15 **Abstract**

16 In the Arctic Ocean, climate change effects such as warming and ocean acidification (OA) are  
17 manifesting faster than in other regions. Yet, we are lacking a mechanistic understanding of the  
18 interactive effects of these drivers on Arctic primary producers. In the current study, one of the  
19 most abundant species of the Arctic Ocean, the prasinophyte *Micromonas pusilla*, was exposed  
20 to a range of different pCO<sub>2</sub> levels at two temperatures representing realistic current and future  
21 scenarios for nutrient-replete conditions. We observed that warming and OA synergistically  
22 increased growth rates at intermediate to high pCO<sub>2</sub> levels. Furthermore, elevated temperatures  
23 shifted the pCO<sub>2</sub>-optimum of biomass production to higher levels. Based on changes in cellular  
24 composition and photophysiology, we hypothesise that the observed synergies can be explained  
25 by beneficial effects of warming on carbon fixation in combination with facilitated carbon  
26 acquisition under OA. Our findings help to understand the higher abundances of picoeukaryotes  
27 such as *M. pusilla* under OA, as has been observed in many mesocosm studies.

## 28 **1 Introduction**

29 With the progress in using molecular tools to describe marine biodiversity in the past decades,  
30 the scientific community has become increasingly aware of the underestimated importance of  
31 picoeukaryotes, for both primary and export production of the world's oceans (Richardson and  
32 Jackson, 2007; Worden and Not, 2008). Larger phytoplankton such as diatoms are efficient  
33 vectors for carbon export due to aggregate formation and ingestion by large zooplankton  
34 leading to the production of fast-settling faecal pellets (Sherr et al., 2003). In contrast,  
35 picoeukaryotes are mainly grazed by smaller heterotrophic protists such as ciliates, which have  
36 a low carbon retention, excrete relatively more dissolved material, and thus fuel recycled  
37 production (Sherr and Sherr, 2002). Hence, changes in the relative abundance of pico- and  
38 nanoeukaryotes can have large implications for food webs and biogeochemistry (Worden et al.,  
39 2015).

40 Picoeukaryotes tend to dominate low nutrient environments, which is often attributed to  
41 their high surface:volume ratios and mixotrophic capacities (Raven, 1998; McKie-Krisberg and  
42 Sanders, 2014). The low nutrient concentrations in the Arctic surface ocean, for example, cause  
43 picoeukaryotes to be particularly successful in this region. In fact, the globally occurring  
44 prasinophyte *Micromonas pusilla* is considered the most abundant species in the Arctic ocean  
45 (Šlapeta et al., 2006; Lovejoy et al., 2007; Marquardt et al., 2016). In this environment, strong  
46 stratification causes low nutrient concentrations throughout the summer and autumn months  
47 (Tremblay et al., 2015), and the occurrence of the polar night requires organisms to either form  
48 resting stages or to have heterotrophic capacities (Tremblay et al., 2009; Lovejoy, 2014; Berge  
49 et al., 2015; Vader et al., 2015).

50 Climate change effects manifest faster in the Arctic than anywhere else on the planet  
51 (Stocker, 2014). In this region, for example, temperatures are rising more than twice as fast as  
52 at the rest of the globe (Miller et al., 2010). The concurrent rapid reduction in ice cover allows  
53 for more light penetration and longer growing seasons, while increased stratification due to ice  
54 melt and warming constrain nutrient supply to surface waters, both of which will change the  
55 dynamics of primary production (Arrigo et al., 2008; Wassmann and Reigstad, 2011). Ocean  
56 acidification (OA) is also especially pronounced in the Arctic Ocean, because low temperatures  
57 and alkalinity make the system sensitive to anthropogenic CO<sub>2</sub> loading (AMAP, 2013; Qi et  
58 al., 2017). Picoeukaryotes such as *M. pusilla* may benefit from these changes and are considered  
59 potential winners of climate change. In the Canadian Arctic, for example, picoeukaryote  
60 abundances are increasing as surface waters get warmer, fresher and more oligotrophic (Li et  
61 al., 2009). Regarding OA effects, the majority of studies on natural phytoplankton assemblages

62 have shown picoeukaryotes, particularly *M. pusilla*, to increase in relative abundance with  
63 increasing pCO<sub>2</sub> levels (Engel et al., 2008; Meakin and Wyman, 2011; Newbold et al., 2012;  
64 Brussaard et al., 2013; Hussherr et al. 2017; Schulz et al., 2017). Despite the evident sensitivity  
65 of *M. pusilla* to changes in pCO<sub>2</sub> levels, a detailed assessment of the OA effects, their  
66 interaction with warming as well as the underlying mechanisms in this important species is still  
67 missing.

68 Like all photosynthetic organisms, cells of *M. pusilla* need to maintain a balance  
69 between energy sources (i.e. light harvesting by the photosynthetic apparatus) and sinks (most  
70 importantly carbon fixation in the Calvin cycle) to prevent harmful levels of excitation pressure  
71 on the photosynthetic electron transport chain (Behrenfeld et al., 2008). Light harvesting and  
72 electron transport in the photosystems are largely independent of changes in temperature and  
73 pCO<sub>2</sub> (Mock and Hoch, 2005; Hoppe et al., 2015), but the impact of these drivers on energy  
74 sinks can potentially affect the energy balance of the cell: The beneficial effects of elevated  
75 pCO<sub>2</sub> observed in phytoplankton are thought to be caused by increased diffusive CO<sub>2</sub> supply,  
76 reduced CO<sub>2</sub> leakage, or by lowered costs to operate their CO<sub>2</sub> concentrating mechanisms (Rost  
77 et al., 2008; Bach et al., 2013). Elevated temperatures, on the other hand, can change enzyme  
78 kinetics including those involved in the Calvin cycle, thus leading to a larger sink of excitation  
79 energy (Maxwell et al., 1994; Toseland et al., 2013). Hence, both ocean warming and  
80 acidification potentially increase the efficiency of photosynthesis and biomass production, at  
81 least up to the organisms' respective optimum levels. Above these levels, temperatures and  
82 proton concentrations start to disrupt enzymatic processes, increase the investment into pH  
83 homeostasis, and impair the delicate regulation of cellular processes (Levitt, 1980; Taylor et  
84 al., 2001; Flynn et al., 2012). Thus, the complex balance between beneficial and detrimental  
85 effects will determine whether the combination of warming and OA will synergistically  
86 promote or deteriorate phytoplankton growth and biomass build-up.

