13

14 **Abstract**

15 A large anomalously warm water patch (the “Blob”) appeared in the NE Pacific Ocean in
16 the winter of 2013–14 and persisted through 2016 causing strong positive upper ocean
17 temperature anomalies at Ocean Station Papa (OSP, 50°N, 145°W). The effect of the
18 temperature anomalies on annual net community production (ANCP) was determined by upper
19 ocean chemical mass balances of O₂ and DIC using data from a profiling float and a surface
20 mooring. Year-round oxygen mass balance in the upper ocean (0 to 91–111 m) indicates that
21 ANCP decreased after the first year when warmer water invaded this area and then returned to
22 the “pre-blob” value (2.4, 0.8, 2.1, and 1.6 mol C m⁻² yr⁻¹ from 2012 to 2016, with a mean value
23 of 1.7 ± 0.7 mol C m⁻² yr⁻¹). ANCP determined from DIC mass balance has a mean value that is
24 similar within the errors as that from the O₂ mass balance but without significant trend (2.0, 2.1,
25 2.6, and 3.0 mol C m⁻² yr⁻¹ with a mean value of 2.4 ± 0.6 mol C m⁻² yr⁻¹). This is likely due to
26 differences in the air-sea gas exchange, which is a major term for both mass balances. Oxygen
27 has a residence time with respect to gas exchange of about one month while the CO₂ gas
28 exchange response time is more like a year. Therefore the biologically induced oxygen saturation
29 anomaly responds fast enough to record annual changes whereas that for CO₂ does not.
30 Phytoplankton pigment analysis from the upper ocean shows lower chlorophyll-*a* concentrations
31 and changes in plankton community composition (greater relative abundance of picoplankton) in
32 the year after the warm water patch entered the area than in previous and subsequent years. Our
33 analysis of multiple physical and biological processes that may have caused the ANCP decrease
34 after warm water entered the area suggests that it was most likely due to the temperature-induced
35 changes in biological processes.

36 **1 Introduction**

37 Net community production (NCP) in the upper ocean is defined as net organic carbon
38 production, which equals biological production minus respiration. At steady state when
39 integrated over a period of at least one year, the annual NCP (ANCP) is equivalent to the flux of
40 biologically-produced organic matter from the upper ocean to the interior. Both biological
41 production and respiration processes are temperature dependent, and heterotrophic activities such
42 as community respiration and zooplankton grazing are usually considered to be more sensitive to
43 temperature change than autotrophic production (Allen et al., 2005; Brown et al., 2004; Gillooly
44 et al., 2001; López-Urrutia et al., 2006; Regaudie-De-Gioux and Duarte, 2012; Rose and Caron,
45 2007). This implies that rising temperature should lead to enhanced heterotrophy and lower NCP
46 (López-Urrutia et al., 2006). In contrast, it has also been suggested (e.g., Chen and Laws, 2017)
47 that the main effect of temperature on community metabolism is likely due to differences in
48 phytoplankton community composition (e.g. cyanobacteria dominate in warm, oligotrophic
49 waters, whereas diatoms dominate in cold, nutrient-rich areas) rather than to lower temperature
50 sensitivity of phytoplankton production.

51 From the winter of 2013, a large anomalously warm water patch (the “Blob”) appeared in
52 the NE Pacific Ocean (Bond et al., 2015). The “Blob” had stretched from Alaska to Baja
53 California by the end of 2015 (Di Lorenzo and Mantua, 2016) and caused widespread changes in
54 the marine ecosystem, such as geographical shifts of plankton species, harmful algal blooms, and
55 strandings of fishes, marine mammals, and seabirds (Cavole et al., 2016). Here we calculate the
56 ANCP with upper ocean oxygen (O₂) and dissolved inorganic carbon (DIC) mass balances using
57 data from Ocean Station Papa in the NE Pacific (OSP, 50°N, 145°W, Figure 1), to determine if
58 there were significant NCP changes during the anomalous warm event. The monthly Sea Surface

59 Temperature Anomaly (SSTA) at OSP from 2012 to 2016 (Figure 2) indicates that for most of
60 the 1st year (starting from June 2012) sea surface temperature (SST) was lower than usual, but
61 then transitioned to strong positive temperature anomaly from 2013 to 2014. The positive
62 anomaly continued with a magnitude of ~ 2°C to June 2015, and then dropped back to “normal”
63 in the summer of 2016.

64 Our field location is in the subarctic northeast Pacific Ocean at OSP, where repeat
65 hydrographic cruises have been carried out since 1981 by Fisheries and Oceans Canada with a
66 frequency of two to three times per year (Freeland, 2007). A NOAA surface mooring has been
67 deployed at OSP since 2007, for physical and biogeochemical measurements such as
68 temperature, salinity, wind, ocean current, radiation, oxygen and total gas pressure, pH, and
69 carbon dioxide (CO₂) (Emerson et al. 2011; Cronin et al. 2015; Fassbender et al. 2016). In
70 addition, Argo profiling floats have been deployed near OSP since the 2000s (Freeland and
71 Cummins, 2005). The first floats measured only temperature, salinity, and pressure but then
72 measurements of oxygen and nitrate were added (Bushinsky and Emerson, 2015; Johnson et al.,
73 2009). NCP at OSP has been determined using various approaches over the years, including
74 bottle incubations (Wong, 1995), ²³⁴Th methods (Charette et al., 1999), carbon/nutrient
75 drawdown (Fassbender et al., 2016; Plant et al., 2016; Takahashi et al., 1993; Wong et al., 2002a,
76 2002b), and oxygen mass balance (Bushinsky and Emerson, 2015; Emerson, 1987; Emerson et
77 al., 1991, 1993; Giesbrecht et al., 2012; Juranek et al., 2012; Plant et al., 2016).

