20 **Abstract**

21 The disequilibrium between  $^{210}\text{Po}$  activity and  $^{210}\text{Pb}$  activity in seawater samples was  
22 determined along the GEOTRACES GA01 transect in the North Atlantic during the GEOVIDE  
23 cruise (May – June 2014). A steady-state model was used to quantify vertical export of  
24 particulate  $^{210}\text{Po}$ . Vertical advection was incorporated into one version of the model using time-  
25 averaged vertical velocity, which had substantial variance. This resulted in large uncertainties for  
26 the  $^{210}\text{Po}$  export flux in this model, suggesting that those calculations of  $^{210}\text{Po}$  export fluxes  
27 should be used with great care. Despite the large uncertainties, there is no question that the  
28 deficits of  $^{210}\text{Po}$  in the Iberian Basin and at the Greenland Shelf have been strongly affected by  
29 vertical advection. Using the export flux of  $^{210}\text{Po}$  and the particulate organic carbon (POC) to  
30  $^{210}\text{Po}$  ratio on total ( $> 1 \mu\text{m}$ ) particles, we determined the POC export fluxes along the transect.  
31 Both the magnitude and efficiency of the estimated POC export flux from the surface ocean  
32 varied spatially within our study region. Export fluxes of POC ranged from negligible to 10  
33  $\text{mmol C m}^{-2} \text{d}^{-1}$ , with enhanced POC export in the Labrador Sea. The cruise track was  
34 characterized by overall low POC export relative to net primary production (export efficiency  $<$   
35 1-15%); but relatively high export efficiencies were seen in the basins where diatoms dominated  
36 the phytoplankton community. The particularly low export efficiencies in the Iberian Basin, on  
37 the other hand, were explained by the dominance of smaller phytoplankton, such as  
38 cyanobacteria or coccolithophores. POC fluxes estimated from the  $^{210}\text{Po}/^{210}\text{Pb}$  and  $^{234}\text{Th}/^{238}\text{U}$   
39 disequilibria agreed within a factor of 3 along the transect, with higher POC estimates generally  
40 derived from  $^{234}\text{Th}$ . The differences were attributed to integration timescales and the history of  
41 bloom events.

42

## 43 1. Introduction

44 The oceans play an essential role in the regulation of atmospheric CO<sub>2</sub> and the buffering of the  
45 global climate system (e.g. Sabine, 2004) by removing carbon from the atmosphere via  
46 dissolution and photosynthesis in the surface ocean, and storing it in the dissolved or particulate  
47 forms. An important component of this oceanic sequestration is the biological carbon pump,  
48 driven by sinking particles from the surface to the deep ocean (e.g. Falkowski et al., 1998;  
49 Ducklow et al., 2001).

50 The magnitude of particulate organic carbon (POC) export flux from the upper ocean was  
51 traditionally obtained from time-series sediment traps (e.g. Honjo et al., 2008) and the natural  
52 radiotracer pair, <sup>234</sup>Th/<sup>238</sup>U (e.g. Bhat et al., 1968; Buesseler et al., 1992). Here we focus on the  
53 application of another natural radionuclide pair: polonium-210 (<sup>210</sup>Po,  $T_{1/2} = 138.4$  d) and its  
54 progenitor lead-210 (<sup>210</sup>Pb,  $T_{1/2} = 22.3$  y). The <sup>210</sup>Po/<sup>210</sup>Pb pair has a different particle-binding  
55 dynamic compared to the <sup>234</sup>Th/<sup>238</sup>U pair since both isotopes are particle-reactive, whereas <sup>238</sup>U  
56 is conservative and remains dissolved in seawater (Djogic et al., 1986). However, the nature of  
57 the particle association differs between the isotopes. Lead-210 and <sup>234</sup>Th are only adsorbed to  
58 particle surfaces, whereas <sup>210</sup>Po is both adsorbed to surfaces and biologically reactive so can be  
59 assimilated by organisms and even bioaccumulated (Fisher et al., 1983; Cherrier et al., 1995;  
60 Stewart and Fisher, 2003a; 2003b). This behavior leads to a higher partitioning coefficient  
61 (relative association between the isotope and the particulate vs. the dissolved phase) of <sup>210</sup>Po  
62 compared to that of <sup>210</sup>Pb (e.g. Masqué et al., 2002; Wei et al., 2014; Tang et al., 2017).

