -20°C until analysis at LEMAR. Between casts, filter holders were thoroughly rinsed with Milli-Q, placed in an acid bath (5% Trace metal grade HCl) for 24 hours, then rinsed with Milli-Q.

At each station, process blanks were collected as follows: 2L of a deep (1000 m) and a shallow (40 m) seawater samples were first filtered through a 0.2 µm pore size capsule filter (Pall Gelman Acropak 200) mounted on the outlet of the GO-FLO bottle before to pass through the particle sampling filter, which was attached directly to the swinnex filter holder.

2.3. Analytical methods

Back in the home laboratory, sample handling was performed inside a clean room (Class 100). All solutions were prepared using ultrapure water (Milli-Q) and all plasticware had been acid-cleaned before use. Frozen filters, collected within the mixed layer depth or within nepheloid layers, were first cut in half using a ceramic blade: one filter half was dedicated to total digestion (see below), while the other half was archived at -20°C for SEM analyses or acid leaching of "labile" metals (Berger et al., 2008; to be published separately).

Filters were digested following the method described in Planquette and Sherrell (2012). Filters were placed on the inner wall of acid-clean 15mL PFA vials (Savillex^{TM}), and 2 mL of a solution containing 2.9 mol L^{-1} hydrofluoric acid (HF, suprapur grade, Merck) and 8 mol L^{-1} nitric acid (HNO_3, Ultrapur grade, Merck) was added to each vial. Vials were then closed and refluxed at 130°C on a hot plate for 4 hours and filters removed. After cooling, the digest solution was evaporated at 110°C until near dryness. Then, 400 µL of concentrated HNO_3 (Ultrapur grade, Merck) was added, and the solution was re-evaporated at 110°C. Finally, the obtained residue was dissolved with 3mL of a 0.8 mol L^{-1} HNO_3 (Ultrapure grade, Merck). This archive solution was transferred to an acid cleaned 15 mL polypropylene centrifuge tube (Corning®) and stored at 4°C until analyses.

All analyses were performed on a sector field inductively coupled plasma mass spectrometer (SF-ICP-MS Element2, Thermo-Fisher Scientific). Samples were diluted by a factor of 7 on the day of analysis in acid-washed 13 mm (outer diameter) rounded bottom, polypropylene centrifuge tubes (VWR) with 0.8 mol L^{-1} HNO_3 (Ultrapur grade, Merck) spiked with 1µg L^{-1} of Indium (^{115}In) solution in order to monitor the instrument drift. Samples were introduced with a PFA-ST nebulizer connected to a quartz cyclonic spray chamber (Elemental Scientific Incorporated, Omaha, NE) via a modified SC-Fast introduction system consisting of an SC-2 autosampler, a six-port valve and a vacuum-rinsing pump. The autosampler was contained under a HEPA filtered unit (Elemental Scientific). Two 6-points, matrix-matched multi-element standard curves with concentrations bracketing the range of the samples were run at the beginning, the middle and the end of each analytical run. Analytical replicates were made every 10 samples, while accuracy was determined by performing digestions of the certified reference material BCR-414 (plankton, Community Bureau of Reference,

Field Code Changed

Commission of the European Communities), PACS-3 and MESS-4 (marine sediments, National Research Council Canada), following the same protocol as for samples. Recoveries were typically within 10% of the certified values (and within the error of the data, taken from replicate measurements, Table 1). Once all data were normalized to an ^{115}In internal standard and quantified using an external standard curve, the dilution factor of the total digestion was accounted for. Obtained element concentrations per filter (pmol/filter) were then corrected by the process blanks described above. Finally, pmol/filter values were divided by the volume of water filtered through stacked filters.

Total concentrations (sum of small size fraction (0.45-5 µm) and large (>5 µm) size fraction) of particulate trace elements are reported in Table S1 ~~(supplementary data)~~.

~~*2.4. Ancillary data:*~~

~~Potential temperature (θ), salinity (S), and transmissometry data were retrieved from the CTD sensors (CTD SBE911 equipped with a SBE43).~~

2.~~4~~. Positive matrix factorisation

Positive Matrix Factorisation (PMF) was run to characterise the main factors influencing the particulate trace elements variances along the GEOVIDE section. In addition to PFe, PAl, PMn, and PP, nine additionnal elements were included in the PMF: Y, Ba, Pb, Th, Ti, V, Co, Cu and Zn. The analysis has been conducted on samples where all the 13 elements previously cited were above the detection limits; after selection, 445 of the 549 existing data points were used. Analyses were performed using the PMF software, EPA PMF 5.0, developed by the USA Environmental Protection Agency (EPA). Models have been tested with several factors number (from 3 to 6), after full error estimation of each model, we decide to use the configuration providing the lowest errors estimations and in consequence the most reliable.

In consequence, models were set up with four factors and were run 100 times to observe the stability of the obtained results. After displacement, error estimations and bootstraps error estimations, the model was recognised as stable.

2.~~6~~5. Derived and ancillary parameters

To investigate ~~The PFe/PAl ratio can be used to estimate~~ the proportion of lithogenic ~~particles~~iron within the bulk particulate ~~fracti~~ir~~on~~, we use~~. A comparison with~~ the Upper Continental Crust (UCC) Fe/Al molar ratio of Taylor and McLennan (1995), 0.21, ~~was used~~ to calculate the lithogenic components of particles ($\%PFe_{litho}$) following Eq. (1):

$$\%\text{PFe litho} = 100 * \left(\frac{\text{PAl}}{\text{PFe}}\right)\text{sample} * \left(\frac{\text{PFe}}{\text{PAl}}\right)\text{UCC ratio} \quad (1)$$

Then the non-lithogenic PFe is ~~simply~~ obtained using Eq. (2):

$$\%\text{PFe non\_litho} = 100 - \%\text{PFe litho} \quad (2)$$

Note that while t~~Both the lithogenic and non-lithogenic fraction of PFe are estimated using the UCC ratio. Spatial and temporal variation of the lithogenic components ratio may falsely influence the estimated fraction value. T~~he $\%PFe_{litho}$ and $\%PFe_{non\text{-}litho}$ proxies are interesting tools to evaluate the importance of lithogenic and non-lithogenic (either biogenic or authigenic), ~~but~~they have to be used carefully, as spatial and temporal variation of the lithogenic component ratios may falsely influence the estimated fraction value.

In addition to PAl, PMn can be used as a tracer of inputs from shelf resuspension (Lam and Bishop, 2008). Indeed, Mn is really sensitive to oxidation mediated by bacteria (Tebo et al., 1984; Tebo and Emerson, 1985) and forms manganese oxides (MnO_2). These authigenic particles lead to an enrichment of Mn in particle compositions. In order to track the influence of shelf resuspension, a percentage of sedimentary inputs "%bulk sediment inputs" can be estimated using PMn/PAl ratio from GEOVIDE samples and the PMn/PAl UCC value (0.0034; Taylor and McLennan, 1995) according to the following equation:

$$\%\text{bulk sediment PMn} = 100 * \left(\frac{\text{PAl}}{\text{PMn}}\right)\text{sample} * \left(\frac{\text{PMn}}{\text{PAl}}\right)\text{UCC ratio} \quad (3)$$

This proxy ~~is~~can be a good indicator of direct and recent sediment resuspension. We assume that particles newly resuspended in water column will have the same PMn/PAl ratio than the UCC ratio leading to a "%bulk sediment Mn" of 100%. This value will decrease by authigenic formation of Mn oxides. This proxy assumes homogeneity of the sediment PMn/PAl ratio through the section which ~~is~~ may~~be~~ not be completely the case at every station. In consequence, this proxy is only a tool to identify new benthic resuspension at specific location and inter-comparison between several locations is not possible. When a sample presents a "%bulk sediment Mn" greater than 100%, we assign a value of 100% to simplify the following discussion. As the Mn cycle can also be affected by biologic uptake (e.g. Peers and Price, 2004; Sunda and Huntsman, 1983), this proxy is only used at depths where biologic activity is negligible (i.e. below 150m depth).

Potential temperature (θ°~~θ~~), salinity (S), and transmissometry data were retrieved from the CTD sensors (CTD SBE911 equipped with a SBE43).

Formatted: Font: Italic

3. Results

3.1. Hydrography ~~and biological~~ setting

Here, we briefly describe the hydrography encountered during the GEOVIDE section (Figure 2), as a thorough description is available in García-Ibáñez et al. (2015). In the beginning of the section~~-~~, T~~t~~he warm and salty Mediterranean Water (MW, S=36.50, θ°=11.7°C) was sampled between 600 and 1700 m in the Iberian Abyssal Plain (IAP). MW resulted from the mixing between the Mediterranean Overflow Water plume coming from the Mediterranean Sea and local waters. Surface water above the Iberian Shelf was characterised by low salinity (S=34.95) at station 2 and 4 compared to surrounding water masses. Close to the floor of the Iberian Abyssal Basin, the North East Atlantic Deep Water (NEADW, S=34.89, θ°=2.0°C) spread ~~south~~northward. The North Atlantic Central Water (NACW, S>35.60, θ°>12.3°C) was the warmest water mass of the transect and was

observed in the subsurface layer of the Western European Basin and Iberian Abyssal Plain. An old Labrador Sea Water (LSW, S=34.87, θ°=3. 0°C) flowed inside the Western European and Icelandic Basins, between 1000 and 2500m depth.

In the Icelandic Basin, below the old LSW, the Iceland-Scotland Overflow Water (ISOW, S=34.98, θ°=2.6°C) spread along the Reykjanes Ridge slope. This cold water, originating from the Arctic, led to the formation of NEADW after mixing with surrounding waters. North Atlantic hydrography was impacted by the northward flowing of the North Atlantic Current (NAC), which carried up warm and salty waters from the subtropical area. By air-sea interactions and mixing with surrounding water, the NACW is cooled down and freshened in the subpolar gyre and is transformed in Subpolar Mode Water (SPMW). ~~When NAC crossed the Mid-Atlantic ridge through the Charlie-Gibbs Fracture Zone (CGFZ), it created the Subpolar Mode Water (SPMW).~~ The ~~recirculation~~ formation of SPMW inside the Icelandic and Irminger Basins led to the formation of regional modal waters: the Iceland Subpolar Mode Water (IcSPMW, S=35.2, θ°=8.0°C) and the Irminger Subpolar Mode Water (IrSPMW, S=35.01, θ°=5.0°C) respectively. IcSPMW was a relatively warm water mass with potential temperature up to 7°C (García-Ibáñez et al., 2015). Another branch of the NAC mixed with Labrador Current waters to form the relatively fresh SubArctic Intermediate Water (SAIW, S=<34.8, 4.5°C<θ°<6°C).