87 In the current study, we aim to investigate the responses of an Arctic *M. pusilla* strain  
88 to warming and OA. To this end, *M. pusilla* was grown at four pCO<sub>2</sub> levels ranging from  
89 preindustrial to future scenarios (180-1400  $\mu$ atm) under 2°C and 6°C, which represent the  
90 magnitude of the projected future temperature increase in this region (Collins et al., 2013), but  
91 also the current spring and summer temperatures in the environment where the strain was  
92 isolated (Hegseth et al., in press).

## 93 **2 Material & Methods**

94

### 95 **2.1 Culture conditions**

96 Monoclonal cultures of the picoeukaryote *Micromonas pusilla* (Butcher) I. Manton & M. Parke  
97 (isolated in 2014 by K. Wolf in Kongsfjorden, Svalbard, 79°N; local temperature range -1.5 to  
98 8°C) taxonomic identification confirmed by rDNA sequencing of SSU, LSU and ITS  
99 sequences) were grown in 1-L glass bottles in semi-continuous dilute-batch cultures (max  
100 129,000 cells mL<sup>-1</sup>; diluted every 3-4 days) under constant irradiances of 150 ± 26 μmol  
101 photons m<sup>-2</sup> s<sup>-1</sup>. Media consisted of 0.2 μm sterile-filtered Arctic seawater with a salinity of  
102 32.7 enriched with macronutrients, trace metals and vitamins according to F/2R medium  
103 (Guillard and Ryther, 1962). Light intensities were provided by daylight lamps (Philips Master  
104 TL-D 18W; emission peaks at wavelength of 440, 560 and 635 nm), adjusted by neutral density  
105 screens and monitored using a LI-1400 data logger (Li-Cor) equipped with a 4π-sensor (Walz).  
106 Cells were growing at four different CO<sub>2</sub> partial pressures (pCO<sub>2</sub>; 180, 380, 1000, and 1400  
107 μatm) and two temperatures (2.2 ± 0.3°C and 6.3 ± 0.2°C). Cultures were acclimated to these  
108 conditions for at least 7 generations prior to sampling.

109 Different pCO<sub>2</sub> conditions were achieved by aeration of the incubation bottles with air  
110 of the respective pCO<sub>2</sub> levels delivered through sterile 0.2-μm air-filters (Midisart 2000,  
111 Sartorius stedim) for 24 h prior to inoculation. Gas mixtures were generated using a gas flow  
112 controller (CGM 2000 MCZ Umwelttechnik), in which CO<sub>2</sub>-free air (<1 ppmv CO<sub>2</sub>; Dominick  
113 Hunter) was mixed with pure CO<sub>2</sub> (Air Liquide Deutschland). The pCO<sub>2</sub> levels in the gas  
114 mixtures were regularly monitored with a non-dispersive infrared analyzer system (LI6252, LI-  
115 COR Biosciences), calibrated with CO<sub>2</sub>-free air and purchased gas mixtures of 150 ±10 and  
116 1000 ±20 ppmv CO<sub>2</sub> (Air Liquide Deutschland).

117

### 118 **2.2 Carbonate chemistry**

119 Samples for total alkalinity (A<sub>T</sub>) were filtered through 0.7-μm glass fibre filters (GF/F,  
120 Whatman) and stored in borosilicate bottles at 3°C. A<sub>T</sub> was estimated from duplicate  
121 potentiometric titration (Brewer et al., 1986) using a TitroLine alpha plus (Schott Instruments).  
122 A<sub>T</sub> values were corrected for systematic errors based on measurements of certified reference  
123 materials (CRMs provided by Prof. A. Dickson, Scripps, USA; batch #111; reproducibility ±5  
124 μmol kg<sup>-1</sup>). Total dissolved inorganic carbon (C<sub>T</sub>) samples were filtered through 0.2-μm  
125 cellulose-acetate filters (Sartorius stedim) and stored in gas-tight borosilicate bottles at 3°C. C<sub>T</sub>  
126 was measured colorimetrically in triplicates with a QuAatro autoanalyzer (Seal; Stoll et al.

127 2001). The analyser was calibrated with NaHCO<sub>3</sub> solutions (with a salinity of 35, achieved by  
128 addition of NaCl) to achieve concentrations ranging from 1800 to 2300 μmol C<sub>T</sub> kg<sup>-1</sup>. CRMs  
129 were used for corrections of errors in instrument performance such as baseline drifts  
130 (reproducibility ±8 μmol kg<sup>-1</sup>). Seawater pH<sub>total</sub> was measured potentiometrically with a two-  
131 point calibrated glass reference electrode (IOLine, Schott Instruments). An internal TRIS-based  
132 reference standard (Dickson et al., 2007) was used to correct for variability on electrode  
133 performance (reproducibility ±0.015 pH units). Following recommendations by Hoppe et al.  
134 (2012), seawater carbonate chemistry including pCO<sub>2</sub> was calculated from A<sub>T</sub> and pH using  
135 CO<sub>2</sub>SYS (Pierrot et al., 2006). The dissociation constants of carbonic acid of Mehrbach et al.  
136 (1973), as refitted by Dickson and Millero (1987), were used for calculations. Dissociation  
137 constants for KHSO<sub>4</sub> were taken from Dickson (1990).