63 Lead-210 in the water column comes both from atmospheric deposition and in situ production  
64 via the decay of <sup>226</sup>Ra. The residence time of <sup>210</sup>Pb in the atmosphere is only days to weeks  
65 (Moore et al., 1974; Turekian et al., 1977). Polonium-210 (produced by decay of <sup>210</sup>Pb via <sup>210</sup>Bi)  
66 activities in aerosols, and the subsequent fluxes to the surface ocean, are only about 10 – 20%  
67 those of <sup>210</sup>Pb (Masqué et al., 2002). The large difference in their particle reactivity-and half-lives  
68 often leads to a disequilibrium between <sup>210</sup>Po and <sup>210</sup>Pb activities in the upper water column as  
69 particles sink.

70 This deviation from secular equilibrium, often in the form of a deficit of <sup>210</sup>Po activity with  
71 respect to <sup>210</sup>Pb activity, can be used to estimate POC export in a similar manner to the  
72 application of the <sup>234</sup>Th/<sup>238</sup>U disequilibrium (Friedrich and Rutgers van der Loeff, 2002; Verdeny  
73 et al., 2009; Wei et al., 2011). Particle export fluxes estimated from the <sup>234</sup>Th/<sup>238</sup>U and the

74  $^{210}\text{Po}/^{210}\text{Pb}$  disequilibria integrate export that has occurred on time scales of weeks to months  
75 prior to the sampling time, respectively. The use of both isotope pairs could provide  
76 complementary information on the causes, timing, and efficiency of export fluxes of POC (e.g.  
77 Murray et al., 2005; Stewart et al., 2007; Roca-Martí et al., 2016).

78 In this study along the GEOTRACES GA01 transect in the North Atlantic, we first used a  
79 traditional scavenging model with the assumptions of steady state and negligible physical  
80 transport to derive  $^{210}\text{Po}$  fluxes over different depths of the water column at 11 stations. Then,  
81 vertical advection (primarily upwelling) was considered, and its impact on  $^{210}\text{Po}$  flux was  
82 assessed. Using the POC concentration, and particulate  $^{210}\text{Po}$  activity in the particles collected by  
83 in situ pumps, sinking fluxes of POC were then calculated. The magnitude and efficiency of  
84 carbon export derived from the  $^{210}\text{Po}/^{210}\text{Pb}$  disequilibrium was considered in relation to the  
85 composition of the phytoplankton community. Finally, the POC export fluxes estimated from  
86  $^{210}\text{Po}/^{210}\text{Pb}$  disequilibria were compared with those derived from  $^{234}\text{Th}/^{238}\text{U}$  disequilibria.

87

## 88 **2. Methods**

### 89 **2.1. Cruise track and hydrographic setting**

90 The GEOVIDE cruise (GEOTRACES GA01 transect) was carried out in May - June 2014  
91 from Lisbon to Newfoundland (Fig. 1). Seawater and particulate samples for  $^{210}\text{Po}$  and  $^{210}\text{Pb}$   
92 activity analysis were collected from the water column at 11 stations (Fig. 1). The GA01 transect  
93 can be separated into five sections according to their biogeochemical characteristics, described in  
94 detail by Lemaitre et al., (2018). From east to west, these are: the Iberian Basin (stations 1, 13),  
95 the Western European Basin (stations 21, 26), the Iceland Basin (stations 32, 38), the Irminger  
96 Basin (stations 44, 60), and the Labrador Basin (stations 64, 69, 77).

97

### 98 **2.2. Radionuclides sampling and analysis**

99 Radionuclide data were produced by two collaborating laboratories to ensure higher counting  
100 statistics for  $^{210}\text{Po}$  activity in the samples: the Laboratori de Radioactivitat Ambiental at  
101 Universitat Autònoma de Barcelona (UAB) (samples from stations 1, 13, and 21) and the Stewart  
102 Laboratory at Queens College (QC) (samples from stations 26, 32, 38, 44, 60, 69, and 77). The  
103 sampling method for total and particulate  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  samples and the determination of the  
104 radionuclides activities were described in Tang et al., (2018). In brief, water samples (5 – 10 L