The Irminger Basin is a complex area with a multitude of water masses. In the middle of the basin, an old LSW, formed one year before (Straneo et al., 2003), spread between 500 and 1200 m depth. Close to the bottom, the Denmark Strait Overflow Water (DSOW, S=34.91) flowed across the basin. Greenland coastal waters were characterised by low salinity values, down to S=33. The strong East Greenland Current (EGC) flowed southward along the Greenland shelf in the Irminger Basin. When reaching the southern tip of Greenland, this current entered the Labrador Basin along the west coast of Greenland and followed the outskirts of the basin until the Newfoundland shelf. In the Labrador Basin, the deep convection of SPMW at 2000 m was involved in the formation of the LSW (S=34.9, θ°C=3.0°C) (García-Ibáñez et al., 2015; Yashayaev and Loder, 2009). Above the Newfoundland Shelf, surface waters were affected by discharge from rivers and ice-melting and characterised by extreme low salinity for open ocean waters, below 32 in the first 15 meters.

3.2. Section overview

Total particulate iron ~~(PFe)~~, aluminium ~~(PAl)~~, manganese ~~(PMn)~~ and phosphorus ~~(PP)~~ concentrations spanned a large range of concentrations from below detection to 304, 1544, -3.5 and 402 nmol L^{-1} respectively. The ranges of concentrations are comparable to other studies recently published (Table 2).

PFe, PAl, and PMn were predominantly found (>90%) in particles larger than 5 µm, except in surface waters, where 9 ± 8.6 % of PFe~~, 38.8 ± 8.6 % of PP~~, 10.9 ± 15.4 % of PAl and 32.8 ± 16.6 % of PMn , 38.8 ± 8.6 % of PP were hosted by smaller particles (0.45-5 µm). ~~The ranges of concentrations are comparable to other studies recently published (Table 2).~~ Data are shown in Figure 3.

3.3. Open Ocean ~~stations :~~stations: from the Iberian Abyssal Plain ~~(stations 11 to 17), Western European Basin (stations 19 to 29), Icelandic Basin (stations 32 to 36), Reykjanes Ridge (station 38), Irminger Basin (stations 40 to 60; except Stations 53 and 56) and~~to the Labrador Basin ~~(stations 6311 to 77, except stations 53, 56amd 61)~~

This concerns all stations ~~between~~from station 11 to 77, with the exception of stations 53, 56 and 61 that were sampled close to the Greenland ~~and Newfoundland~~ coast (Figure 1)~~s, respectively~~.

Particulate iron concentration ~~vertical~~ profiles ~~presented~~ showed identical patterns at all of the open ocean stations ~~sampled in each oceanic basin~~ encountered along the section. Median PFe were low at 0.25 nmol L^{-1} within the first 100 m and steadily increased with depth. However, at two stations, elevated concentrations were determined in the upper 100m, up to 4.4 nmol L^{-1} at station 77 at 40 m and 7 nmol L^{-1} at station 63 between 70 and 100 m depth. PFe concentrations gradually increased with depth, with a median PFe of 1.74 nmol L^{-1} below 1000m. Close to the seafloor of some stations (26, 29, 32, 34, 49, 60, and 71), high concentrations of PFe were observed, up to 88 nmol L^{-1} (station 71 at 3736 m). These high PFe values were associated with low beam transmissometry value inferior or equal to 977 %. ~~(Figure 9b and supplementary table S2).~~

Particulate aluminium (PAl) and manganese (PMn) profiles were similar to PFe profiles, with low concentrations measured in the first 100 m (1.88 nmol L^{-1} and 55 pmol L^{-1}, respectively) and increased towards the seafloor. Close to the seafloor, high concentrations were determined at the same stations cited above for PFe, with a maximum of 264 nmol L^{-1} and 3.5 nmol L^{-1} for PAl and PMn respectively at station 71 (supplementary Table S1). Highest particulate phosphorus (PP) concentrations were in the first 50m, with a median value of 66 nmol L^{-1}. Deeper in the water column, below 200m, PP concentrations decreased to values below 10 nmol L^{-1}. Inter-basins differences were observed within the surface samples, with median PP concentration being higher in the Irminger Basin (127 nmol L^{-1}) than in the Iberian Abyssal Plain (28 nmol L^{-1}) (Figure 3).

Finally, above the Reykjanes Ridge, PP, PMn, PAl and PFe concentrations were in the same range than the surrounding open ocean stations. However, close to the seafloor, high concentrations were measured, with PFe, PAl, and PMn reaching 16.2 nmol L^{-1}, 28.8 nmol L^{-1}, and 0.51 nmol L^{-1} at 1354 m, respectively (Figure 3 and ~~supplementary material~~ Table S1).

3.4. Margins and Shelves: Iberian Margin (stations 1 to 4), Greenland coast (stations 53, 56 and 61) and Newfoundland Shelf (station78)

The Iberian margin was characterised by low beam transmissometry values at station 2 (88% at 140 m, Figure ~~4~~9b) suggesting significant particle concentrations. Particulate iron concentrations varied between 0.02 nmol L^{-1} to 304 nmol L^{-1}. Within the first 50m, PFe concentrations decreased towards the shelf break where PFe dropped down from 2.53 nmol L^{-1} (station 2) to 0.8 nmol L^{-1} (Station 1). At tall three stations, PFe concentrations increased with depth ~~at all three stations~~ and reached a maximum ~~at the bo~~close to the seafloor. As an exemple, 300 nmol L^{-1} of PFe was measured at 138.5m at ~~t~~tom of station 2 ~~(138.5 m) with more than 300 nmol L^{-1} of PFe~~. Lithogenic tracers, such as PAl or PMn, presented similar profiles to PFe with concentrations ranging between 0.11 and 1544 nmol L^{-1}, and from below detection limit to 2.51 nmol L^{-1} respectively (Figure 3, ~~supplementary material~~ Table S1). Total particulate phosphorus (PP) concentrations were relatively low in the surface ranging from undetectable values to 38 nmol L^{-1}; concentrations decreased with depth and were less than 0.7 nmol L^{-1} below 1000 m depth.

In the vicinity of the Greenland shelf, PFe concentrations had a high median value of 10.8 nmol L^{-1} and were associated with high median PAl and PMn concentrations of 32.3 nmol L^{-1} and 0.44 nmol L^{-1}, respectively. Concentrations of PP were high at the surface with a value of 197 nmol L^{-1} at 25 m of station 61. Then, PP

Formatted: Superscript

concentrations decreased strongly, less than 30 nmol L^{-1}, below 100 meters depth. Furthermore, beam transmissometry values in surface waters at these three stations, were the lowest of the entire section, with values below 85 %.

Close to the Newfoundland margin, surface waters displayed a small load of particulate trace metals as PFe, PAl, and PMn were below 0.8 nmol L^{-1}, 2 nmol L^{-1}, and 0.15 nmol L^{-1} respectively. Then close to the bottom of station 78, at 371 m, beam transmissometrytry values dropped to 94% and were associated with extremely high concentrations of PFe=168 nmol L^{-1}, PAl=559 nmol L^{-1}, and PMn=2 nmol L^{-1}. Total PP concentrations in the first 50 m ranged from 35 to 97 nmol L^{-1}. Below the surface, PP remained relatively high with values up to 16 nmol L^{-1} throughout the water column. (Figure 3 and supplementary material Table S1).

4. Discussion

Our goal in this work was to investigate mechanisms that drive the distribution of PFe in the North Atlantic, in particular the different routes of supply and removal. Possible candidate sources of PFe include lateral advection offshore from margins, atmospheric inputs, continental run-off, melting ice shelves and icebergs, resuspended sediments, hydrothermal inputs and biological uptake. Removal processes include remineralization, and dissolution processes and sediment burial.

In the following sections, we examine each of these sources and processes, explore the evidence for their relative importance, and use compositional data to estimate the particle types and host phases for iron and associated elements.

4.1. Analysis of the principal factors controlling variance: near-ubiquitous influence of crustal particles in the water column

The positive matrix factorisation analysis (Figure 5) has been realised on the entire dataset, in consequence, the factors described below are highly influenced by the major variations of particulate element concentrations (usually at the interface, i.e. margin, seafloor, surface layer). The positive matrix factorisation, shown in Figure 5, indicatefactorisation, shown in Figure 5, indicates the overall variances explained by each of the 45 factors.

The first factor is characterised by lithogenic elements, representing 86.8% of the variance of PFe, 75.8% of PAl and 90.5% of PTi. The second factor is correlated with both Mn and Pb and explains no less than 76.5% and 77.0% of their respective variances. Ohnemus and Lam (2015) observed this co-relation between manganese and lead particles and explained it by the co-transport on Mn-oxides (Boyle et al., 2005). The formation of barite is causing the third factor constraining 87.7% of the Ba variance in the studied regions. Biogenic barite accumulation within the mesopelagic layer is related to bacterial activity and organic remineralisation of biogenic material (Lemaitre et al., 2018a). A biogenic component is the fourth factor and explained most of particulate phosphorus variance, 83.7%. The micronutrient trace metals, copper, cobalt and zinc, had more than a quarter of their variances influenced by this factor. Note that tThe biogenic contribution to particulate iron and other particulate trace elements will be discussed in another paper (Planquette et al., in prep).