78 **2 Methods**

79 **2.1 Measurements of O₂, DIC, and phytoplankton biomass**

80 Autonomous in situ oxygen measurements were made on a profiling float deployed by
81 the University of Washington (Special Oxygen Sensor Argo float, SOS-Argo F8397, WMO #

82 5903743, Figure 1). The complete dataset is available at
83 <https://sites.google.com/a/uw.edu/sosargo/>, and some of the data have been published previously
84 by Bushinsky and Emerson (2015) and Yang et al. (2017). Oxygen measurements on the SOS-
85 Argo float were obtained using an Aanderaa optode oxygen sensor with air-calibration
86 mechanism (Bushinsky et al., 2016) capable of providing the air-sea difference in oxygen
87 concentration with an accuracy of about $\pm 0.2\%$ and a vertical resolution of 3-5 m in the top 200
88 m of water column. This float was operated at a cycle interval of ~ 5 days covering depths from
89 surface to 1800 m.

90 Partial pressure of seawater CO_2 ($p\text{CO}_2$), temperature, and salinity data were obtained
91 from the NOAA mooring at OSP (WMO # 4800400). The complete dataset is available at
92 http://cdiac.ornl.gov/oceans/Moorings/Papa_145W_50N.html, and some of the data were
93 published by Fassbender et al. (2016). DIC was calculated using the total alkalinity (TA)- $p\text{CO}_2$
94 pair in CO2sys program Version 1.1 (van Heuven et al. 2011), where TA was calculated using
95 the linear relationship with salinity developed in Fassbender et al. (2016) ($\text{TA} = 37 \times S + 988$)
96 for the OSP vicinity. The calculation was performed on the total pH scale using the carbonate
97 dissociation constants (K_1' and K_2') of Lueker et al. (2000), the HSO_4^- dissociation constant from
98 Dickson et al. (1990), and the B_T/S ratio from Lee et al. (2010). The DIC data were normalized
99 to the annual mean salinity at OSP (32.5), to eliminate the influence from evaporation/dilution.

100 Water samples for phytoplankton abundance and community composition were collected
101 at OSP during 14 Line P repeat hydrographic cruises aboard the CCGS John P. Tully from 2012
102 to 2016 (February, June, and August for each year). Phytoplankton biomass, measured as total
103 chlorophyll *a* (chl-*a*) concentrations, and the contribution of the main taxonomic groups of
104 phytoplankton to chl-*a* were determined from high performance liquid chromatography (HPLC)

105 measurements of phytoplankton pigment concentrations (chlorophylls and carotenoids, Zapata
106 et al. 2000) followed by CHEMTAX v1.95 analysis (Mackey et al., 1996). Eight algal groups
107 were included in the chemotaxonomic analysis: diatoms, haptophytes, chlorophytes,
108 pelagophytes, prasinophytes, dinoflagellates, cryptophytes, and cyanobacteria. However,
109 cryptophytes were not found since their biomarker pigment, alloxanthin was not detected in any
110 of our samples. Pigment ratios for each algal group were obtained from Higgins et al. (2011) and
111 used as ‘seed’ values for multiple trials (60 runs) from randomized starting points, as described
112 by Wright et al. (2009). The same initial pigment ratios (Table 1a) were used in all cruises but
113 each cruise was run separately to allow potential variations in the CHEMTAX optimization to be
114 expressed. The range of final pigment ratios are given in Table 1b and the final ratios for each
115 cruise are given in Peña et al. (2018). The six best solutions (those with the lowest residuals)
116 were averaged for estimating the taxonomic abundances.

117 **2.2 Models used for NCP calculation**

118 **2.2.1 Oxygen mass balance model**

119 Oxygen, temperature, and salinity data from SOS-Argo F8397 and wind speed (U_{10}) data
120 from NOAA PMEL OSP mooring (<https://www.pmel.noaa.gov/ocs/data/disdell/>,
121 <https://www.pmel.noaa.gov/ocs/data/fluxdisdell/>) were used in a multi-layer upper ocean O_2
122 mass balance model to calculate NCP. This model frame (Figure 3) is similar to what was used
123 in Bushinsky and Emerson (2015), which compartmentalizes the upper ocean (0-150 m) into a
124 mixed layer box (with variable height) with one meter boxes below. This model assumes that
125 horizontal processes are not important. Because horizontal gradients of oxygen are small, lateral
126 transport has much less influence on this property than fluxes from air-sea gas exchange, vertical
127 advection, and diapycnal eddy diffusion. A detailed assessment of this assumption is given in

128 Yang et al. (2017). Furthermore, the temperature time series measured by the SOS-Argo (Figure
129 S1) shows no significant intrusions of fronts/eddies, and the continuity of water mass during the
130 study period also allows us to use this simplified model that ignores horizontal processes.