105 each) for total  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  activity were collected using Niskin bottles at 10 full water  
106 column stations (16 – 22 depths/station) and at 1 station to 1000 m (9 depths), for a total of 200  
107 samples. Particulate  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  were collected at 3 – 10 depths per station between 15 and  
108 800 m by using McLane *in-situ* pumps equipped with a 53  $\mu\text{m}$  PETEX screen to capture the  
109 large size particles and a 1  $\mu\text{m}$  quartz fiber QMA filter to capture small particles. The average  
110 equivalent volume filtered for particulate  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  samples through the PETEX screen  
111 was 200 L and through the QMA filter was 70 L.

112 For water samples, Po and Pb isotopes (including the added chemical yield tracers of  $^{209}\text{Po}$   
113 and stable lead) were co-precipitated with cobalt-ammonium pyrrolidine dithiocarbamate (Co-  
114 APDC) (Fleer and Bacon, 1984) at sea, but digested using concentrated HCl and  $\text{HNO}_3$  back at  
115 the home laboratories. Particulate samples were spiked with  $^{209}\text{Po}$  and stable lead before acid  
116 digestions (UAB:  $\text{HNO}_3/\text{HCl}/\text{HF}$ , QC:  $\text{HNO}_3/\text{HCl}$ ). Polonium isotopes ( $^{209}\text{Po}$  and  $^{210}\text{Po}$ ) were  
117 plated by deposition onto a silver disc (Flynn, 1968) and their activities were determined by  
118 alpha spectrometry. After removing any remaining Po isotopes by running the plating solution  
119 through an anion exchange column, the solution was respiked with  $^{209}\text{Po}$  and stored for at least 6  
120 months. Lead-210 activity was determined by plating the ingrowth of  $^{210}\text{Po}$  from  $^{210}\text{Pb}$ .

121 The activities of  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  at the sampling date were determined by correcting for  
122 nuclide decay, ingrowth, chemical recoveries, detector backgrounds, and blank contamination  
123 (Rigaud et al., 2013).

124

### 125 **2.3. The $^{210}\text{Po}$ flux method**

126 The export flux of  $^{210}\text{Po}$  was estimated from total  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  activities using a one-box  
127 model (Broecker et al., 1973; Matsumoto, 1975; Savoye et al., 2006). The  $^{210}\text{Po}$  activity in the  
128 surface ocean is the result of a balance between atmospheric input, continuous production from  
129 the decay of  $^{210}\text{Pb}$  in seawater, radioactive decay of  $^{210}\text{Po}$ , removal onto sinking particles, and  
130 transport into or out of the box by advection and diffusion. Therefore, the general form of the  
131 mass balance equation for  $^{210}\text{Po}$  between sources and sinks is:

132

$$133 \quad \partial P_o / \partial t = F_{P_o} + \lambda_{P_o} I_{P_b} - \lambda_{P_o} I_{P_o} - P + V, \quad \text{Eq. (1)}$$

134

135 where  $\partial P_{Po}/\partial t$  is the change in  $^{210}\text{Po}$  activity with time,  $F_{Po}$  ( $\text{dpm m}^{-2} \text{d}^{-1}$ ) is the atmospheric flux  
136 of  $^{210}\text{Po}$  to the sea surface,  $\lambda_{Po}$  is the decay constant of  $^{210}\text{Po}$  ( $0.005 \text{d}^{-1}$ ),  $I_{Pb}$  and  $I_{Po}$  ( $\text{dpm m}^{-2}$ )  
137 are the inventories of  $^{210}\text{Pb}$  and  $^{210}\text{Po}$  activities, respectively,  $P$  ( $\text{dpm m}^{-2} \text{d}^{-1}$ ) is the removal flux  
138 of  $^{210}\text{Po}$  via sinking particles, and  $V$  ( $\text{dpm m}^{-2} \text{d}^{-1}$ ) is the sum of the advective and diffusive  
139 fluxes.