These results indicate that along the GA01 section, PFe distributions were predominantly controlled by lithogenic material and to a smaller extent by remineralisation processes (as seen by a Factor 3 contribution of 4.1%). This does not rule out some biogenic influence on PFe distribution, especially in surface, but this contribution is veiled by the high lithogenic contribution. The PMF analysis has been realised on the entire

dataset, in consequence, the factors described are highly influenced by the major variations of particulate element concentrations (usually at the interface, i.e. margin, seafloor, surface layer,...).

To further investigate the influence of crustal material on the distribution of PFe, it is instructive to examine the distribution of the molar ratio of PFe/PAl, and the resulting $\%PFe_{litho}$ (see section 2.6 for definition of this parameter) along the section as a way to assess the lithogenic inputs (Lannuzel et al., 2014; Ohnemus and Lam, 2015; Planquette et al., 2009) (Figure 6) along the section.

The PFe/PAl ratio can be used to estimate the proportion of lithogenic particles within the bulk particulate material. A comparison with the Upper Continental Crust (UCC) ratio of Taylor and McLennan (1995), 0.21, was used to calculate the lithogenic components of particles (PFe_{litho}) following Eq. (1):

$$\%PFe\ litho = 100 * \left(\frac{PAl}{PFe}\right)sample * \left(\frac{PFe}{PAl}\right)UCC\ ratio \quad (1)$$

Then the non-lithogenic PFe is simply obtained using Eq. (2):

$$\%PFe\ non\_litho = 100 - \%PFe\ litho \quad (2)$$

Both the lithogenic and non-lithogenic fraction of PFe are estimated using the UCC ratio. Spatial and temporal variation of the lithogenic components ratio may falsely influence the estimated fraction value. The PFe_{litho} and $PFe_{non\text{-}litho}$ proxies are interesting tools to evaluate the importance of lithogenic and non-lithogenic (either biogenic or authigenic), but have to be used with consideration.

Overall, the estimated lithogenic contribution to PFe varies from 25% (station 60, 950 m) to 100% at stations located within the Western European Basin. Note that 100% of estimated lithogenic PFe does no't necessary mean that biogenic particles are absent; they may just be masked by the important load of lithogenic particles. Important inter-basins variations are observed along the section (Figure 6). The IAP and WEB basins are linked with high median value of the proxy $\%PFe_{litho}$, 90%., which is also reflected in the MW and NEADW PFe/PAl ratio , that displays a value PFe/PAl close to the crustal one (Figure 7). ou 8 dans la nouvelle version??). This could be linked to a lateral advection of iron rich lithogenic particles sourced from the Iberian margin and to atmospheric particles (Shelley et al., 2017). This point is discussed with more detail in section 4.32.14. Then, between the stations 26 and 29, the $\%PFe_{litho}$ proxy values dramatically decreased, and reached values under 55%; between the stations 26 and 29, to reach median $\%PFe_{litho}$ value under 55% in the Iceland, Irminger and the Labrador basins. This feature is likely be associated to the presence of the Sub-Arctic Front, located between 49.5 and 51°N latitude and 23.5 and 22°W longitude (Zunino et al., 2017). Indeed, this front which separates cold and fresh water of subpolar origin from warm and salty water of subtropical origin was clearly identifiable at station 26 by the steep gradient of the isotherms and isohalines between station 26 and 29; salinity dropping from 35.34 psu to 35.01 psu (Figure 2). North of of the Sub-Arctic Front, LSW and ISOW display high PFe/PAl ratios, ranging from 0.36 to 0.44 mol mol^{-1}. These high ratios, compared to the crustal one, could be associated to higher content of PFe from biogenic origin, especially in the case of the LSW.

While the Iceland, Irminger and the Labrador basins are characterised with median %PFe value under 55%. An interesting feature observable was the dramatic decrease of the %PFe proxy values happening at the station 26

(Figure 6). This feature is likely be associated to the presence of the Sub-Arctic Front, located between 49.5 and 51°N latitude and 23.5 and 22°W longitude (Zunino et al., 2017). Indeed, this front which separates cold and fresh water of subpolar origin from warm and salty water of subtropical origin was clearly identifiable at station 26 by the steep gradient of the isotherms and isohalines (Figure 2).

4.2. Fingerpriting watermasses

The GEOVIDE section crossed several distinct water masses along the North AtlanticBased on , each of them being distinguishable by their salinity and potential temperature signatures (García-Ibáñez et al., 2015; Figure 2). Based on this study, we applied a Kruskal-Wallis test on molar PFe/PAl ratios of nine water masses (Figure 7) in order to test the presence of significant differences. Water masses for which we had less than 5 data points for PFe/PAl were excluded from this test. As the differences in the median values among the treatment groups were greater than would be expected by chance; the difference in PFe/PAl between water masses is statistically significant (P = <0.001).

As previously seen, the lithogenic inprint is dominant in the WEB, with MW and NEADW showing PFe/PAl values close to the UCC value of 0.21 mol mol^{-1}. Interestingly, the PFe/PAl signature of 0.36 mol mol^{-1} within the old LSW$_{WEB}$ is probably due to the effect of biologic inputs associated with the strong bloom encountered in the Irminger Sea than in the WEB (see section 4.3.5). While it appears that lithogenic particles are dominating the water column in the FWEB and that some water masses have a clear PFe/PAl fingerprint, it is important to discuss the origin of these signatures, which is the purpose of the following sections.

4.23. Tracking the different inputs of particulate iron

4.23.1. Inputs at margins: Iberian, Greenland and Newfoundland

Inputs from continental shelves and margins have been demonstrated to support high productivity in shallow coastal areas. Inputs of iron from continental margin sediments supporting the high productivity found in shallow coastal regions have been demonstrated in the past (e.g. Cullen et al. (2009), Elrod et al. (2004), Jeandel et al. (2011), Ussher et al. (2007)) and sometimes, were shown to be advected at great distances from the coast (e.g. Lam and Bishopet al., 2008).

In the following section, we will investigate these possible candidate sources in proximity of the different margins encountered. Along the GEOVIDE section, sediments at margins were of various compositions (Dutkiewicz et al., 2015). Sediments originating from the Iberian margin were mainly constituted of silts and clays (Cacador et al., 1996; Duarte et al., 2014). East Greenland margin sediments were a mixture of sands and grey/green muds, while, sediments from the West Greenland margin were mainly composed of grey/green muds (Loring and Asmund, 1996). At the western end of the section, sediments from the Newfoundland margin were composed of gravelly and sandy muds (Mudie et al., 1984). The different sediment compositions of the three margins sampled during GEOVIDE have different mineralogy/composition, which are reflected in their

different PFe/PAl ratios (Figure 8). While the Iberian Margin had a PFe/PAl close to UCC ratio, the highest ratio could be seen at the East Greenland (stations 53 and 56) and West Greenland (station 61) Margins, with median PFe/PAl reaching 0.45 mol mol^{-1}. The Newfoundland margin displayed an intermediate behaviour, with Fe/Al ratios of 0.35 mol mol^{-1}.

In addition to PAl, PMn can be used as a tracer of inputs from shelf resuspension (Lam and Bishop, 2008). Indeed, Mn is really sensitive to oxidation mediated by bacteria (Tebo et al., 1984; Tebo and Emerson, 1985) and forms manganese oxides (MnO_2). These authigenic particles lead to an enrichment of Mn in particle compositions. In order to track the influence of shelf resuspension, a percentage of sedimentary inputs "%bulk sediment inputs" can be estimated using PMn/PAl ratio from GEOVIDE samples and the PMn/PAl UCC value (0.0034; Taylor and McLennan, 1995) according to the following equation:

$$\%\text{bulk sediment PMn} = 100 * \left(\frac{PAl}{PMn}\right)\text{sample} * \left(\frac{PMn}{PAl}\right)\text{UCC ratio} \quad (3)$$

This proxy is a good indicator of direct and recent sediment resuspension. We assume that particles newly resuspended in water column will have the same PMn/PAl ratio than the UCC ratio leading to a "%bulk sediment Mn" of 100%. This value will decrease by authigenic formation of Mn oxides. This proxy assumes homogeneity of the sediment PMn/PAl ratio through the section which is maybe not completely the case at every station. In consequence, this proxy is only a tool to identify new benthic resuspension at specific location and inter-comparison between several locations is not possible. When a sample presents a "%bulk sediment Mn" greater than 100%, we assign a value of 100% to simplify the following discussion. As the Mn cycle can also be affected by biologic uptake (e.g. Peers and Price, 2004; Sunda and Huntsman, 1983), this proxy is only used at depths where biologic activity is negligible (i.e. below 150m depth).

The Iberian margin

The Iberian margin was an important source of lithogenic-derived iron-rich particles in the Atlantic Ocean during GEOVIDE; shelf resuspension impact was perceptible until 280 km away from the margin (Station 11) in the Iberian Abyssal Plain (Figure 8).

On the shelf, at station 2 high sediment resuspension was observable by low beam transmissometry value (87.6%) at the immediate vicinity of the seafloor (153m). This sediment resuspension led to an extensive input of lithogenic particles within the water column associated with high concentrations of PFe (304 nmol L^{-1}), PAl (1500 nmol L^{-1}), and PMn (2.5 nmol L^{-1}) (Figure 3, Table S1). Moreover, ~~one hundred percent~~100% of PFe ~~is~~was estimated to have a lithogenic origin (Figure 8~~10~~) while 100% of the PMn was estimated to be the result of a recent sediment resuspension according to the $\%Fe_{litho}$ and "%bulk sediment Mn" proxies (~~supplementary material, Table S2~~Figure 8), confirming the resuspended particle input.