138

### 139 **2.3 Growth, elemental composition and production rates**

140 Samples for cell counts were fixed with glutaraldehyde (0.5% final concentration). After gentle  
141 mixing, samples were stored at room temperature in the dark for 15 min, and subsequently  
142 frozen in liquid nitrogen and stored at -80°C. Prior to analysis, samples were thawed on ice and  
143 mixed thoroughly. After addition of 10 μL SybrGreen working solution (dissolved in DMSO)  
144 and 10 μL YG beads working solution (1μm-Flouresbrite calibration beads grade YG,  
145 Polyscience), samples were counted on an Accuri C6 flow cytometer (BD Biosciences)  
146 equipped with a blue solid-state laser (488 nm excitation wavelength) run on medium fluidics  
147 settings (35 μL min<sup>-1</sup>; 16 μm core size) with a limit of 50,000 events or 250 μL. Analysis was  
148 performed based on red (FL3 channel, >670 nm) and green (FL1 channel, 533 ± 30 nm)  
149 fluorescence, as well as sideward and forward light scattering. Specific growth rates constants  
150 (μ) were determined from exponential fits of cell counts over 4 consecutive days.

151 Particulate organic carbon (POC) and nitrogen (PON) were measured after filtration  
152 onto precombusted (15h, 500 °C) GF/F filters (Whatman) and stored at -20 °C. and dried for  
153 at least 12 h at 60 °C prior to sample preparation. Analysis was performed using a CHNS-O  
154 elemental analyser (Euro EA 3000, HEKAtech). Contents of POC and PON were corrected for  
155 blank measurements and normalised to filtered volume and cell densities to yield cellular  
156 quotas. Production rates of POC were calculated by multiplying the cellular quota with the  
157 division rate constant *k* of the respective incubation. Samples for determination of chlorophyll  
158 *a* (Chl *a*) were filtered onto GF/F filters (Whatman), immediately placed into liquid nitrogen  
159 and stored at -80°C until analysis. Chl *a* was subsequently extracted in 8 mL 90% acetone at

160 4°C over night. Chl *a* concentrations were determined on a fluorometer (TD-700, Turner  
161 Designs), using an acidification step (1M HCl) to determine phaeopigments (Knap et al., 1996).

162

## 163 **2.4 Variable Chl *a* fluorescence**

164 Photophysiological characteristics, based on photosystem II (PSII) variable Chl *a* fluorescence,  
165 were measured using a fast repetition rate fluorometer (FRRf; FastOcean PTX, Chelsea  
166 Technologies) in combination with a FastAct Laboratory system (Chelsea Technologies). The  
167 excitation wavelength of the fluorometer's light-emitting diodes (LEDs) was 450 nm, and the  
168 applied light intensity was 21587  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ . The FRRf was used in single turnover  
169 mode, with a saturation phase comprising 100 flashlets on a 2  $\mu\text{s}$  pitch and a relaxation phase  
170 comprising 40 flashlets on a 50  $\mu\text{s}$  pitch. Measurements from all replicates (n=3) were  
171 conducted in a temperature-controlled chamber ( $\pm 0.2^\circ\text{C}$ ) at the respective treatment  
172 temperature.

173 After subtraction of a blank value, the minimum ( $F_0$  and  $F_0'$  for light-and dark-  
174 acclimated measurements, respectively) and maximum Chl *a* fluorescence ( $F_m$ , and  $F_m'$  for  
175 light-and dark-acclimated measurements, respectively) were estimated from iterative  
176 algorithms for induction (Kolber et al., 1998) and relaxation phase (Oxborough, 2012) after 15  
177 min of dark acclimation, which was sufficient to achieve a dark-acclimated state (data not  
178 shown). All fluorescence parameters were calculated by standard equations (Genty et al., 1989;  
179 Maxwell and Johnson, 2000). Maximum quantum yields of PSII (apparent PSII photochemical  
180 quantum efficiency;  $F_v/F_m$ ) were calculated as

$$181 \quad F_v/F_m = (F_m - F_0)/F_m \quad (1)$$

182 Fluorescence based photosynthesis-irradiance curves (PI) were conducted at six irradiances (I)  
183 between 33 and 672  $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ , with an acclimation time of 10 min per light step.  
184 Electron transfer rate through PSII (ETR [ $\text{mol e}^- (\text{mol RCII})^{-1} \text{s}^{-1}$ ]) for each light step was  
185 calculated as:

$$186 \quad \text{ETR} = ((F_m' - F_0')/F_m') * I \quad (2)$$

187 Following the suggestion by Silsbe and Kromkamp (2012), the light-use efficiency ( $\alpha$  [ $\text{mol e}^-$   
188  $\text{m}^2 (\text{mol RCII})^{-1} (\text{mol photons})^{-1}$ ]) and the maximum electron transfer rates per RCII ( $\text{ETR}_{\text{max}}$   
189 [ $\text{mol e}^- (\text{mol RCII})^{-1} \text{s}^{-1}$ ]) were estimated by fitting the data to the model by (Webb et al., 1974):

$$190 \quad \text{ETR} = \text{ETR}_{\text{max}} * [1 - e^{-(\alpha * I)/\text{ETR}_{\text{max}}}] \quad (3)$$

191 The light saturation index ( $E_k$  [ $\mu\text{mol photons m}^{-2} \text{s}^{-1}$ ]) was then calculated as  $\text{ETR}_{\text{max}}/\alpha$ .  
192 Maximum non-photochemical quenching of Chl *a* fluorescence (NPQ) at irradiances of 672

193  $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$  (i.e. the highest irradiance step of the PI curve) were calculated using the  
194 normalized Stern-Volmer coefficient, also termed NSV, as described in McKew et al. (2013):

$$195 \quad (F_q'/F_v')-1 = F_0'/F_v' \quad (4)$$

196 where  $F_q'$  is the differences between measured and maximal fluorescence (Suggett et al., 2010).

197  $F_0'$  was measured after each light step (with a duration of 90 s).

198

## 199 **2.5 Statistics**

200 All data is given as the mean of three biological replicates with  $\pm$  one standard deviation. To

201 test for significant differences between the treatments, two-way analyses of variance (ANOVA)

202 with additional normality (Kolmogorov-Smirnov) and Post Hoc (Holm-Sidak) tests were

203 performed. The significance level was set to 0.05. Statistical analyses were performed with the

204 program SigmaPlot (SysStat Software Inc, Version 12.5).