131 We define ANCP as the flux of organic carbon that escapes the “upper ocean” after a
132 complete seasonal cycle. To be consistent with this definition NCP is integrated vertically from
133 the surface ocean to the winter mixed layer depth, which in this location is roughly equal to the
134 pycnocline depth. Because internal waves cause a 10 to 20 meter variation in the depth of density
135 surfaces in this location, we used the annual mean pycnocline depth as the base of the modeled
136 “upper ocean” to conserve mass in the model. Fluxes across the base of the upper ocean are
137 calculated using measured gradients in oxygen at the density of the pycnocline, independent of
138 its depth.

139 Oxygen concentration changes over time in the modeled “upper ocean” with depth of h
140 ($dh[O_2]/dt$) are the sum of: gas exchange fluxes (F_{A-W}), vertical advection flux (F_V), diapycnal
141 eddy diffusion (F_{Kz}), entrainment between the mixed layer and the water below (F_E), and net
142 biological oxygen production (J_{NCP}).

$$\frac{dh[O_2]}{dt} = F_{A-W} + F_V + F_{Kz} + F_E + J_{NCP} \quad \text{mol m}^{-2} \text{ d}^{-1} \quad (1)$$

143
144 F_{A-W} is calculated only for the mixed layer box, using a gas exchange model that includes both
145 diffusion and bubble processes (Emerson and Bushinsky, 2016; Liang et al., 2013). With the
146 time step (3 h) used in our case, the mixed layer change between time steps is always smaller or
147 equal to 1 m, so entrainment occurs only between the mixed layer box and the box below. The
148 entrainment flux (F_E) that gets out of the mixed layer box ends up going into the box below and
149 vice versa, so F_E for these two boxes have the same value but different signs and cancel each

150 other out. F_V is calculated from Ekman pumping rate (derived from wind speed) and oxygen
151 gradient from SOS-Argo measurements. F_{Kz} is calculated with oxygen gradient and diapycnal
152 eddy diffusion coefficient from Cronin et al. (2015), which decreases with depth from the base of
153 the mixed layer to a background value of $10^{-5} \text{ m}^{-2} \text{ s}^{-1}$ (Whalen et al., 2012) with a $1/e$ scaling
154 described in Sun et al. (2013) (See also Bushinsky and Emerson, 2015). For the mixed layer
155 reservoir F_{Kz} and F_V are considered only at the base of the box. For all the boxes below the mixed
156 layer, F_{Kz} and F_V are considered both on the top and at the base of each box. Biological oxygen
157 production, J_{NCP} , is the difference between the calculated fluxes and the measured time rate of
158 change (left hand side of Equation 1). This value is converted from oxygen to carbon production
159 (i.e. ANCP) using a constant oxygen to carbon ratio of 1.45 (Hedges et al., 2002).

160 The uncertainty of ANCP was estimated using a Monte Carlo approach. Confidence
161 intervals for oxygen measurements and the gas exchange mass transfer coefficients used in the
162 oxygen mass balance model were assigned to the model, and varied randomly while ANCP was
163 calculated in two hundred runs for each calculation. Details of this approach are presented in the
164 supporting information and Yang et al. (2017).

165 **2.2.2 DIC mass balance model**

166 We used a similar mass balance model for DIC, in which the base of the modeled “upper
167 ocean” is set to the annual mean pycnocline depth (the same as the oxygen mass balance model).
168 This choice of the upper ocean depth distinguishes this model from the mixed layer model used
169 in Fassbender et al. (2016). Fluxes at the base of the upper ocean in our model use DIC
170 gradients, diapycnal eddy diffusion coefficients, and upwelling velocities determined at the mean
171 pycnocline depth while Fassbender et al. (2016) used the values at the bottom of the mixed layer.
172 Because the OSP surface mooring provided only the mixed layer DIC data, we assumed that

173 there is no annual net DIC change in the depth region between the mixed layer and the annual
174 mean pycnocline depth. The depth gradient of DIC used to calculate fluxes across the
175 pycnocline was calculated from measured oxygen gradients assuming dO_2/dz to $dDIC/dz$ ratio of
176 1.45 (Hedges et al., 2002). Thus, we assume for this calculation that the DIC change at the
177 pycnocline depth is only due to degradation of organic matter, which ignores the change due to
178 $CaCO_3$ dissolution (Fassbender et al., 2016). For the DIC mass balance the multi-layer model is
179 equivalent to a one-layer model:

$$\frac{dh[DIC]}{dt} = F_{A-W} + F_V + F_{Kz} + F_E + J_{NCP} \quad \text{mol m}^{-2} \text{d}^{-1} \quad (2)$$

180
181 where the DIC change ($dh[DIC]/dt$) for the modeled upper ocean (the air-sea interface to the
182 mean depth of the pycnocline) is due to air-water CO_2 exchange (F_{A-W}) at the air-sea interface,
183 vertical advection (F_V) and diapycnal eddy diffusion (F_{Kz}) at the base of the modeled “upper
184 ocean”, and net biological carbon production (J_{NCP}) in between. For this one-layer model,
185 entrainment occurred within the same layer (box) and therefore there is no net entrainment flux
186 ($F_E = 0$). The air-sea gas-exchange mass transfer coefficient is calculated as a function of wind
187 speed using equations from Wanninkhof (2014). The DIC gradients used for F_V and F_{Kz} are
188 derived from oxygen gradients at the pycnocline depth as described above.