Coastal waters of the Iberian Shelf are impacted by the runoff for the Tagus River, which is characterised by high suspended matter discharges, ranging between 0.4 to 1 × 10^6 tons yr^{-1}, and with a high anthropogenic signature (Jouanneau et al., 1998). During the GEOVIDE section, the freshwater input was observable at stations 1, 2 and 4 in the first 20 m; salinity was below 35.2 psu while surrounding waters masses had salinity up to 35.7 psu. Within the freshwater plume, particulate concentrations were important at station 2 with PFe of

~~1.83 nmol L^{-1}. Further away from the coast, the particulate concentrations remained low at 20m depth, with PFe, PAl, and PMn concentrations of 0.77 nmol L^{-1}, 3.5 nmol L^{-1}, and 0.04 nmol L^{-1}, respectively at station 1. The low expansion of the Tagus plume is likely due to the rapid settling of suspended matter. Indeed, our coastal station 2 was already located at around 50 km of the Iberian coast and according to Jouanneau et al. (1998), the surface particle load can be observable at a maximum 30km of the Tagus estuary.~~

Besides, ADCP data acquired during GEOVIDE (Zunino et al., 2017) and several studies have reported an intense current spreading northward coming from Strait of Gibraltar and Mediterranean Sea, leading to a strong resuspension of benthic sediments above the Iberian Shelf, e.g. Biscaye and Eittreim (1977), Eittreim et al. (1976), McCave and Hall (2002), Spinrad et al. (1983). ~~The importance of the sediment resuspension was observable by low beam transmissometry value (87.6%) at the bottom of station 2. This important sediment resuspension led to an extensive input of lithogenic particles within the water column associated with high concentrations of PFe (304 nmol L^{-1}), PAl (1500 nmol L^{-1}), and PMn (2.5 nmol L^{-1}) (Figure 3, Table S1).~~

~~Moreover, one hundred percent of PFe is estimated to have a lithogenic origin (Figure 10) while 100% of the PMn was estimated to be the result of a recent sediment resuspension according to the $\%Fe_{litho}$ and "%bulk sediment Mn" proxies (supplementary material, Table S2), confirming the resuspended particle input.~~

At distance from the shelf, within the Iberian Abyssal Plain, an important lateral advection of PFe from the margin was observable (Figure ~~10~~8). These lateral inputs occurred at two depth ranges: between 400 and 1000 m as seen at stations 4 and 1, with PFe concentrations reaching 4 nmol L^{-1}, and between 2500 m and the bottom (3575 m) of station 1, with PFe concentrations reaching 3.5 nmol L^{-1}. While 100% of PFe had a lithogenic signature, the sedimentary source input estimation decreased, between 40% and 90% of the PMn (Figure ~~10~~8). Transport of lithogenic particles was observable until station 11 (12.2°W) at 2500 m where PFe concentration was 7.74 nmol L^{-1} and 60% of PMn had a sedimentary origin (Figure 49). Noteworthy, no particular increase in PFe, PMn or PAl was seen between 500 and 2000 m depth, where the MOW spreads, which is consistent with that was observed DFe concentrations (Tonnard et al., this issue); yet in contrast with the dissolved aluminium values (Menzel~~-~~ Barraqueta et al, ~~subm.~~2018, this issue) which were high in the MOW and with the study of Ohnemus and Lam (2015) that reported a maximum PFe concentration at 695 m depth associated with the particle-rich Mediterranean Overflow Water (Eittreim et al., 1976) in the IAP. However, their station was located further south of our station 1. The shallower inputs observed at stations 1 and 4 could therefore be attributed to sediment resuspension from the Iberian margin and nepheloid layer at depth for station 1.

Surface coastal waters of the Iberian Shelf are impacted by the runoff for the Tagus River, which is characterised by high suspended matter discharges, ranging between 0.4 to 1 × 10^6 tons yr^{-1}, and with a high anthropogenic signature (Jouanneau et al., 1998). During the GEOVIDE section, the freshwater input was observable at stations 1, 2 and 4 in the first 20 m; salinity was below 35.2 ~~psu~~ while surrounding waters masses had salinity up to 35.7 ~~psu~~. Within the freshwater plume, particulate concentrations were high at station 2 with PFe of 1.83 nmol L^{-1}. Further away from the coast, the particulate concentrations remained low at 20m depth, with PFe, PAl, and PMn concentrations of 0.77 nmol L^{-1}, 3.5 nmol L^{-1}, and 0.04 nmol L^{-1}, respectively at station 1. The low expansion of the Tagus plume is likely due to the rapid settling of suspended matter. Indeed, our coastal station 2 was already located at around 50 km of the Iberian coast and according to Jouanneau et al.

Formatted: Space After: 10 pt

(1998), the surface particle load can be observable at a maximum 30km of the Tagus estuary. Overall, the Iberian margin appears to be an important source of lithogenic-derived iron rich particles in the Atlantic Ocean. ~~Therefore, the Iberian margin appears to be an important source of lithogenic-derived iron-rich particles in the Atlantic Ocean; shelf resuspension impact was perceptible until 280 km away from the margin (Station 11) in the Iberian Abyssal Plain.~~

South Greenland

~~Several studies already demonstrated the importance of icebergs and sea ice as source of dissolved and particulate iron (e.g. van der Merwe et al., 2011a, 2011b; Planquette et al., 2011; Raiswell et al., 2008). The Greenland shelf is highly affected by external fresh water inputs as ice-melting or riverine runoff (Fragoso et al., 2016), that are important sources of iron to the Greenland Shelf (Bhatia et al., 2013; Hawkings et al., 2014; Statham et al., 2008).~~ Along GEOVIDE, Greenland shelves were a source of particulate-rich meteoric water leading to a transfer of DFe to PFe by an enhanced biological activity. Indeed,

~~Both~~both East and West Greenland shelves (stations 53 and 6~~0~~1) had high concentration of particles (beam transmissometry of 83%) and particulate trace elements, reaching 22.1 nmol L^{-1} and 18.7 nmol L^{-1} of PFe, respectively (station 53 at 100m and station 61 at 136 m). Several studies already demonstrated the importance of icebergs and sea ice melting as sources of dissolved and particulate iron (e.g. van der Merwe et al., 2011a, 2011b; Planquette et al., 2011; Raiswell et al., 2008). The Greenland shelf is highly affected by external fresh water inputs such as sea-ice-melting or riverine runoff (Fragoso et al., 2016), that are important sources of iron to the Greenland Shelf (Bhatia et al., 2013; Hawkings et al., 2014; Statham et al., 2008).

During the cruise, the relative freshwater observed (S<33 psu) within the first 25 meters of stations 53 and 61 were associated with high PFe (19 nmol L^{-1}), PAl (61 nmol L^{-1}), PMn (0.6 nmol L^{-1}) and a low beam transmissometry (≤ 85%) (Figure ~~9~~4 and Table S1). Particles associated were enriched in iron compared to aluminium, as PFe/PAl ratio was 0.3 within the meteoric water plume. High biological production, in agreement with PP concentrations reaching 197 nmol L^{-1} induced by the supply of bioavailable dissolved iron from meteoric water (Raiswell et al., 2008; Statham et al., 2008;, Tonnard et al., submitted, this issue), led to a transfer of DFe to the particulate phase. This is in line with the fact that around 30% PFe had a non-lithogenic origin. In addition, only 40% PMn originated from resuspended sediments. Interestingly, these two proxies remained constant from the seafloor to the surface (Station 49, Figure ~~10~~8), with around 25% of the PMn of sedimentary origin, which could be due to an important mixing happening on the shelf. The lithogenic PFe could result from the release of PFe from Greenland bedrock captured during the ice sheet formation on land~~.~~.

The spatial extent of the off-shelf lateral transport of particles was not important on the east Greenland coast. Indeed, no visible increase of particulate trace metal concentrations was visible at the first station off-shelf, station 60 (Figure ~~10~~8), except at 1000 m depth, where a strong increase (up to 90%) of sedimentary PMn was seen. This is probably due to the East Greenland Coastal Current (EGCC) that was located at station 53 constrained these inputs while stations 56 and 60 were under the influence of another strong current, the East Greenland-Irminger current (EGIC) (Zunino et al., 2017).

To the west of the Greenland margin, lateral transport of particles was slightly more important. Noticeable concentrations of particulate lithogenic elements were observable until station 64 located 125 km away from shoreline. These particles had decreasing PFe lithogenic contribution (50%) with a similar (25%) sedimentary

PMn content than closer to the margin. The increasing nature of non-lithogenic PFe is linked to the bloom in surface (associated with a PFe/PAl ratio of 0.30 mol mol^{-1}, a PP of 197 nmol L^{-1} at station 61 and a ~~Chl-a concentrations of 6.21 mg~~Chl-a concentration of 6.21 mg m^{-3}), with the biogenic PFe settling down along the transport of particles.

Therefore, particles newly resuspended from Greenland sediments are an important source, representing around one~~a~~ third of the pMn pool, combined with surface inputs such as riverine runoff and/or ice-melting that are delivering particles on the shelf and biological production. Unlike the Iberian shelf, Greenland margin was not an important provider of particulate metals inside the Irminger and Labrador Basin, due to the circulation that constrained the extent of the margin plume.

~~Therefore, particles newly resuspended from Greenland sediments are an important source, representing around a third of the pMn pool, combined with surface inputs such as riverine runoff and/or ice-melting that are delivering particles on the shelf and biological production. Unlike the Iberian shelf, Greenland margin was not an important provider of particulate metals inside the Irminger and Labrador Basin, due to the circulation that constrained the extent of the margin plume.~~

The Newfoundland Shelf

Previous studies already described the influence of fresh water on the Newfoundland shelf from the Hudson Strait and/or Canadian Artic Archipelago (Fragoso et al., 2016; Yashayaev, 2007). Yashayaev (2007) also monitored strong resuspension of sediments associated with the spreading of Labrador Current along the West Labrador margin.

Close to the Newfoundland coastline, at station 78, high fresh water discharge (≤ 32 psu) was observed in surface (Benetti et al., 2017). Interestingly, these freshwater signatures were not associated with elevated particulate trace metal concentrations. Distance of meteoric water sources implied a long travel time for the water to spread through the Labrador Basin to our sampling stations. Along the journey, particles present originally may have been removed from water column by gravitational settling.

The proportion of lithogenic PFe was relatively high and constant in the entire water column, with a median value of 70%. At station 78, 100% of the PMn had a sedimentary origin close to the seafloor (371 m). The spreading of the recent sediment resuspension was observable until 140 m depth where the contribution of sedimentary Mn was still 51% (Figure ~~10~~8, Table S2). This could correspond to an intense nepheloid layer as previously reported by Biscaye and Eittreim (1977) (see also section 3.3.2). The high PFe concentration (184 nmol L^{-1}, station 78, 371 m) associated with a high percentage of sedimentary PMn (95%) observed at the bottom of this station, was therefore the result of an important resuspension of shelf sediments. This was confirmed with low transmissometry values of 95%.