205

## 206 **3 Results**

207

### 208 **3.1 Carbonate Chemistry**

209 Regular dilution of cultures with pre-aerated seawater medium kept carbonate chemistry stable  
210 over the course of the experiment. More specifically, in each bottle the drift in  $A_T$  and  $C_T$   
211 compared to initial values was  $\leq 3\%$  and  $\leq 4\%$ , respectively (data not shown). Final carbonate  
212 chemistry in the  $2^\circ\text{C}$  treatments yielded  $p\text{CO}_2$  levels of  $197 \pm 3$ ,  $323 \pm 12$ ,  $959 \pm 22$  and  $1380$   
213  $\pm 53 \mu\text{atm}$  (Table 1). In the  $6^\circ\text{C}$  treatments,  $p\text{CO}_2$  levels were  $198 \pm 6$ ,  $394 \pm 10$ ,  $1036 \pm 31$  and  
214  $1449 \pm 18 \mu\text{atm}$ . Please note that the same  $p\text{CO}_2$  level translates into differing dissolved  $\text{CO}_2$   
215 concentrations at different temperatures due to the temperature dependency of the carbonate  
216 system. Specifically, the treatment  $p\text{CO}_2$  values translated into up to 13% lower dissolved  $\text{CO}_2$   
217 concentrations in the  $6^\circ\text{C}$  compared to the  $2^\circ\text{C}$  treatment (Table 1; cf. Figure SII).  
218 Concurrently, the  $p\text{CO}_2$  levels at  $2^\circ\text{C}$  corresponded to  $\text{pH}_{\text{total}}$  values of  $8.30 \pm 0.01$ ,  $8.11 \pm 0.01$ ,  
219  $7.68 \pm 0.01$  and  $7.52 \pm 0.02$ , respectively. In the  $6^\circ\text{C}$  treatment,  $\text{pH}_{\text{total}}$  values of the four  $p\text{CO}_2$   
220 treatments were  $8.30 \pm 0.01$ ,  $8.04 \pm 0.01$ ,  $7.65 \pm 0.01$  and  $7.52 \pm 0.01$ , respectively.

221

### 222 **3.2 Growth and biomass build-up**

223 Growth rates constants of exponentially growing *M. pusilla* cultures were significantly affected  
224 by the applied treatments (Figure 1, Table 2, SII). Depending on the  $p\text{CO}_2$  level, temperature  
225 increased growth by 20 to 60% with an average of  $0.80 \text{ d}^{-1}$  under low and  $1.10 \text{ d}^{-1}$  under high  
226 temperature conditions (two-way ANOVA,  $F = 328$ ,  $p < 0.001$ ). Overall, there was also a  
227 positive  $p\text{CO}_2$  effect on growth (two-way ANOVA,  $F = 9$ ,  $p = 0.001$ ), even though no linear  
228 trends with either  $p\text{CO}_2$  or  $[\text{CO}_2]$  were observed (Figure 1, SII). The observed  $p\text{CO}_2$  responses  
229 also differed between temperature levels, indicating a significant interaction between both  
230 drivers (two-way ANOVA,  $F = 12$ ,  $p < 0.001$ ): Under low temperature, growth increased  
231 significantly from 180 to 380  $\mu\text{atm}$   $p\text{CO}_2$  (post-hoc,  $t = 3.1$ ,  $p = 0.04$ ), while there was a  
232 declining, yet insignificant trend in growth with further increases in  $p\text{CO}_2$ . Under high  
233 temperature, growth was significantly higher under 1000 compared to lower (180  $\mu\text{atm}$ ; post-  
234 hoc,  $t = 5.6$ ,  $p < 0.001$ ) and higher  $p\text{CO}_2$  levels (1400  $\mu\text{atm}$ ; post-hoc,  $t = 5.9$ ,  $p < 0.001$ ). Thus,  
235 warming shifted the optimum range for growth to higher  $p\text{CO}_2$  levels (Figure 1A).

236 This trend was also observed in terms of POC production rates (Figure 1B, Table 2),  
237 with significant effects of temperature (Table SII; two-way ANOVA,  $F = 356$ ,  $p < 0.001$ ),  $p\text{CO}_2$   
238 (two-way ANOVA,  $F = 7$ ,  $p = 0.003$ ), and their interaction (two-way ANOVA,  $F = 29$ ,  $p$   
239  $< 0.001$ ). At low temperatures, higher production rates were observed at 180 and 380  $\mu\text{atm}$

240 compared to those at 1000 and 1400  $\mu\text{atm}$   $\text{pCO}_2$  (post-hoc tests,  $t = 3.5$ ,  $p = 0.016$  and  $t = 3.0$ ,  
241  $p = 0.046$ , respectively). At high temperatures, POC production rates were significantly higher  
242 at 1000  $\mu\text{atm}$  than at all other  $\text{pCO}_2$  levels (post-hoc tests, e.g.  $t = 9.1$ ,  $p < 0.001$  for 380 vs.  
243 1000  $\mu\text{atm}$  and  $t = 7.4$ ,  $p < 0.001$  for 1000 vs. 1400  $\mu\text{atm}$ ), again indicating an upward shift in  
244 the  $\text{pCO}_2$  optimum with warming.

245

### 246 **3.3 Cellular composition**

247 Overall, POC quota (Figure 2 a, Table 2, Table SII) were significantly higher under elevated  
248 compared to low temperature (two-way ANOVA,  $F = 24$ ,  $p < 0.001$ ), but no overarching trend  
249 with  $\text{pCO}_2$  was observed. Under low temperature, cells had significantly higher POC quota at  
250 low  $\text{pCO}_2$  levels (180 and 380  $\mu\text{atm}$ ) compared to high  $\text{pCO}_2$  levels (1000 and 1400  $\mu\text{atm}$ ; all  
251 four post-hoc tests significant, e.g. 380 vs 1000 $\mu\text{atm}$ :  $t = 2.8$ ,  $p = 0.033$ ). This trend reversed  
252 under high temperature, where POC quota were highest under 1000 and 1400  $\mu\text{atm}$  (post-hoc  
253 test,  $t = 3.5$ ,  $p = 0.024$ ). Thus, temperature and  $\text{pCO}_2$  levels exhibited a significant interactive  
254 effect on POC quota (two-way ANOVA,  $F = 10$ ,  $p < 0.001$ ).