189 **2.3 Temperature dependence of NCP derived from the metabolic theory of ecology**

190 The correlation between NCP variation and environmental temperature could be
191 attributed to the temperature dependence of planktonic metabolism. Regaudie-De-Gioux and
192 Duarte (2012) derived the temperature dependences of gross primary production (GPP) and
193 community respiration (CR) using the metabolic theory of ecology and a large historical dataset
194 on volumetric planktonic metabolism in different seasons and ocean regimes (1156 estimates of

195 volumetric metabolic rates and the corresponding water temperature). Equations 3 & 4 below are
 196 their linear regressions between the natural logarithm of the specific metabolic rates ($GPP/Chla$
 197 and $CR/Chla$) and the inverted water temperature ($1/kT$),

$$\ln \frac{GPP}{Chla} = a_p \frac{1}{kT} + b_p \quad (3)$$

$$\ln \frac{CR}{Chla} = a_r \frac{1}{kT} + b_r \quad (4)$$

198
 199 where $Chla$ is the chlorophyll- a concentration, k is the Boltzmann's constant, T is the
 200 environmental temperature in Kelvin, and a_p , b_p , a_r , b_r are slopes and intercepts for each linear
 201 regression. The temperature dependence of GPP/CR can be derived by combining Equations
 202 3 & 4:

$$\frac{GPP}{CR} = EXP \left[(a_p - a_r) \frac{1}{kT} + (b_p - b_r) \right] \quad (5)$$

203
 204 Since the community respiration (CR) includes the respiration of both autotrophs and
 205 heterotrophs, NCP can be calculated as the difference between GPP and CR.

$$NCP = GPP - CR = GPP \left(1 - \frac{1}{\frac{GPP}{CR}} \right) \quad (6)$$

206 Combining Equations 5 and 6 gives us the NCP-temperature relationship.

$$NCP = GPP \left\{ 1 - \frac{1}{EXP \left[(a_p - a_r) \frac{1}{kT} + (b_p - b_r) \right]} \right\} \quad (7)$$

207

208 **3 Results**

209 **3.1 Oxygen and DIC measurements**

210 The evolutions of density, oxygen concentration, and the oxygen anomaly in percent
211 supersaturation ($\Delta O_2 = ([O_2]/[O_2]_{\text{sat}} - 1) \times 100$) determined by the profiling float at OSP from 2012
212 to 2016 are presented in Figure 4(a-c). The saturation concentration of oxygen ($[O_2]_{\text{sat}}$) was
213 calculated using equations from Garcia and Gordon (1992, 1993). The thin black line indicates
214 the mixed layer depth, which is defined by a density offset from the value at 10 m using a
215 threshold of 0.03 kg m^{-3} (de Boyer Montégut, 2004). The thick blue line indicates the pycnocline
216 with a density of $\sigma_\theta = 25.8 \text{ kg m}^{-3}$, which follows $[O_2]$ gradients well (Figure 4b). The white
217 boxes indicate the modeled “upper ocean” for each year, in which base of the modeled “upper
218 ocean” is the mean pycnocline depth for each year. Oxygen in the mixed layer was
219 supersaturated from mid April to October/November, and near saturation or slightly
220 undersaturated for the rest of the year (Figure 4c).

221 The evolution of salinity normalized DIC in the mixed layer determined by the OSP
222 mooring is presented in Figure 4d. The $p\text{CO}_2$ sensor stopped working during two periods in 2013
223 and 2016 (indicated with dash line boxes), and therefore the data for these two periods is filled
224 with interpolated values. Strong summertime DIC drawdown was observed in each year with the
225 lowest DIC around September.

226 **3.2 Annual Net Community Production**

227 All the terms of the oxygen mass balance calculation in each year are presented in Table
228 2a. The ANCP results (2.4 ± 0.6 , 0.8 ± 0.4 , 2.1 ± 0.4 and $1.6 \pm 0.4 \text{ mol C m}^{-2} \text{ yr}^{-1}$, with a mean
229 value of $1.7 \pm 0.7 \text{ mol C m}^{-2} \text{ yr}^{-1}$) indicate that ANCP initially decreased after warmer water
230 invaded this area (2013-14) and then returned to the “pre-blob” value of 2012-13 in subsequent
231 years. Given the uncertainty in the estimate of ANCP in each year, the value during year 2013-14
232 is significantly different at the 95% confidence interval (as determined by t-test, Bethea et al.,

233 1975). With the exception of the unusually low value for 2013-14, ANCP values from oxygen
234 mass balance calculation are very close to the historical ANCP estimates at OSP (2.3 ± 0.6 mol
235 $\text{C m}^{-2} \text{ yr}^{-1}$, Emerson 2014).