The important phytoplanktonic community present (maximum Chl-a= 4.91 mg m^{-3}, Tonnard et al., in prep), is linked to low PFe of 0.79 nmol L^{-1} at 10 m, but, with a high PFe/PAl ratio, up to 0.4, and PP concentration of 97 nmol L^{-1}, confirming the biologic influence. Either the biogenic particles settled quickly, and/or they were quickly remineralized. Concerning this latter process, intense remineralization at station 77 (7 mmol C m^{-2} d^{-1} compared to 4 mmol C m^{-2} d^{-1} in the Western European Basin) has been reported by Lemaitre et al. (2018a and 2018b), which could explain the low PFe values throughout the water column.

~~Along the GEOVIDE section, continental shelves provided an important load of particles within the surrounding water column. The three margins sampled during GEOVIDE behaved differently; the Iberian margin discharged high quantities of lithogenic particles far away from the coast while the Greenland and Newfoundland margins did not reveal important PFe concentrations. Spreading of particles is tightly linked to hydrodynamic conditions, which in the case of the Greenland margin, prevented long distance seeding of PFe. Moreover, each margin showed a specific PFe/PAl ratio (Figure 8) indicating different composition of the resuspended particles. Resuspended particles represent the composition of sediment at the margin if oxido-reductive transformation of iron and aluminium are considered negligible under these circumstances. Differences between margins were due to the presence of non-crustal particles, either biogenic or authigenic. Biological production in surface waters and authigenic formation of iron hydroxide produce particles with a higher PFe/PAl content and their export through the water column to the sediment increased the PFe/PAl ratio at depth. Regions where biological production is intense such as in the vicinity of Newfoundland presented higher PFe/PAl ratios of resuspended benthic particles.~~

Along the GEOVIDE section, continental shelves provided an important load of particles within the surrounding water column. The three margins sampled during GEOVIDE behaved differently; the Iberian margin discharged high quantities of lithogenic particles far away from the coast while the Greenland and Newfoundland margins did not reveal important PFe concentrations. Spreading of particles is tightly linked to hydrodynamic conditions, which in the case of the Greenland margin, prevented long distance seeding of PFe. Moreover, each margin showed a specific PFe/PAl ratio (Figure 98) indicating different composition of the resuspended particles. Resuspended particles represent the composition of sediment at the margin if ~~oxido-reductive~~redox transformation of iron and aluminium are considered negligible under these circumstances. Differences between margins were due to the presence of non-crustal particles, either biogenic or authigenic. Biological production in surface waters and authigenic formation of iron hydroxide produce particles with a higher PFe/PAl content and their export through the water column to the sediment increased the PFe/PAl ratio at depth. Regions where biological production is intense such as in the vicinity of Newfoundland presented higher PFe/PAl ratios of resuspended benthic particles.

4.23.2 Benthic resuspended sediments

Along the GEOVIDE section, Benthic nepheloid layers (BNLs) ~~BNLs~~ are providing high concentrations of particulate trace element in the deep open ocean, contributing highly to the total trace elements budget as iron. Along the GA01 section, BNLs were observable in each province with different strengths (Figures 3 and 120).

~~Benthic nepheloid layers (BNLs) are important layers where local resuspension of sedimentary particles (Bishop and Biscaye, 1982; Eittreim et al., 1976; Rutgers Van Der Loeff et al., 2002) occur due to strong hydrographic stresses (i.e. boundary currents, benthic storms and deep eddies) interacting with the ocean floor (Biscaye and Eittreim, 1977; Eittreim et al., 1976; Gardner et al., 2017, 2018). Along the GA01 section, BNLs were observable in each province with different strengths (Figures 3 and 12).~~

In BNLs located within the WEB, PFe concentrations reached up to 10 nmol L^{-1} (stations 26 and 29, Table S1). These concentrations were smaller than PFe concentrations encountered in BNL from the Icelandic (stations 32 and 34), Irminger (stations 42 and 44) and Labrador Basins (stations 68, 69 and 71), where benthic resuspension

led to PFe concentrations higher than 40 nmol L^{-1}, even reaching 89 nmol L^{-1} at the bottom of station 71 (3736 m). Moreover, in the Irminger and Labrador Basins, PFe/PAl molar ratios within BNLs were higher than the ones measured within the WEB at station 26 and 29. In the Irminger Basin, PFe/PAl reached 0.4 mol mol^{-1} (Figure 10~~1~~), which could reveal a mixture of lithogenic and biogenic matter previously exported. This feature was also observed in the Labrador Basin, with PFe/PAl ratio ranging between 0.34 and 0.44 mol mol^{-1}. In contrast, BNLs sampled in the WEB have clearly a lithogenic imprint, with PFe/PAl molar ratios close to the crustal one. Resuspended sediments with a non-crustal contribution seem to hold a higher PFe content than sediments with a lithogenic characteristic. Nevertheless, interestingly all BNLs present during GEOVIDE were spreading identically, with impacts observable up to 200 meters above the oceanic seafloor (Figure 10~~1~~), as reflected in beam transmissometry values, and PFe concentrations, that returned to a background level at 200 m above the seafloor. The presence of these BNLs has also been reported by Le Roy et al. (submitted, this issue) using radium-226 activity. Important differences of PFe intensities could also be due to different hydrographic components and topographic characteristics. BNLs are occurring due to strong hydrographic stresses (i.e. boundary currents, benthic storms and deep eddies) interacting with the ocean floor (Biscaye and Eittreim, 1977; Eittreim et al., 1976; Gardner et al., 2017, 2018). They are ~~As previously explained, two main triggers of BNLs are benthic storms and deep eddies;~~ by definition ~~these processes are~~ highly variable geographically and temporally, but no physical data could allow us to investigate further this hypothesis.

~~Benthic nepheloid layers (BNLs) are important layers where local resuspension of sedimentary particles (Bishop and Biscaye, 1982; Eittreim et al., 1976; Rutgers Van Der Loeff et al., 2002) occur due to strong hydrographic stresses (i.e. boundary currents, benthic storms and deep eddies) interacting with the ocean floor (Biscaye and Eittreim, 1977; Eittreim et al., 1976; Gardner et al., 2017, 2018). Along the GA01 section, BNLs were observable in each province with different strengths (Figures 3 and 12).~~

~~Along the GEOVIDE section, BNLs are providing high concentrations of particulate trace element in the deep open ocean, contributing highly to the total trace elements budget as iron.~~

4.2~~3~~.3. Reykjanes Ridge inputs

Above the ridge, high PFe concentrations were measured, reaching 16 nmol L^{-1} just above the seafloor, while increased DFe concentrations were reported to the East of the ridge (Tonnard et al., this issue). The exact sources of iron-rich particles cannot be well constrained, as they could come from active hydrothermal vents or resuspension of particulate matter from new crustal matter produced at the ridge. According to the oceanic circulation (Zunino et al., 2017; Garcia-Ibanez et al., 2017), hydrothermal particles could have been seen in the ISOW within the Icelandic Basin. Nevertheless, at the vicinity of the ridge, scanning electron microscope (SEM) analyses of our samples did reveal a number of biological debris and clays but not the presence of iron (oxy-)hydroxide particles (supplementary figure S1), which are known to be highly produced close to hydrothermal vents (Elderfield and Schultz, 1996). Their absence could thus indicate an absence of vents. However, other proxies, such as helium-3, are necessary to claim with more accuracy the presence or absence of an hydrothermal source close to station 38.

4.3~~2~~.4. Atmospheric inputs

Atmospheric deposition is an important input of trace elements in surface of the open ocean (e.g. (Jickells et al., 2005). Atmospheric inputs, both wet and dry, were reported to be low during the GEOVIDE cruise (Menzel-Bbarraqueta et al., 2018, this issue; Shelley et al., 2017; 2018). In fact, oceanic particles measurements in surface waters along the section did not reveal high PFe or PAl ~~concentrations;~~concentrations. ~~therefore, the surface composition of particles did not seem to be highly affected by atmospheric deposition at the time of the cruise.~~ One pattern is ~~also~~ interesting to note: the surface waters of the Iberian Abyssal Plain and Western European Basin, between stations 11 and 23 presented a characteristic feature with really low PFe/PAl elemental ratios, of 0.11, smaller than the UCC ratio of 0.21 (Figure 6). Such low ratios have been reported in the same region by Barrett et al. (2012). One possible explanation is given by Buck et al. (2010) who described Fe-depleted aerosols in this area of the North Atlantic with PFe/PAl ratio below UCC ratio. However, Shelley et al. (2017) found a higher PFe/PAl ratio around 0.25 is this area (their sample geoa5-6). This result, highlights some of the difficulties that link atmospheric inputs to water column data (Baker et al., 2016), and implies a probable fractionation after aerosol deposition. In addition, there is high spatial and temporal variability of atmospheric deposition (Mahowald et al., 2005) and a certain degree of uncertainty about the dissolution processes of atmospherically-transported particles (Bonnet and Guieu, 2004).

5. Conclusions

The investigation of the PFe compositions of suspended particulate matter along the GEOVIDE section in the North Atlantic reflects the pervasive influence of crustal particles, augmented by sedimentary inputs at margins, and within benthic nepheloid layers at depths. In consequence, variance of particulate iron along the section is mainly explained by lithogenic factors.

Resuspension of sedimentary particles from continental shelves are responsible of high particulate iron concentration within the surrounding water column, and could be observed at long distances, in the case of the Iberian margin. ~~Due to the hydrodynamics conditions, lithogenic particles are exported off shore up to 280 km away off the Iberian margin.~~ Our results also demonstrate the impact of arctic meteoric water ~~in the biogeochemical cycle of trace elements~~ on the Greenland shelf while in surface, the enhancement of productivity by new bioavailable iron is leading to a transfer of dissolved iron to the particulate phase.