255 Similar trends were observed in terms of cellular PON quota (Figure 2 b, Table 2, Table  
256 SII), where temperature (two-way ANOVA,  $F = 5$ ,  $p = 0.045$ ) and its interaction with  $\text{pCO}_2$   
257 (two-way ANOVA,  $F = 10$ ,  $p < 0.001$ ) significantly affected the results. Here, opposing  $\text{pCO}_2$   
258 effects under different temperatures were more subtle, with PON quota under low temperatures  
259 only being significantly decreased between 380 and 1400  $\mu\text{atm}$  (post-hoc test,  $t = 3.3$ ,  $p =$   
260  $0.027$ ), while under high temperature PON quota significantly increased from 180 and 380 to  
261 1000  $\mu\text{atm}$   $\text{pCO}_2$  (post-hoc tests,  $t = 3.7$ ,  $p = 0.012$  and  $t = 2.8$ ,  $p = 0.028$ , respectively).

262 Regarding cellular Chl *a* quota, there were no significant effects of temperature or  $\text{pCO}_2$   
263 alone (Figure 2 c, Table 2, Table SII), but a significant interaction between the two drivers  
264 (two-way ANOVA,  $F = 18$ ,  $p < 0.001$ ): Under low temperature, Chl *a* quota decreased from low  
265 (180  $\mu\text{atm}$ ) to high  $\text{pCO}_2$  levels (1000 and 1400  $\mu\text{atm}$ ; post-hoc tests,  $t = 5.0$ ,  $p < 0.001$  and  $t =$   
266  $3.9$ ,  $p = 0.006$ , respectively). Under high temperature, the opposite trend was observed, where  
267 Chl *a* quota increased from low (180 and 380  $\mu\text{atm}$ ) to high  $\text{pCO}_2$  levels (1000 and 1400  $\mu\text{atm}$ ;  
268 all four post-hoc tests significant, e.g. 380 vs 1000 $\mu\text{atm}$ :  $t = 3.0$ ,  $p = 0.027$ ).

269 Molar C:N ratios of the biomass (Table 2, Table SII) increased with temperature (two-  
270 way ANOVA,  $F = 14$ ,  $p = 0.002$ ), yet this overall difference was mainly driven by results at  
271 low  $\text{pCO}_2$  levels (180 and 380  $\mu\text{atm}$ ; post-hoc tests,  $t = 2.7$ ,  $p = 0.017$  and  $t = 3.5$ ,  $p = 0.003$ ,  
272 respectively). By itself,  $\text{pCO}_2$  did not significantly affect C:N ratios.

273 The ratios of C:Chl *a* (Figure 2 d, Table 2, Table SII) were elevated under high

274 compared to low temperature conditions (two-way ANOVA,  $F = 14$ ,  $p = 0.002$ ), an effect that  
275 was most pronounced at  $p\text{CO}_2$  levels of  $180 \mu\text{atm}$  (post-hoc test,  $t = 5.5$ ,  $p < 0.001$ ). While there  
276 was no effect of  $p\text{CO}_2$  on C:Chl *a* at low temperature, C:Chl *a* decreased with increasing  $p\text{CO}_2$   
277 at high temperature (two-way ANOVA, interaction term,  $F = 6$ ,  $p = 0.007$ ;  $180$  vs.  $1400 \mu\text{atm}$   
278 at  $6^\circ\text{C}$  post-hoc test,  $t = 3.9$ ,  $p = 0.008$ ).

279

### 280 **3.4 Chl *a* fluorescence-based photophysiology**

281 The effects of the applied treatments on photophysiology were studied by means of FRRf,  
282 which investigates photochemistry at photosystem II (PSII). No effects of the applied  
283 treatments were observed in most parameters investigated (Table 3, SI1). This was true for the  
284 dark-acclimated quantum yield efficiency of PSII ( $F_v/F_m$ ), which was similar in all treatments  
285 with values of  $0.45 \pm 0.06$ , as well as for absorption cross section of PSII light harvesting ( $\sigma_{\text{PSII}}$ ).

286 Furthermore, the fitted parameters of FRRf-based PI curves ( $\alpha$ ,  $\text{ETR}_{\text{max}}$  and  $E_K$ ) were  
287 independent of the experimental treatments (Table 3, SI1). In contrast, the rate constant of the  
288 reopening of PSII reaction centres ( $\tau_{\text{ES}}$ ; Table 3, SI1) was slightly yet significantly smaller  
289 under high temperatures (two-way ANOVA,  $F = 6$ ,  $p = 0.029$ ), even though this overall  
290 response also depended on the applied  $p\text{CO}_2$  levels (two-way ANOVA, interaction term,  $F = 4$ ,  
291  $p = 0.033$ ).

292 Maximum non-photochemical quenching ( $\text{NPQ}_{\text{max}}$ ; Table 3, SI1) increased  
293 significantly with  $p\text{CO}_2$  (Table SI1; two-way ANOVA,  $F = 0$ ,  $p = 0.002$ ) while temperature had  
294 no effect. Post-hoc tests revealed that this response was mainly driven by high  $\text{NPQ}_{\text{max}}$  values  
295 at  $1000 \mu\text{atm}$ , which were significantly higher than in any other  $p\text{CO}_2$  treatment (e.g.  $t = 4.1$ ,  $p$   
296  $= 0.006$  for  $380$  vs.  $1000 \mu\text{atm}$  and  $t = 3.1$ ,  $p = 0.030$  for  $1000$  vs.  $1400 \mu\text{atm}$ ).