140 The atmospheric flux of  $^{210}\text{Po}$  is usually ignored as it represents only  $\sim 2\%$  of the in-situ  
141 production of  $^{210}\text{Po}$  from  $^{210}\text{Pb}$  in the upper water column of the open ocean (e.g. Cochran, 1992;  
142 Masqué et al., 2002; Murray et al., 2005; Verdeny et al., 2008). We first used a steady state (SS)  
143 model that assumes the negligible atmospheric input of  $^{210}\text{Po}$  activity and ignores advection and  
144 diffusion. In this case, the  $^{210}\text{Po}$  flux ( $P$ ) can be simplified as follows:

145

$$146 \quad P = \lambda_{Po}(I_{Pb} - I_{Po}). \quad \text{Eq. (2)}$$

147

148 The influences of advection and non-steady state (NSS) processes on the overall  $^{210}\text{Po}$  activity  
149 balance are discussed below in sections 4.1 and 4.2, respectively.

150 Many previous studies have used a single fixed integration depth for export calculations at all  
151 sampling locations (e.g. 100 m in the Antarctic Circumpolar Current, Rutgers van der Loeff et al.,  
152 1997; 120 m in the central Equatorial Pacific, Murray et al., 2005). The GA01 transect, however,  
153 crossed diverse physical and biogeochemical conditions. Thus, investigating export at a single  
154 fixed depth for every station may bias the spatial comparisons of particle export. In this study,  
155 four site-specific integration depths were used for each station: the mixed layer depth (MLD), the  
156 depth of the euphotic zone ( $Z_{1\%}$ ), the primary production zone (PPZ), and the  $^{234}\text{Th}$ - $^{238}\text{U}$   
157 equilibrium depth (ThEq). MLD was defined as a change in potential density of  $0.03 \text{kg m}^{-3}$   
158 relative to the potential density at 10 m (Weller and Plueddemann, 1996).  $Z_{1\%}$  was defined as the  
159 depth where photosynthetic available radiation was 1% of its surface value (Jerlov, 1968). PPZ  
160 was the depth at which the fluorescence reaches 10% of its maximum (Owens et al., 2015). ThEq  
161 was the depth at the bottom of the total  $^{234}\text{Th}$  water column deficit, where the activity of  $^{234}\text{Th}$   
162 equals that of  $^{238}\text{U}$  (data from Lemaitre et al., 2018). These depths were used both to calculate  
163  $^{210}\text{Po}$  and POC export and in order to compare the POC export fluxes estimated from the  
164  $^{210}\text{Po}/^{210}\text{Pb}$  disequilibria to those derived from the  $^{234}\text{Th}/^{238}\text{U}$  disequilibria. Among the 11  
165 stations, the depths of the MLD ( $23 \pm 7 \text{m}$ ) were similar to those at  $Z_{1\%}$  ( $31 \pm 9 \text{m}$ ), whereas the

166 depths of the PPZ ( $72 \pm 29$  m) and ThEq ( $95 \pm 43$  m) were deeper and comparable to each other.  
167 For the depths of MLD,  $Z_{1\%}$ , PPZ, and ThEq at which total radionuclides data are not available,  
168 the measured values of total  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  activities were linearly interpolated (Table 1).

169 The  $^{210}\text{Po}$  flux was then used to derive the flux of POC by multiplying the deficit of  $^{210}\text{Po}$  by  
170 the ratio of POC concentration to  $^{210}\text{Po}$  activity ( $\text{POC}/^{210}\text{Po}$ ) of the total particulate material.  
171 Particulate  $^{210}\text{Po}$  and POC data were not always available at the depths of the MLD,  $Z_{1\%}$ , PPZ,  
172 and ThEq at our study sites. To estimate  $\text{POC}/^{210}\text{Po}$  ratios at these depths, a regression was  
173 performed between the measured  $\text{POC}/^{210}\text{Po}$  ratios and depth for each basin using a single power  
174 law function.

175

#### 176 **2.4. Quantification of the influence of the vertical advection on $^{210}\text{Po}$ export**

177 Cyclonic/anticyclonic eddies constantly impact the horizontal velocity fields at our study  
178 sites (Zunino et al., 2018), changing the current directions and making it difficult to estimate the  
179 magnitude of horizontal velocities. This constant variability, together with the patchiness of  
180 sampling resolution, meant we could not assess the influence of horizontal advective processes  
181 on  $^{210}\text{Po}$  export estimates.