Above the Reykjanes Ridge, resuspension of particles were responsible of the PFe enrichment of the Iceland Scottish Overflow Water.

Our dataset allowed the investigation of scavenging processes that were sometimes visible at depths greater than 1000m, these effects being the most pronounced within the WEB.

Overall, particulate iron distribution in the North Atlantic is strongly affected by sources at its boundaries. This work, within the frame of the GEOTRACES program, will allow a better understanding of the cycle of particulate iron, when combined to other datasets in a modelling exercise for example.

~~This investigation of the PFe compositions of suspended particulate matter along the GEOVIDE section in the North Atlantic indicates~~ reflects ~~the pervasive influence of crustal particles, augmented by sedimentary inputs at margins, and at depths, within benthic nepehloid layers. Rary particlesare responsible of highconcentration In~~

~~particular, hallowed the exportof while in surface, twill Il faudrait une phrase d'ouverture plutôt~~

~~Indeed, along the GEOVIDE section, continental shelves provided an important load of particles within the surrounding water column, with PFe mostly residing in non-biogenic particulate form. The Iberian margin discharged high quantities of lithogenic particles originating from riverine inputs far away from the coast while the Greenland margin did not reveal a long distance seeding of PFe, due to hydrodynamic conditions. Both Greenland and Newfoundland margins PFe resuspended particles were under a strong biogenic influence that were exported at depth. This resulted in different remineralisation fluxes among the different provinces. Scavenging processes could also be visible at depths greater than 1000 m, these effects being the most pronounced within the Labrador Basin.~~

~~Finally, resuspended sediments above the Reykjanes Ridge increased the PFe composition of the Iceland Scottish Overflow Water. A similar feature occurs for the Labrador Sea Water, as it flows from the Irminger Basin to the Western European Basin.~~

Acknowledgments

We are greatly indebted to the captain and crew of the N/O Pourquoi Pas? for their help during the GEOVIDE mission and clean rosette deployment. We would like to give special thanks to Fabien Pérault and Emmanuel de Saint Léger for their technical expertise, to Catherine Schmechtig for the GEOVIDE database management and Greg Cutter for his guidance in setting up the new French clean sampling system. We also would like to thanks Reiner Schlitzer for the Ocean Data View software (ODV).

This work was supported by the French National Research Agency (ANR-13-BS06-0014, ANR-12-PDOC-0025-01), the French National Centre for Scientific Research (CNRS-LEFE-CYBER), the LabexMER (ANR-10-LABX-19), and Ifremer. It was supported for the logistic by DT-INSU and GENAVIR.

Figure 1: Map of stations where suspended particle samples were collected with GO-FLO bottles during the GEOVIDE cruise (GA01). Biogeochemical provinces are indicated by red squares, IM: Iberian Margin, IAP: Iberian Abyssal Plain, WEB: Western European Basin, IcB: Iceland Basin, RR: Reykjanes Ridge, IrB: Irminger Basin, GS: Greenland Shelf, LB: Labrador Basin, NS: Newfoundland Shelf. This figure was generated by Ocean Data View (Schlitzer, R., Ocean Data View, odv.awi.de, 2017).

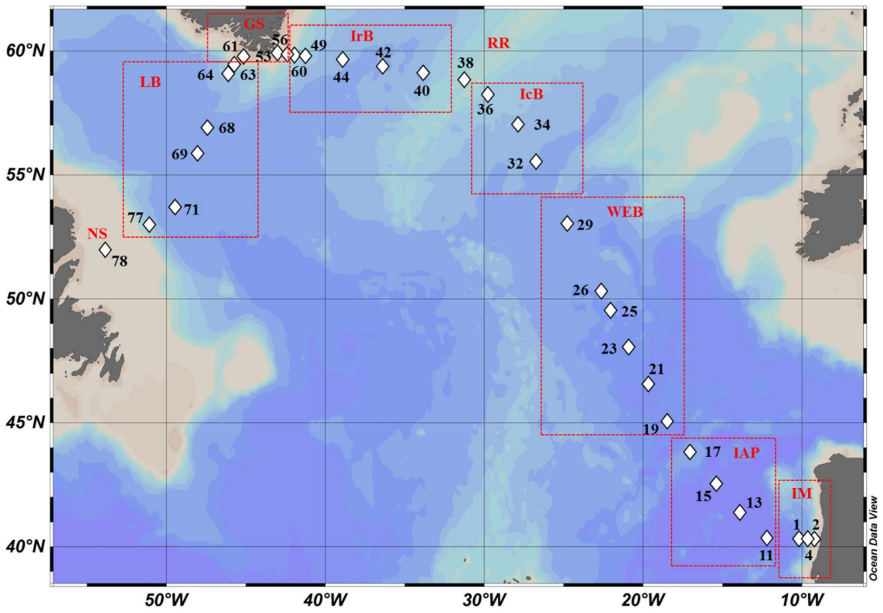

Figure 2: Salinity section during the GEOVIDE cruise. Water masses are indicated in black, MW: Mediterranean Water; NACW: North Atlantic Central Water; NEADW: North East Atlantic Deep Water; LSW: Labrador Sea Water; DSOW: Denmark Strait Overflow Water; ISOW: Iceland-Scotland Overflow Water; SAIW: Sub-Arctic Intermediate Water; IcSPMW: Iceland Sub-Polar Mode Water; IrSPMW: Irminger Sub-Polar Mode Water. Stations locations are indicated by the numbers. Biogeochemical provinces are indicated in blue font above station

numbers. Contour of salinity = 35.8psu have been applyied to identify the Mediterranean Water. This figure was generated by Ocean Data View (Schlitzer, R., Ocean Data View, odv.awi.de, 2017).

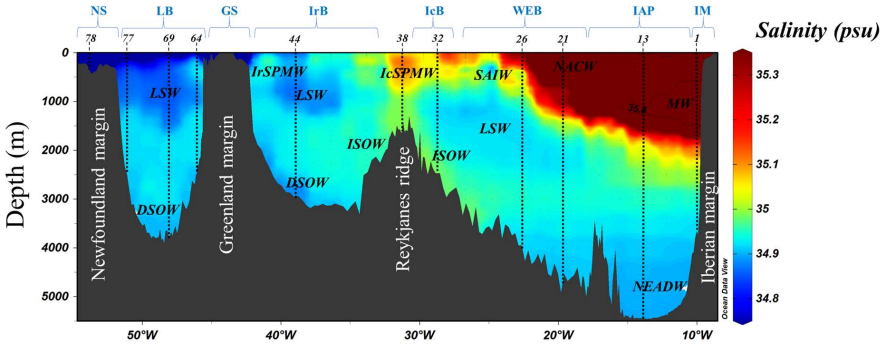

Figure 3: Left) Distribution of total particulate iron (a, PFe), aluminium (b, PAl), manganese (c, PMn) and phosphorus (d, PP) concentrations (in nmol L^{-1}) along the GEOVIDE section. Right) Contribution of small size fraction (0,45-5 µm) expressed as percentage (%) of the total concentration of PFe (e), PAl (f), PMn (g) and PP (h). Station IDs and biogeochemical region are indicated on top of section a. This figure was generated by Ocean Data View (Schlitzer, R., Ocean Data View, odv.awi.de, 2017).

Formatted: Font: (Default) Times New Roman, 10 pt

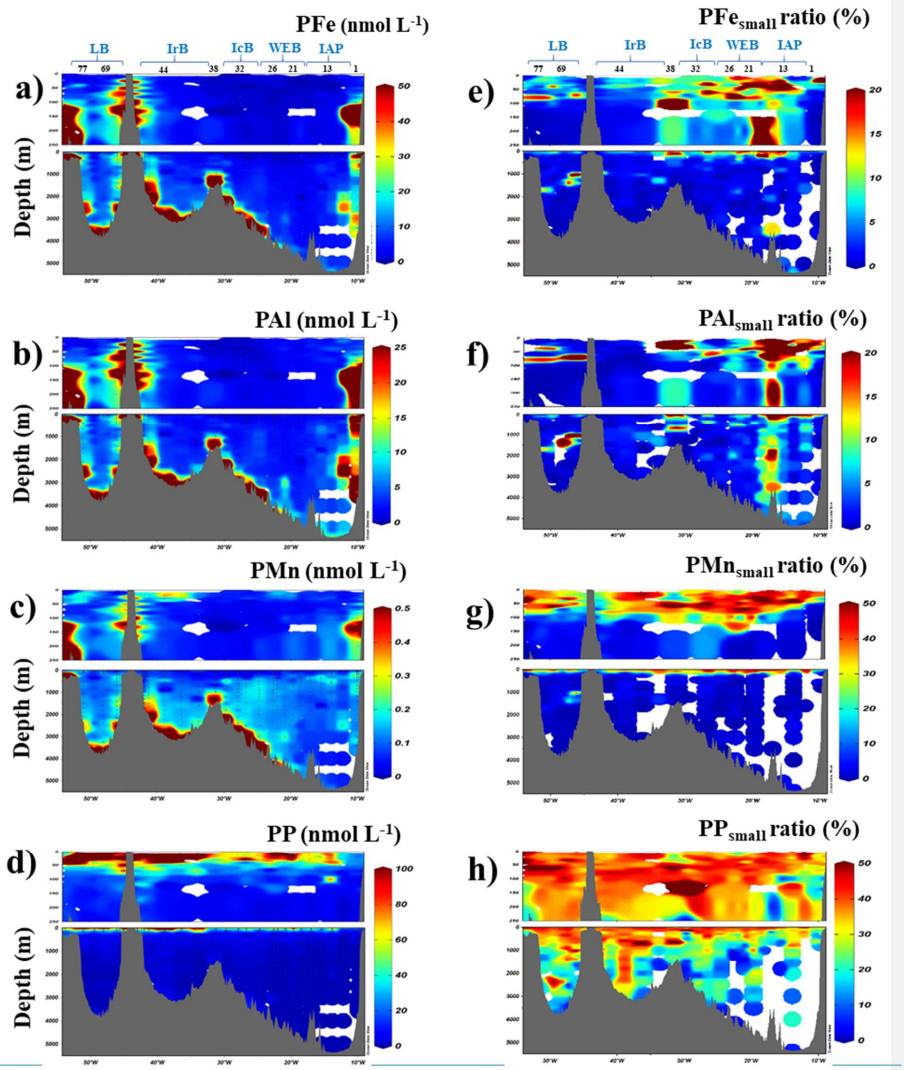

Figure 4: Section of derived contribution of sedimentary inputs manganese bulk sediment proxy (a) and transmissometry (b) along the GA01 section. Station IDs and biogeochemical region are indicated above the section (a). This figure was generated by Ocean Data View (Schlitzer, R., Ocean Data View, odv.awi.de, 2017).