## 297 **4 Discussion**

298

### 299 **4.1 *Micromonas pusilla* benefits from warming**

300 We observed a strong stimulation of growth rates and biomass build-up with increasing  
301 temperature (Figure 1, Table 2). Even though the isolate stems from 1.8°C water temperature,  
302 the beneficial effects of warming from 2°C to 6°C are not surprising: *M. pusilla* is known to  
303 dominate Arctic phytoplankton assemblages in the summer and autumn situations (Lovejoy et  
304 al., 2007; Marquardt et al., 2016) when surface temperatures of 6°C or more can be reached  
305 (Hegseth et al., in press). Our results are also in line with mesocosm experiments that indicate  
306 stimulatory effects of warming on picoplankton abundances (Daufresne et al., 2009; Sommer  
307 et al., 2015) as well as with the temperature optimum of 6-8°C observed for another Arctic  
308 strain of *M. pusilla* (Lovejoy et al., 2007).

309 Below the temperature optimum of a cell, warming causes an acceleration of the entire  
310 metabolism, as enzymatic reactions run faster under these conditions (Eppley, 1972; Brown et  
311 al., 2004). In this study, warming caused higher growth rates, POC quotas and biomass  
312 production (Figure 2, Tables 2, SI1), indicating that particularly the fixation and storage of  
313 carbon was facilitated by increasing temperature. Electron transport processes, on the other  
314 hand, were largely independent of temperature (Tables 3, SI1). Thus, temperature affected the  
315 balance between electron transport ('light reaction') and carbon fixation in the Calvin cycle  
316 ('dark reactions'). Especially under relatively low temperatures, as investigated here, warming  
317 can decrease the excitation pressure on the electron transport chain of the photosystems by  
318 increasing the temperature-limited turnover rates of enzyme reaction such as RuBisCO (Mock  
319 and Hoch, 2005). Thus, cells grown under low temperature need to invest relatively more  
320 energy into biosynthesis than into photochemistry compared to cells grown under high  
321 temperature (Toseland et al., 2013). While it has been shown that Antarctic diatoms can  
322 compensate for slow RuBisCO kinetics by increasing the expression of this enzyme (Young et  
323 al., 2014), it is unknown whether such acclimation responses also occur in prasinophytes.  
324 Regarding the C:Chl *a* ratio, this can be taken as an indicator on how much resources the cell  
325 retains as carbon biomass (e.g. structural and storage compounds) relative to how much is  
326 invested into its light harvesting capacities (Halsey and Jones, 2015). In this study, the strong  
327 temperature-dependent increase in C:Chl *a* (Figure 2, Table SI1) under potentially limiting  
328 pCO<sub>2</sub> levels of 180 µatm suggests that under warming, the balance between light harvesting  
329 and carbon fixation was indeed more beneficial for biomass build-up. Furthermore, elevated  
330 temperature significantly decreased  $\tau_{ES}$  (Table 3, SI1), which can serve as a proxy of the rate

331 at which down-stream processes can remove electrons from PSII (Kolber et al., 1998). Thus,  
332 our results indicate that the drainage of electrons into carbon fixation was faster under warmer  
333 conditions, explaining the higher growth and biomass production under these conditions.

334

#### 335 **4.2 Warming shifts CO<sub>2</sub> optima towards higher pCO<sub>2</sub> levels**

336 Under 6°C and pCO<sub>2</sub> levels expected to be reached by the end of this century, OA had a  
337 significantly positive effect on growth and biomass build-up (Figure 1). This finding is in line  
338 with previous studies, which have shown that picoeukaryotes can benefit strongly from OA in  
339 both laboratory and mesocosm studies (Meakin and Wyman, 2011; Newbold et al., 2012;  
340 Schaum et al., 2012; Brussaard et al., 2013; Maat et al., 2014; Schulz et al., 2017). Such positive  
341 response to OA could indicate that picoeukaryotes such as *M. pusilla* are mainly dependent on  
342 diffusive CO<sub>2</sub> supply and thus directly benefit from higher CO<sub>2</sub> concentrations (Brussaard et  
343 al., 2013; Schulz et al., 2013; Schulz et al., 2017). While this could be related to the large surface  
344 to volume ratio of small cells, opposite trends within the group of diatoms (i.e. higher sensitivity  
345 of larger compared to smaller diatoms; Wu et al., 2014; Sett et al. 2018) suggest more complex  
346 underlying mechanisms at play.

347 Despite this overall effect, growth rates of *M. pusilla* tended to follow a non-linear  
348 response curve over the tested range of glacial to elevated future pCO<sub>2</sub> levels (i.e. 180 to 1400  
349 µatm), i.e. growth increased with increasing pCO<sub>2</sub> from low to intermediate, but decreased  
350 again under the highest pCO<sub>2</sub> levels (Figure 1). Such an optimum behaviour can be expected  
351 for most environmental drivers (Harley et al., 2017) and has previously been observed in  
352 response to OA (Sett et al., 2014; Wolf et al., 2018). The response patterns in these studies were  
353 attributed to a combination of beneficial effects of rising pCO<sub>2</sub> under potentially carbon-  
354 limiting conditions for photosynthesis, and negative effects of declining pH on cellular  
355 homeostasis and enzyme performance, which manifest mainly at high pCO<sub>2</sub> (Bach et al., 2013).  
356 This non-linearity in the observed pCO<sub>2</sub> effects emphasises the importance of experiments with  
357 more than two pCO<sub>2</sub> levels in order to properly describe OA-response patterns of organisms.

358 On a more general level, apparent discrepancies between OA studies can be attributed  
359 to actual differences in the environmental settings and their interactive effects with pCO<sub>2</sub>  
360 (Riebesell and Gattuso, 2015). When comparing the two most commonly applied pCO<sub>2</sub> levels,  
361 i.e. the present-day and the anticipated end-of-century situation, the effects of OA on most of  
362 the investigated physiological parameters are reversed under 6°C compared to 2°C (Figure 3).  
363 This illustrates how difficult it is to infer responses to OA from experiments applying only one  
364 set of environmental conditions. It is also noteworthy that the combination of OA and warming

365 led to more densely packed cells (no change in cell size based on flow cytometric  
366 measurements; data not shown) with similar stoichiometry compared to the control treatment  
367 (Table 2). This indicates that cells managed to cope well with the experienced future conditions.  
368 Furthermore, warming altered the OA-dependent change in most of the investigated parameters  
369 in a direction that indicates higher fitness compared to low temperatures (e.g. higher growth  
370 rates and higher elemental quota; Figure 3). Thus, the increase in growth under future compared  
371 to ambient conditions was larger than what would be expected by the respective responses to  
372 warming and OA in isolation, indicating synergistic beneficial effects of both drivers.