236 If we integrate the ANCP from the ocean surface to the depth of the mixed layer
237 ($\text{ANCP}_{\text{mixed layer}}$ in Table 2a) instead of to the annual mean depth of the pycnocline, the results are
238 higher (3.4, 1.3, 2.3 and 2.3 mol $\text{C m}^{-2} \text{ yr}^{-1}$, with a mean value of 2.4 ± 0.9 mol $\text{C m}^{-2} \text{ yr}^{-1}$).
239 While the mean value is higher because it includes some organic carbon flux that is degraded
240 between the mixed layer and pycnocline in summer, the annual trend, in which ANCP is
241 significantly lower in year two (2013-14), is the same as that in which ANCP values were
242 determined for the depth interval above the pycnocline.

243 In comparison, ANCP values determined from DIC mass balance are 2.0, 2.1, 2.6, 3.0
244 mol $\text{C m}^{-2} \text{ yr}^{-1}$, with a mean value of 2.4 ± 0.5 mol $\text{C m}^{-2} \text{ yr}^{-1}$ (Table 2b). The mean value is
245 similar within the errors of the value determined from the oxygen mass balance (1.7 ± 0.7 mol C
246 $\text{m}^{-2} \text{ yr}^{-1}$) but there is no significant change between the second year (2013-14) and those before
247 and after. The somewhat higher value could be due to the assumption we made about DIC
248 change below the mixed layer or because we neglected horizontal advection (See Discussion).

249 **3.3 Phytoplankton abundance and community composition**

250 *Chl-a* concentration, an indicator of phytoplankton biomass, was about 50% lower (0.22
251 mg m^{-3}) during the period from August 2013 to June 2014 than during the rest of the 2012 to
252 2016 period (Figure 5a) and the historical annual average at OSP (Peña and Varela, 2007). *Chl-a*
253 resumed to the 2012-13 level in August 2014 and had a significant increase in the summer of
254 2016. 19'-hexanoyloxyfucoxanthin (Hex), which is mainly derived from prymnesiophytes, was
255 found to be the most abundant pigment after T-chla (Figure 5b). Fucoxanthin (Fuco), a pigment

256 associated with diatoms, haptophytes and pelagophytes, was also abundant and showed increased
257 concentration (0.54 mg m^{-3}) in June 2016, coinciding with increased T-chla. After Hex, and
258 Fuco, chlorophyll-b was the most abundant pigment (0.36 to 0.27 mg m^{-3}), indicating the
259 presence of green algae. We also detected occasionally lutein (0 - 0.125 mg m^{-3}), violaxanthin (0 -
260 0.012 mg m^{-3}) and, prasinoxanthin (0 - 0.005 mg m^{-3}), which are biomarkers for green algae.

261 The CHEMTAX analysis detected the presence of seven classes of phytoplankton
262 (Figure 5c) and showed an increase in the relative contribution of cyanobacteria and
263 chlorophytes during the “Blob” period with the highest proportion of the former group in June of
264 2014 and the latter in June 2015 (Figure 5c). There was also a decrease in the abundance of
265 diatoms from August 2013 to June 2015. The remainder of the phytoplankton community was
266 primarily composed of haptophytes and the contribution of the other phytoplankton groups was
267 variable and showed no consistent year-to-year variability. By August 2015 the phytoplankton
268 community had returned to a similar relative composition as observed in 2012-13, with
269 nanoplankton (mostly haptophytes) being dominant and with microplankton (diatoms and
270 dinoflagellates) increasing in abundance. The input matrix (Table 1a) appeared to describe the
271 environment well since the final pigment ratio matrix did not differ dramatically from the initial
272 input values.

273 **4 Discussion**

274 **4.1 Comparisons of ANCP from oxygen and DIC mass balances**

275 Although the ANCP are integrated to the same depth in our oxygen and DIC mass
276 balance models, as mentioned in Section 3.2, the ANCP determined from DIC mass balance (4-
277 year mean: $2.4 \pm 0.5 \text{ mol C m}^{-2} \text{ yr}^{-1}$) is somewhat higher than the value determined from oxygen
278 mass balance (4-year mean: $1.7 \pm 0.7 \text{ mol C m}^{-2} \text{ yr}^{-1}$), but still within the error of the model.