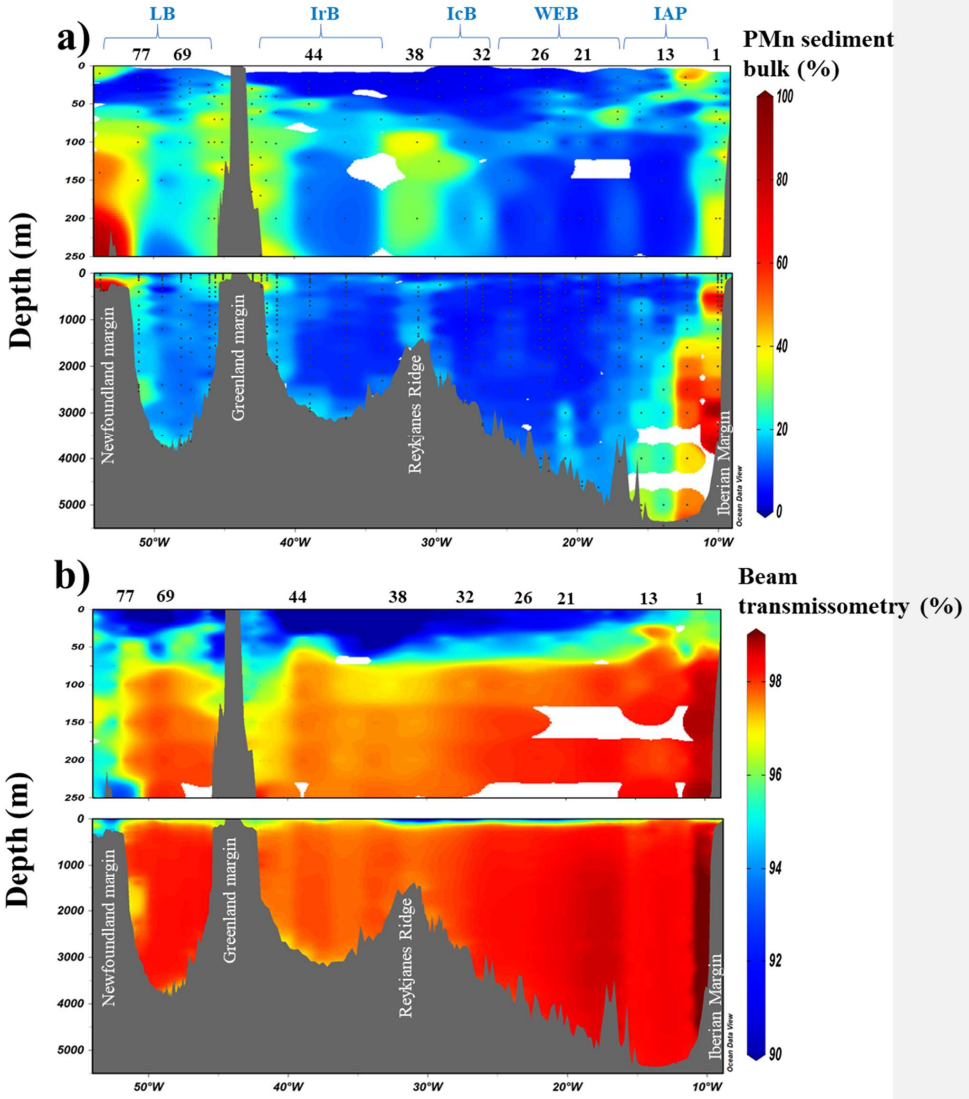

~~Figure 4: Boxplot figure of the particulate iron vertical profile (in nmol L^{-1}) in the a) Iberian abyssal plain (IAP), b) Western European basin (WEB), c) Icelandic basin (IcB), d) Irminger basin (IrB) and e) Labrador basins (LB). Please note the change of PFe scale between the basins. The left boundary of the box represents the 25th percentile while the right boundary represents the 75th percentile, the line within the box marks the median value. Whiskers~~

~~represent the 90th and 10th percentiles and dots are the outlying data. Seven depth boxes have been used (0-100m, 100-200m, 200-500m, 500-1000m, 1000-2000m, 2000-3000m and 3000m-bottom depth).~~

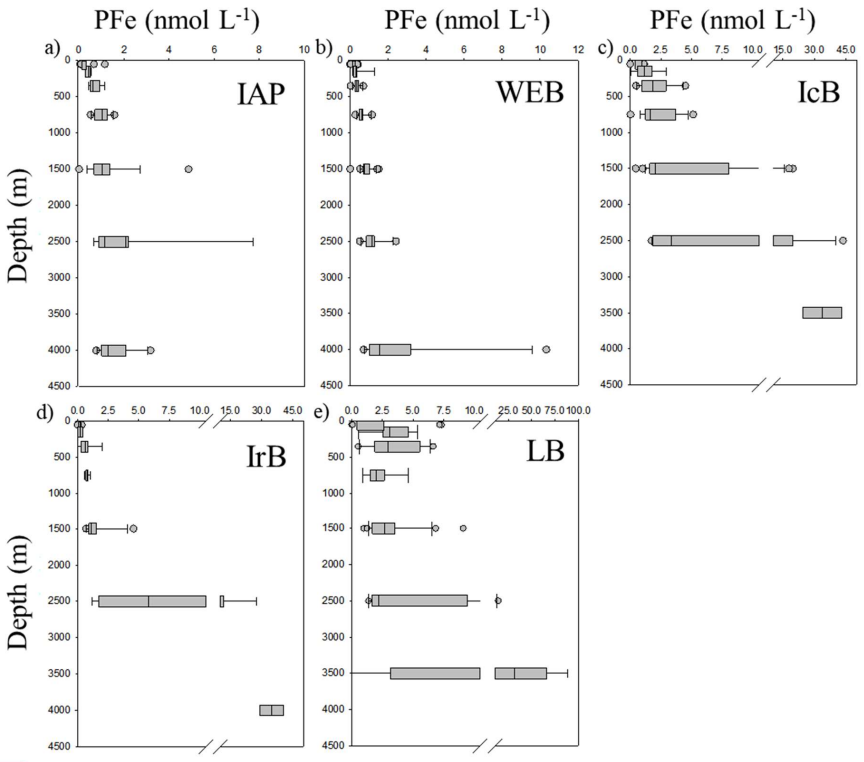

Figure 5: Factor fingerprint of the positive matrix factorisation. The four factors are represented in a stacked bar chart of the percentage of variance explained per element.

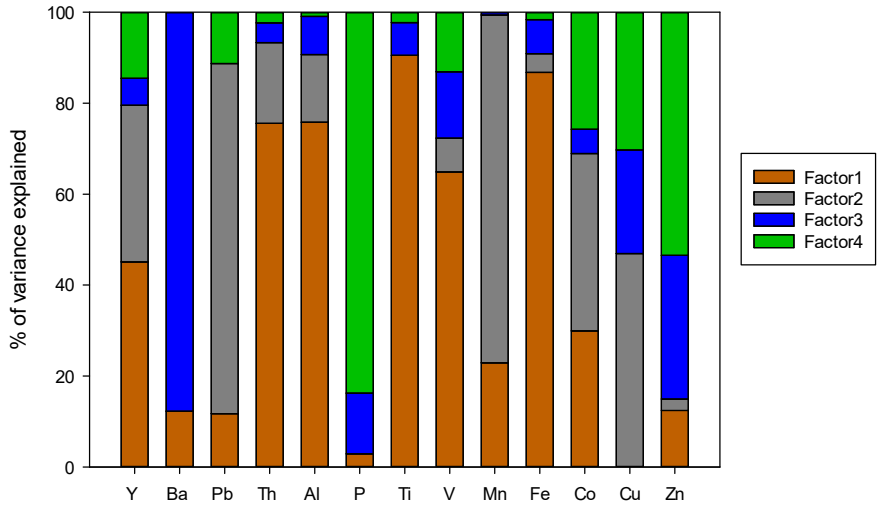

Figure 6: a) Section of the PFe to PAl molar ratio (mol mol^{-1}); (b) contribution of ~~lithogenic~~ PFe_{litho}(%) based on Eq. (1). Station IDs and biogeochemical provinces are indicated above each section. This figure was generated by Ocean Data View (Schlitzer, R., Ocean Data View, odv.awi.de, 2017).