373

#### 374 **4.3 Potential mechanism underlying the interaction between warming and OA**

375 The observed synergistic effects could be explained by their specific impacts on carbon  
376 acquisition and fixation. As outlined in the introduction, light and dark reaction of  
377 photosynthesis need to be balanced to achieve high biomass production while avoiding  
378 photodamage (Behrenfeld et al., 2008). According to our data, this balance is shifted towards  
379 higher biomass production rates under warming and OA.

380 At higher temperatures, seawater CO<sub>2</sub> concentrations were lower than under colder  
381 conditions (Table 1; Zeebe and Wolf-Gladrow, 2001). At the same time, warming from 2°C to  
382 6°C caused up to 60% higher growth and 110% higher biomass build-up rates (Figure 1, Table  
383 2). Furthermore, the decrease in  $\tau_{ES}$  indicates a faster transfer of photochemical energy into  
384 downstream processes such as RuBisCO activity (Table 3). Increased carbon demand in concert  
385 with lower carbon supply at higher temperatures thus increases the risk of CO<sub>2</sub> shortage in the  
386 cell, which in turn causes OA to have larger effects than at colder temperatures. Moreover,  
387 warming changes the kinetics of carbon fixation, with RuBisCO increasing its maximum  
388 turnover rates but decreasing its affinity for CO<sub>2</sub> (Young et al., 2014). At higher temperature,  
389 cells thus have the potential for higher carboxylation rates provided sufficient CO<sub>2</sub> is available  
390 (Kranz et al., 2015). Under elevated pCO<sub>2</sub> levels, diffusive CO<sub>2</sub> supply increases and/or costs  
391 for active carbon acquisition decrease. Consequently, the positive effect of increasing  
392 temperature on the carbon fixation rate can develop its full potential under OA.

393 In conclusion, elevated catabolic activity under warmer conditions can explain the  
394 observed upward shift in the CO<sub>2</sub>-optimum of growth with increasing temperature (Figure 1),  
395 as the corresponding higher carbon demand causes CO<sub>2</sub> fixation to saturate under higher pCO<sub>2</sub>  
396 levels. In combination with a faster and more efficient machinery for pH homeostasis at  
397 elevated temperatures (Morgan-Kiss et al., 2006), this could explain why declining growth rates

398 were only observed at relatively higher pCO<sub>2</sub> levels compared to those under low temperature  
399 conditions (Figure 2).

#### 400 **4.4 Implications for the current and future Arctic pelagic ecosystem**

401 Picoeukaryotes such as *M. pusilla* are considered to be potential winners of climate change:  
402 They are not only thriving in warmer, more stratified environments, which are predicted to  
403 further expand in the future, but also seem to benefit from OA (Li et al., 2009; Schulz et al.,  
404 2017). Our results for *M. pusilla* confirm beneficial effects of warming and OA on growth and  
405 biomass production under nutrient-replete conditions (Figure 1, Table 2). Hence, in warmer  
406 spring conditions of the future, this species may experience growth stimulation under OA,  
407 potentially increasing its importance early in the growing season. Currently, *M. pusilla* already  
408 dominates Arctic phytoplankton assemblages in the nutrient-limited summer and autumn  
409 situations, which were not investigated in this study. Regarding the importance of nutrient  
410 availability, laboratory experiments found beneficial OA effects on *M. pusilla* primary  
411 production to persist also under P limitation (Maat et al., 2014), while in a mesocosm  
412 community, OA-dependent increases in *M. pusilla* abundances disappeared when the system  
413 ran into P and N co-limitation (Engel et al., 2008). Thus, it remains to be seen how the combined  
414 effects of warming and OA manifest under low nutrient conditions as well as how the responses  
415 may depend on sources and types of nutrients (e.g. mixing-delivered nitrate vs. regenerated  
416 ammonium).

417 A species' success in the environment does not only depend on individual performance, but  
418 also on how it compares to that of competing species. When we compare our results with the  
419 responses of the Arctic diatom *Thalassiosira hyalina*, isolated from the same location and  
420 exposed to the same experimental conditions (Wolf et al., 2018), the diatom had higher growth  
421 rates than the picoeukaryote under most treatment conditions, as can be expected for nutrient-  
422 replete conditions (Sarhou et al., 2005). The relative increase in growth rates from ambient (2  
423 or 3°C and 380  $\mu\text{atm pCO}_2$ ) to future conditions (6°C and 1000  $\mu\text{atm pCO}_2$ ) was, however,  
424 much higher for *M. pusilla* than for *T. hyalina*. The fact that our experiments were conducted  
425 under nutrient-replete conditions, which typically favour diatoms over picoeukaryotes, may  
426 indicate an even stronger increase in fitness (Collins et al., 2014) and could mean that *M. pusilla*  
427 gains another competitive advantage over phytoplankton like diatoms in the future, in addition  
428 to those resulting from changes in stratification (Li et al., 2009). Thus, our findings suggest  
429 higher picoplankton contribution to future Arctic phytoplankton assemblages under non-  
430 limiting conditions, e.g. early in the growing season when picoeukaryotes can already  
431 contribute quite substantially to the phytoplankton standing stocks (Marquardt et al, 2017,  
432 Paulsen et al. 2015). How such competition between diatoms and picoeukaryotes would

433 manifest under nutrient-depleted conditions that strongly favour *M. pusilla* is currently  
434 unknown.