279 There are two possible reasons for such discrepancy. First of all, due to the lack of DIC data
280 below the mixed layer, for the DIC model we made an assumption that there is no annual net
281 DIC change in the depth region between the mixed layer and the annual mean pycnocline depth.
282 With this assumption, the ANCP from DIC mass balance is higher because it includes the
283 organic carbon that is degraded between the mixed layer and pycnocline in summer, so the
284 ANCP from DIC mass balance (4-year mean: $2.4 \pm 0.5 \text{ mol C m}^{-2} \text{ yr}^{-1}$) is very similar to the
285 mixed layer ANCP determined from our oxygen mass balance model (4-year mean: 2.4 ± 0.9
286 $\text{mol C m}^{-2} \text{ yr}^{-1}$) and the mixed layer ANCP determined by Fassbender et al. (2016) ($2 \pm 1 \text{ mol C}$
287 $\text{m}^{-2} \text{ yr}^{-1}$). The second possible reason that the 4-year mean value of ANCP determined from the
288 DIC mass balance is higher than the value determined from the oxygen mass balance is
289 horizontal advection. Because gas exchange resets the oxygen saturation anomaly for oxygen
290 about ten times faster than CO_2 , the DIC mass balance is more vulnerable to horizontal fluxes
291 than the O_2 mass balance. If we assumed that the difference in ANCP estimated from these two
292 tracers ($0.7 \text{ mol C m}^{-2} \text{ yr}^{-1}$) is due to horizontal advection, and calculate the horizontal DIC
293 gradient using the 4-year mean horizontal velocity at OSP of 0.08 m s^{-1} , we found that a
294 horizontal DIC gradient of $1 \times 10^{-8} \text{ mol m}^{-4}$ is required to cause the difference of $0.7 \text{ mol C m}^{-2} \text{ yr}^{-1}$
295 ¹, which is possible at this location (horizontal DIC gradient along the 4-year mean horizontal
296 flow at OSP is about $2 \sim 3 \times 10^{-8} \text{ mol m}^{-4}$ from GLODAP v1.1 gridded product, Key et al., 2004).

297 As for the inter-annual changes in ANCP, the oxygen mass balance calculation shows
298 that ANCP had a significant decrease in 2013-14 and then returned to the “pre-blob” level in the
299 following years whereas ANCP calculated from DIC mass balance does not show this trend.
300 Since air-sea exchange is a large part of the flux mass balance for both oxygen and CO_2 (Table
301 2), a likely reason for this discrepancy is due to the shorter residence time with respect to gas

302 exchange for the oxygen compared to the CO₂ saturation anomalies. An example of the residence
303 time calculation is included in the supporting information where it indicates that the gas
304 exchange residence time in the upper ocean for oxygen is about one month and that for CO₂ is
305 about one year (See also Emerson and Hedges, 2008, Chapter 11). Thus, the biologically induced
306 saturation anomaly for oxygen responds fast enough to record annual changes whereas that for
307 *p*CO₂ and DIC does not. On the other hand, as discussed above, since DIC mass balance is more
308 vulnerable to horizontal flux than oxygen mass balance, the DIC signal might already been
309 “smoothed” by the horizontal flux, which may also explain why the inter-annual ANCP changes
310 were not observed by using the DIC mass balance approach. Alternatively, the production ratio
311 of particulate organic carbon (POC) and particulate inorganic carbon (PIC) may cause the inter-
312 annual variation of DIC mass balance. However, in our case since there was no significant bloom
313 of haptophytes (e.g. coccolithophore) during the study period (Figure 5c), it is unlikely that the
314 inter-annual change in POC/PIC ratio would affect the ANCP result calculated from DIC mass
315 balance. Hence, from this point forward we will focus on analyzing the factors that might
316 influence ANCP variations determined by the oxygen mass balance model.

317 **4.2 Causes of ANCP decrease**

318 In the following paragraphs, we analyze connections between ANCP decrease and the
319 “Blob” temperature anomaly in the context of multiple physical and biological processes,
320 including the choices of start time from which ANCP are calculated, the base depth of the
321 modeled “upper ocean”, planktonic metabolism, and changes in phytoplankton community
322 composition.

323 Our observations began in June 2012, 10 – 12 months before the positive SST anomalies.
324 To determine whether the start date for determining the ANCP values affects the results, we

325 began the time series on four different months (Table 3). We are somewhat limited because
326 there is only about 12 “pre-blob” months before June 2012. However, as shown in Table 3, as
327 long as there are more “pre-blob” months than “Blob-affected” months in the 1st year, the
328 significant ANCP decrease from 1st to 2nd year is still observed and the trend of ANCP variation
329 for those 4 years remains.

330 To determine whether the annual mean pycnocline depth (the white rectangles in Figure
331 4a-4c) influences the ANCP trends we calculated ANCP using the 4-year mean depth of 100 m
332 for the modeled “upper ocean”. The ANCP results only change slightly (2.6, 1.0, 1.9, and 1.6
333 mol C m⁻² yr⁻¹) and the decrease in 2013-14 is still statistically significant, indicating that the
334 different base depth used for the modeled “upper ocean” is not the key factor that causes ANCP
335 changes.

336 To test if the temperature dependence of planktonic metabolism is strong enough to
337 cause the ANCP decline we observed (e.g. 1.6 mol C m⁻² yr⁻¹ between 2012-13 and 2013-14), we
338 calculated the GPP from measured NCP of year 1 (2012-13) using Equation 7, and assumed GPP
339 was constant for all four years so we could then determine the effect of temperature on NCP
340 based on the metabolic theory of ecology (Equation 7). Since the specific phytoplankton growth
341 rate increases with increasing temperature (e.g. Regaudie-De-Gioux and Duarte, 2012; Chen and
342 Laws, 2017), if phytoplankton biomass would have remained the same during the “blob”, GPP
343 would have increased. Thus, assuming a constant GPP in this calculation is somewhat
344 speculative, but it at least provides a first-order assessment of the metabolic temperature effect
345 on ANCP. The parameterizations derived with datasets from the Arctic were used (Regaudie-De-
346 Gioux and Duarte, 2012), because it gives the largest change in ANCP. The results (Table 4)
347 indicate that temperature dependence of planktonic metabolism is not strong enough to account

348 for the measured ANCP decrease in the 2nd year (2013-14), suggesting that this is not the major
349 reason for the observed ANCP decline.