Formatted: Subscript

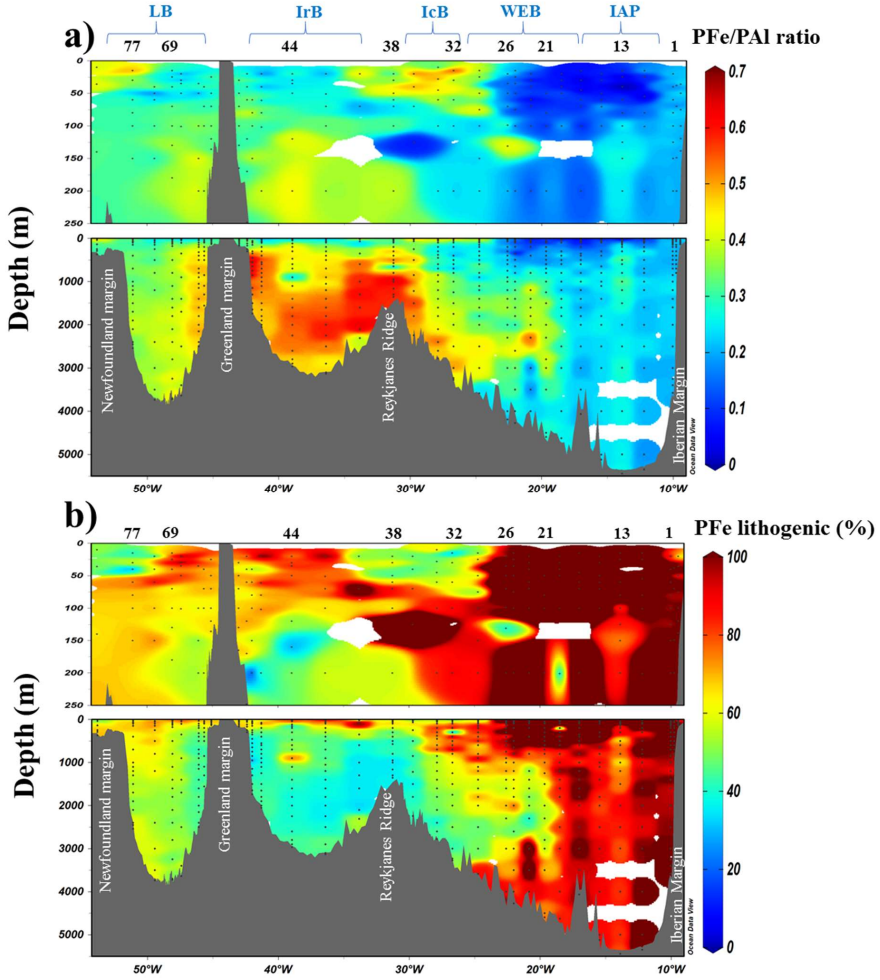

Figure 7: Whisker diagram of PFe/PAl molar ratio (mol mol^{-1}) in the different water masses sampled along the GA01 line. Median values for the water masses were as follows: LSW_{lb}= 0.37; LSW_{Ir}=0.44; LSW_{WEB}=0.36; $ISOW_{east}$=0.48; $ISOW_{west}$=0.58; $DSOW_{lab}$=0.42; $DSOW_{Ir}$=0.47; NEADW=0.23; MW=0.22 mol mol^{-1}. Based on their salinity and potential temperature signatures (García-Ibáñez et al., 2015; Figure 2), we applied a Kruskal-Wallis test on molar

PFe/PAl ratios of nine water masses (Figure 7) in order to test the presence of significant differences. Water masses for which we had less than 5 data points for PFe/PAl were excluded from this test. As the differences in the median values among the treatment groups were greater than would be expected by chance; the difference in PFe/PAl between water masses is statistically significant (P = <0.001).

~~Figure 9: Section of derived contribution of sedimentary inputs manganese bulk sediment proxy (a) and transmissometry (b) along the GA01 section. Station IDs and biogeochemical region are indicated above the section (a). This figure was generated by Ocean Data View (Schlitzer, R., Ocean Data View, odv.awi.de, 2017).~~

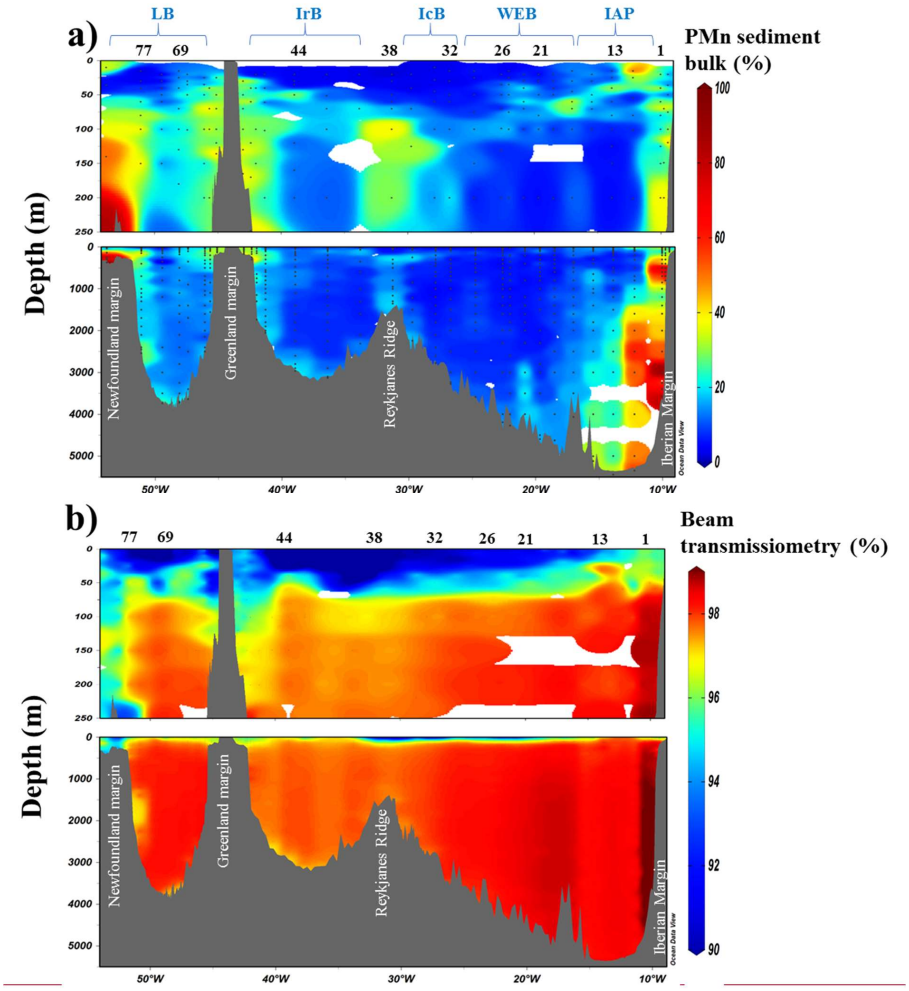

Figure 10: Vertical profiles of PFe (nmol L^{-1}, a), lithogenic proportion of particulate iron (%, b) and sedimentary proportion of particulate manganese (%, c) at the Iberian, East-West Greenland and Newfoundland margins.

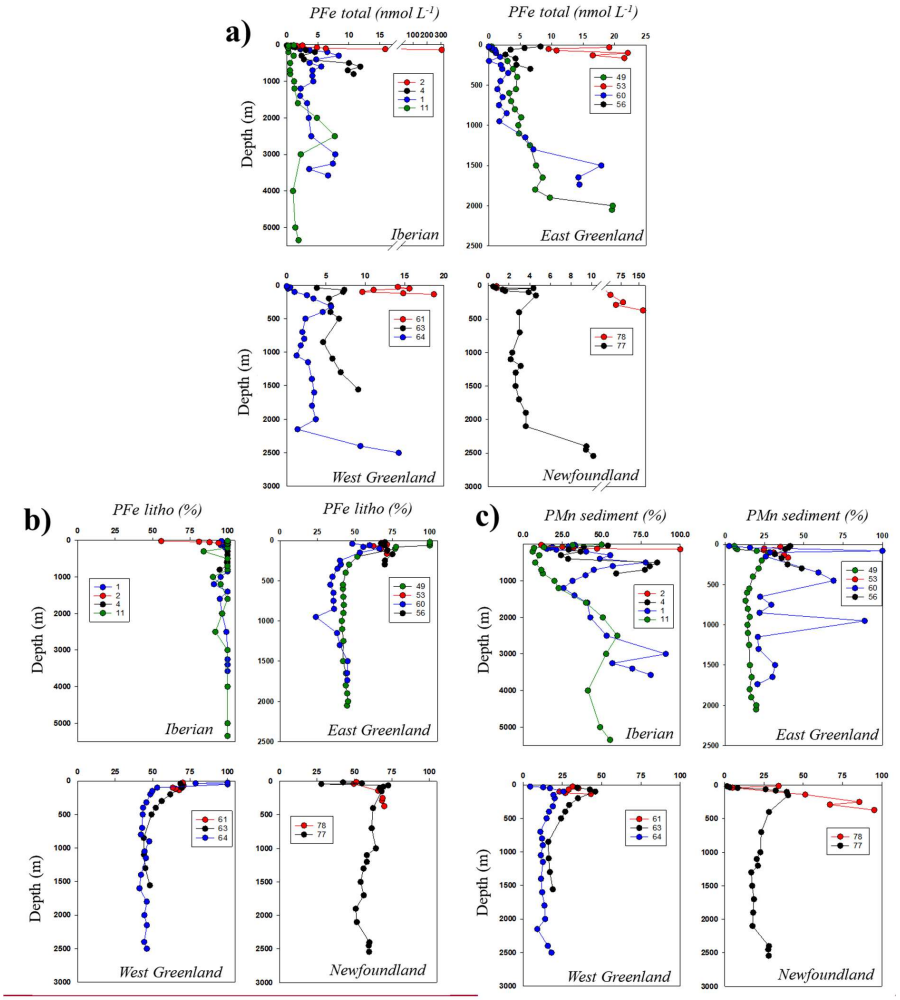

Figure 1~~1~~0: PFe total (a); PFe/PAl ratio (b) and beam transmissometry (%) as a function of depth above the seafloor (m) at selected stations where a decrease in transmissometry was recorded.

		Fe	Al	P	Mn
Blank (nmol L^{-1})	5µm filter	0.072	0.100	0.511	0.003
	0.45µm filter	0.132	0.164	1.454	0.005
Limit of detection (nmol L^{-1})	5µm filter	0.011	0.030	0.365	0.001
	0.45µm filter	0.026	0.046	1.190	0.001
Recovery CRM (%)	BCR-414 (n=10)	88 ± 7			94 ± 7
	MESS-4 (n=5)	98 ± 14	97 ± 14	80 ± 30	110 ± 18
	PACS-3 (n=8)	101 ± 9	99 ± 14	91 ± 34	112 ± 11

Table 1: Blank and limit of detection (nmol L^{-1}) of the two filters and Certified reference material (CRM) recoveries during GEOVIDE suspended particle digestion.

Author	Year	Fraction	Location	Depth range	PFe	PAl	PMn	PP