182 However, because we had relatively high depth resolution at each station, we did attempt to  
183 assess the influences of vertical advection on  $^{210}\text{Po}$  inventories at all the investigated depths by  
184 measuring the vertical gradient of  $^{210}\text{Po}$  activity and multiplying it by a time-averaged vertical  
185 velocity. Because the water column inventory of  $^{210}\text{Po}$  represents an integration of the changes  
186 over approximately the mean life of the isotope, we did not use the vertical velocity measured by  
187 the acoustic doppler current profiler (ADCP) at the sampling time, but a time-averaged vertical  
188 velocity from the Estimating the Circulation and Climate of the Ocean, Phase II (ECCO2). The  
189 activity gradient of  $^{210}\text{Po}$  below the depth  $z$  (i.e., the MLD,  $z_{1\%}$ , PPZ, and ThEq) at each station  
190 was calculated from the depth  $z$  (using the average activity in the layer of  $0$ - $z$  m) as starting point  
191 ( $A_{Po}^1$ ) and linearly interpolated through the measurements  $20$  m below  $z$  ( $A_{Po}^2$ ) at each station. A  
192 positive gradient ( $A_{Po}^2 - A_{Po}^1 > 0$ ) was defined as higher activity at the depth of ( $z + 20$  m) than  
193 the starting point. We labeled the vertical velocity as  $w_{20}$  which was the 30-day (30 days prior to  
194 the sampling date) average vertical velocity between the depths of  $z$  and ( $z + 20$  m). The flux of  
195  $^{210}\text{Po}$  due to vertical advection ( $F_w$ ) was calculated as the following:

196

197  $F_w = w_{20} \times (A_{Po}^2 - A_{Po}^1)$ . Eq. (3)

198

199 Total  $^{210}\text{Po}$  fluxes at each depth, therefore, are the sum of the steady state values based only on  
200 the  $^{210}\text{Po}$  deficit (Eq. 2),  $\lambda_{Po}(I_{Pb} - I_{Po})$ , and vertical advective flux (Eq. 3),  $w_{20} \times (A_{Po}^2 - A_{Po}^1)$ .

201 The ECCO2 vertical velocities were obtained from the Asia-Pacific Data-Research Center  
202 (APDRC, <http://apdrc.soest.hawaii.edu/las/v6/dataset?catitem=1>). The ECCO2 model  
203 configuration uses a cube-sphere grid projection with 18-km horizontal grid spacing and 50  
204 vertical levels among which there are 12 equal vertical layers from the surface to 120 m  
205 (Menemenlis et al., 2008). We selected the ECCO2 grid points closest to the station and  
206 extracted vertical velocities from the depths between  $z$  and  $(z + 20 \text{ m})$  during 30 days prior to the  
207 sampling date at each station. Because the deficit of  $^{210}\text{Po}$  activity in the water column weighs  
208 the changes that occurred shortly prior to the sampling time more heavily than those that  
209 occurred further back in time (Verdeny et al., 2009), we chose to average the vertical velocity  
210 over one month rather than over the mean life of  $^{210}\text{Po}$  (200 days). The 30-day averaged vertical  
211 velocity was then used to calculate vertical advective  $^{210}\text{Po}$  export flux via Eq. (3) at each station.

212

## 213 **2.5. Satellite-based net primary production and phytoplankton composition**

214 The 8-day net primary production (NPP) data with a spatial resolution of  $0.083^\circ$  by  $0.083^\circ$   
215 were obtained from the Oregon State University Ocean Productivity standard products  
216 (<http://www.science.oregonstate.edu/ocean.productivity/>), wherein NPP was estimated by the  
217 Vertically Generalized Production Model (VGPM) (Behrenfeld and Falkowski, 1997). Due to  
218 some missing data between November 2013 and February 2014, NPP for each station was  
219 averaged for the previous 138 days ( $^{210}\text{Po}$  half-life) instead of 200 days ( $^{210}\text{Po}$  mean life).