350 Having ruled out the above likely candidates, we suggest that the observed ANCP
351 decrease is most likely linked to the changes in GPP (e.g. low phytoplankton biomass observed
352 in the 2nd year Figure 5a) and phytoplankton community composition (Figure 5c). In general,
353 larger phytoplankton (i.e. microplankton) are more efficient exporters than smaller nanoplankton
354 and picoplankton (e.g., Chen and Laws, 2016). Given the lower export rates of picoplankton
355 (e.g. cyanobacteria) than those of larger phytoplankton (e.g. diatoms) the observed changes in
356 phytoplankton community composition (Figure 5b) in 2013-14, which included a decrease in the
357 relative abundance of diatoms, and an increase in the relative abundance of cyanobacteria and
358 green algae (chlorophytes), could have further contributed to the decrease in ANCP. After the
359 initial response to the temperature anomaly, chl-*a* concentration and the phytoplankton
360 community composition returned to a level similar to those observed before the warming
361 occurred, suggesting that the plankton community rapidly adapted to the higher temperature and
362 prevailing environmental conditions. These changes in GPP and phytoplankton community
363 composition could be ultimately in response to the lack of micronutrients like iron (due to
364 enhanced stratification from the “blob” that restricted the vertical supply), which has been shown
365 to regulate phytoplankton biomass and composition in this high-nutrient low-chlorophyll region
366 (e.g. Hamme et al., 2010; Marchetti et al., 2006), . Unfortunately, we do not have iron data
367 available to confirm that at this time.

368 **5 Conclusions**

369 The annual net community production (ANCP) at Ocean Station Papa (OSP) in the
370 subarctic Northeast Pacific Ocean was determined from June 2012 to June 2016 to examine the

371 effect of the temperature anomaly on the efficiency of carbon export. The ANCP determined by
372 oxygen mass balance had a four year mean value of $1.7 \pm 0.7 \text{ mol C m}^{-2} \text{ yr}^{-1}$, whereas ANCP
373 determined by DIC mass balance gives a somewhat higher mean value ($2.4 \pm 0.5 \text{ mol C m}^{-2} \text{ yr}^{-1}$).
374 ANCP for individual years determined from O_2 mass balance showed a significant decrease in
375 year 2 (2013-14) after the onset of the temperature anomaly, but no significant decrease in
376 ANCP was found when calculated with DIC mass balance. We believe that this indicates that
377 the DIC concentration and $p\text{CO}_2$ respond too slowly to capture annual changes in ANCP. Based
378 on our observations and historical ANCP estimates at OSP as reference, we found there was a
379 significant ANCP decrease in 2013-14 due to the warm anomaly, which is consistent with the
380 findings from concurrent phytoplankton data. Possible mechanisms for the observed decrease in
381 ANCP by the oxygen mass balance in the second year were analyzed in the context of multiple
382 physical and biological processes that could be affected by temperature anomaly. **Our analysis**
383 **showed that the ANCP decrease, as well as changes in phytoplankton abundance and community**
384 **composition, was most likely due to changes in GPP after the “Blob” entered the area. These**
385 **changes could be ultimately in response to the lack of micronutrients like iron during the “Blob”**
386 **period. However, the ultimate cause cannot be specified by our analysis at this time.**

387

388 *Data availability.*

389 Float data are available online (<https://sites.google.com/a/uw.edu/sosargo/home>). Mooring data
390 is available online at: http://cdiac.ornl.gov/oceans/Moorings/Papa_145W_50N.html.

391 *Author contributions.*

392 BY and SRE designed the experiments. BY developed the model code and process the data. AP
393 provided the data, analysis and interpretation of phytoplankton. BY and SRE prepared the
394 manuscript with contributions from all co-authors.

395 *Competing interests.*

396 The authors declare that they have no conflict of interest.

397 *Acknowledgements.*

398 We thank Dr. Stephen Riser and Dana Swift for their assistance in development of the SOS-Argo
399 float, and scientists of NOAA PMEL and the Institute of Ocean Sciences (IOS) and crews of
400 CCGS John P. Tully, for their work on OSP mooring and Line P cruises. Special thanks are
401 given to Dr. John Crusius for the constructive discussions and comments on this study. This
402 work was supported by National Science Foundation grant OCE-1458888.

Figure 3 Schematic of the multi-layer upper ocean oxygen mass balance model (adapted from *Bushinsky and Emerson, 2015*). Fluxes (F) are from air-sea gas exchange (F_{A-W} , including diffusion and bubble processes), vertical advection (F_V), diapycnal eddy diffusion (F_{Kz}), and entrainment (F_E).