435 Even though picoeukaryotes seem to contribute more to the downward export of organic  
436 matter than previously assumed (Waite et al., 2000; Richardson and Jackson, 2007), in  
437 comparison to e.g. diatoms, they are less efficient vectors for carbon export to depth and have  
438 a lower energy transfer along trophic levels (Sherr et al., 2003). Consequently, Arctic food webs  
439 dominated by picoeukaryotes would look very different from those fuelled by diatom  
440 production (Sherr et al., 2003; Paulsen et al., 2015). Due to its motility and capability to grow  
441 mixotrophically, *M. pusilla* is characterized by an exceptionally high cellular C:N ratio  
442 compared to other Arctic phytoplankton (Table 2; Halsey et al., 2014; McKie-Krisberg and  
443 Sanders, 2014). An increased importance of this species would thus not only affect the food  
444 web due to its small size and concurrent grazer preferences, but also in terms of food quality  
445 (van de Waal and Boersma, 2012). The expected higher growth rates and thus abundances of  
446 this species may thus strengthen the Arctic microbial food web. Together with a concurrent  
447 weakening of the classical diatom-fuelled food web, this could have severe implications for the  
448 flow of energy and nutrients through future marine Arctic ecosystems (Post, 2016).

449

#### 450 **4.5 Conclusions**

451 This study is the first to show synergistic effects of warming and OA on *M. pusilla*, one of the  
452 most abundant species of the worlds' oceans. Individually, both warming and OA cause more  
453 efficient biomass build-up under nutrient-replete conditions. Beneficial effects manifest,  
454 however, even more strongly in combination, when facilitated carbon acquisition (e.g. due to  
455 higher diffusive CO<sub>2</sub> supply) co-occurs with higher fixation rates (e.g. due to higher turnover-  
456 rates of RuBisCO). Our results provide an explanation for the observations of previous  
457 mesocosm studies, which indicated beneficial effects of OA and warming on *M. pusilla* and  
458 other picoeukaryotes. Characterising the responses of this Arctic key species to warming and  
459 OA will help to develop mechanistic phytoplankton functional types and more realistic model  
460 representation of phytoplankton assemblages as well as their responses to multiple drivers.  
461 Future studies are needed to elucidate further multifactorial environmental changes, addressing  
462 both abiotic (e.g. changes in light and nutrients) as well as biotic (e.g. heterotrophy,  
463 competition, grazers, viruses) interactions.

464 **Author Contributions**

465 C.J.M.H. and B.R. designed the study. C.J.M.H. and C.F. conducted the experiment. C.J.M.H.  
466 analysed the data and prepared the manuscript with contributions from B.R. and C.F.

467

468 The authors declare that they have no conflict of interest.

469

470

471 **Acknowledgements**

472 We are grateful for field support by the 2014/15 station team of the AWIPEV base in Ny-  
473 Ålesund (Svalbard) as well as K. Wolf's help with strain isolation and maintenance of *M.*  
474 *pusilla* cultures. We thank U. John and N. Kühne for sequencing and help with the molecular  
475 strain identification. Furthermore, L. Wischniewski, A. Terbrüggen and M. Machnik are  
476 acknowledged for their help with sample analyses.

Figure 1: Specific growth rate constant  $\mu$  (A) and POC production (B) of *M. pusilla* under low (filled symbols) and high temperatures (open symbols) as a function of pCO<sub>2</sub> (n=3; mean  $\pm$ 1 s.d.). Results from statistical analysis can be found in Table SI2.

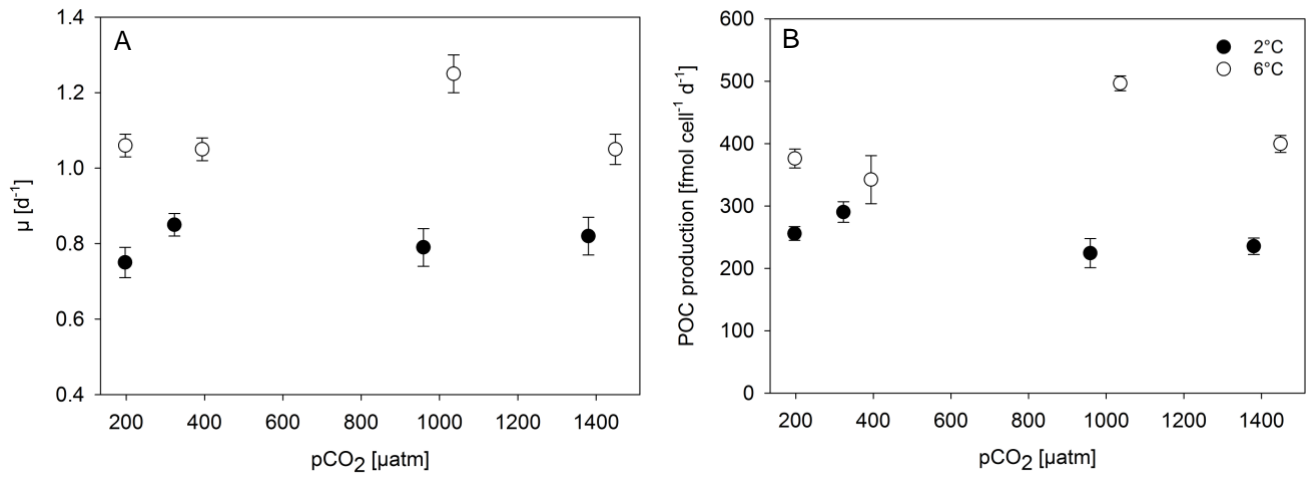

Figure 2: Cellular composition, i.e. POC (A), PON (B) and Chl *a* quota (C) as well as as C:Chl *a* ratios (D), of *M. pusilla* under low (filled symbols) and high temperatures (open symbols) as a function of pCO<sub>2</sub> (n=3; mean ±1 s.d.). Results from statistical analysis can be found in Table SI2.

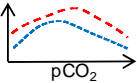

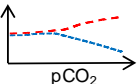

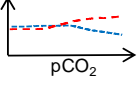

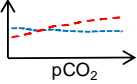

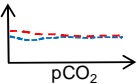

Figure 3: Schematic illustration of results for both temperatures over the entire range of pCO<sub>2</sub> levels as well as focusing on the responses between 380 and 1000 μatm (as the representation for commonly used OA treatments) and their modulation by temperature.

Parameter	Response curves	380 - 1000 μatm effect 2°C → 6°C