578
 579 **Figure 4** (a-c) Upper ocean density, oxygen concentration, and oxygen supersaturation ΔO_2 (%)
 580 from the SOS-Argo float at OSP. The thin black line indicates the mixed layer depth, the thick
 581 blue line indicates the pycnocline depth, and the white rectangles indicate the modeled “upper
 582 ocean” for each of the four years that ANCP were calculated. (d) Mixed layer DIC normalized to
 583 a surface salinity at OSP ($S=32.5$) from June 2012 to June 2016. Dash line boxes indicate
 584 periods when the pCO_2 data were not available and thus were filled with a straight line
 585 interpolation.

586
 587 **Figure 5** Mixed layer mean (a) chl-*a* concentration (mg m⁻³), (b) other pigment concentration
 588 (mg m⁻³), and (c) relative phytoplankton composition (%) at OSP. Values were determined from
 589 HPLC pigment analysis of samples collected in February, June, and August for each year from
 590 2012 to 2016.

591

Table 1. Pigment:Chl *a* ratios for eight algal groups: (a) CHEMTAX initial ratio matrix, and (b) ranges of final pigment ratios obtained by CHEMTAX on the pigment data.

Abbreviations: Cyano, cyanobacteria; Chloro, chlorophytes; Prasino, prasinophytes; Crypto, cryptophytes; Dinofla, dinoflagellates; Pelago, pelagophytes; Hapto, haptophytes; Chl *c*₃, chlorophyll *c*₃; Chl *c*₂, chlorophyll *c*₂; Peri, peridinin; But, 19'-butanoyloxyfucoxanthin; Fuco, fucoxanthin; Pras, prasinoxanthin; Viola, violaxanthin; Hex, 19'-hexanoyloxyfucoxanthin; Allo, alloxanthin; Zea, zeaxanthin; Lut, lutein; Chl *b*, chlorophyll *b*; Chl *a*, chlorophyll.

Table 2 Annual net community production (ANCP) determined from (a) O₂ mass balance, and (b) DIC mass balance. The annually integrated fluxes for each of the important terms (columns 4-9) indicate that the air sea flux and biological production terms dominate for both tracers. Two ANCP values are given in (a): one integrated from the ocean surface to the depth of annual mean pycnocline (column 3), ANCP, and another value integrated over the depth of the mixed layer, ANCP_{mixed layer}. Only the former is a measure of the biological organic carbon that escapes the upper ocean on an annual basis (see text).

a										
Year	Time Period (June to June)	h (m)	Annual oxygen mass balance (mol O ₂ m ⁻² yr ⁻¹)						ANCP = J _{NCP} /1.45 (mol C m ⁻² yr ⁻¹)	ANCP _{mixed layer} (mol C m ⁻² yr ⁻¹)
			dh[O ₂]/dt	F _{A-W} = F _s + F _b	F _E	F _{Kz}	F _V	J _{NCP}		
1	2012-13	91	-0.7	-2.9	0	-0.6	-0.6	3.5	2.4 ± 0.6	3.4
2	2013-14	111	-1.3	-1.5	0	-0.8	-0.2	1.2	0.8 ± 0.4	1.3
3	2014-15	95	-0.6	-1.7	0	-0.9	-1.0	3.0	2.1 ± 0.4	2.3
4	2015-16	103	0.8	-0.1	0	-0.7	-0.3	2.3	1.6 ± 0.4	2.3

b										
Year	Time Period (June to June)	h (m)	Annual DIC mass balance (mol C m ⁻² yr ⁻¹)						ANCP = - J _{NCP} (mol C m ⁻² yr ⁻¹)	
			dh[DIC]/dt	F _{A-W}	F _E	F _{Kz}	F _V	J _{NCP}		
1	2012-13	91	-0.2	1.0	0	0.7	0.1	-2.0	2.0	
2	2013-14	111	-0.1	1.5	0	0.4	0.1	-2.1	2.1

4	2015-16	103	-0.04	2.0	0	0.9	0.1	-3.0	3.0	

Table 3 ANCP calculated from O₂ mass balance with different start dates to determine if the chosen annual period affects the conclusions (see text).

Start Time		6/10/12	7/10/12	8/10/12
ANCP (mol C m ⁻² yr ⁻¹)	1 st year (2012-13)	2.4	2.3	2.4
	2 nd year (2013-14)	0.8	0.9	0.7
	3 rd year (2014-15)	2.1	2.6	2.5
	4 th year (2015-16)	1.6	-	-

Table 4 Comparisons of ANCP measured with O₂ mass balance and ANCP predicted from the temperature dependence parameterization of planktonic metabolism using parameters from the Arctic Ocean [*Regaudie-De-Gioux and Duarte, 2012*]. Gross primary production (GPP) is calculated from ANCP in year 1 and Equation 7, and it is assumed to be the same through years 1 – 4. $ANCP_{diff} = 2.4 \text{ (mol C m}^{-2} \text{ yr}^{-1}) - ANCP_{\text{Predicted or Measured}}$

Year	Mean temperature (°C)	ANCP (mol C m ⁻² yr ⁻¹)		ANCP _{diff} (mol C m ⁻² yr ⁻¹)	
		Predicted	Measured	Predicted	Measured
1	8.4	-	2.4	-	-
2	10.4	1.9	0.8	-0.5	-1.6
3	10.8	1.9	2.1	-0.5	-0.3
4	9.9	2.1	1.6	-0.3	-0.8