220 Monthly average concentrations of diatoms, coccolithophores, cyanobacteria, chlorophytes,  
221 and total chlorophyll with the spatial resolution of  $0.67 \times 1.25^\circ$  were obtained from the Goddard  
222 Earth Science Data and Information Services Center Interactive Online Visualization and  
223 Analysis Infrastructure (“Giovanni”) (<https://giovanni.gsfc.nasa.gov/giovanni/>, Acker and  
224 Leptoukh, 2007). Time-series (October 2013 – July 2014, covering  $> 200$  days before sampling)  
225 data are averages over longitude for each month. We extracted data for the 5 basins individually  
226 and calculated the fraction of each phytoplankton group at each station as the ratio of their  
227 concentration to total chlorophyll concentration.

228

### 229 **3. Results**

#### 230 **3.1. Satellite-derived seasonal NPP and phytoplankton composition**

231 The VGPM modeled NPP data along the GA01 transect was averaged over  $\sim 138$  days prior  
232 to the sampling date (see section 2.5, Table 1). Seasonal NPP at each station varied from low  
233 values of  $44 - 79 \text{ mmol C m}^{-2} \text{ d}^{-1}$  to a maximum value of  $109 \text{ mmol C m}^{-2} \text{ d}^{-1}$  at station 21. The  
234 Western European Basin had the highest seasonal NPP, followed by the Iberian Basin; while the  
235 Iceland Basin, the Irminger Basin, and the Labrador Basin all had similar NPP values in the  
236 range of  $45 - 49 \text{ mmol C m}^{-2} \text{ d}^{-1}$ . There was a shift in the biological community towards larger  
237 phytoplankton (e.g. diatoms) from east to west along the transect (Fig. 2). The basins where  
238 diatoms were the dominant phytoplankton group did not necessarily have higher seasonal  
239 production relative to the basins where smaller phytoplankton (e.g. coccolithophores) were more  
240 abundant. Indeed, the Iberian Basin had the second highest seasonal NPP, despite the fact that  
241 the majority of chlorophyll was produced by coccolithophores. Despite the evidence that earlier  
242 blooms may have been driven by diatoms (see section 4.2), these observations highlight the  
243 possible contribution of small particles to production, and possibly to export (proportional to  
244 their role in production according to Richardson and Jackson, 2007) along the transect. Moreover,  
245 this could be also due to shorter blooms in the Irminger and Labrador Basins where the  
246 phytoplankton growth was light-limited during winter compared to the conditions in the Iberian  
247 and Western European Basins.

248 The satellite-derived phytoplankton species composition demonstrated unique features within  
249 the basins (Fig. 2). The Iberian Basin was dominated ( $> 60\%$ ) by coccolithophores between  
250 October 2013 – July 2014, but had a gradual increase in the contribution of diatoms until April  
251 2014 and a decreasing contribution after that. In the Western European Basin, station 26 was  
252 dominated by diatoms all year around while station 21 was dominated by diatoms except in  
253 October 2013 and July 2014 when the combination of chlorophytes and coccolithophores  
254 contributed  $35 - 77\%$  to the total chlorophyll concentration. The stations in the Iceland,  
255 Irminger, and Labrador Basins were all dominated ( $> 98\%$ ) by diatoms between October 2013  
256 and July 2014.

257

#### 258 **3.2. One-month averaged vertical velocity $w_{20}$**

259 The one-month averaged vertical velocities  $w_{20}$  ranged from  $-36 \times 10^{-6}$  to  $9 \times 10^{-6}$  m s<sup>-1</sup>  
260 along the transect (negative: upwelling, positive: downwelling, Table 1). The standard deviations  
261 of  $w_{20}$  were generally of the same order as the values of  $w_{20}$ . Particularly large standard  
262 deviations, which exceed the typical values of the vertical velocity by a full order of magnitude,  
263 were found at stations 13 (35-55 m, 110-130 m) and station 21 (110-130 m). These high standard  
264 deviations suggest that the data of  $w_{20}$  should be used with great care. Downwelling was seen at  
265 stations 38, 44, 64, and 77 with the velocities in the range of 1 to  $9 \times 10^{-6}$  m s<sup>-1</sup>. Upwelling was  
266 seen at the remaining stations, with highest intensity at station 60 near Greenland (absolute value:  
267  $11 - 36 \times 10^{-6}$  m s<sup>-1</sup>). The upwelling velocities were roughly equivalent at stations 1, 13, 21, 26,  
268 32, and 69 (absolute value:  $1 - 5 \times 10^{-6}$  m s<sup>-1</sup>).

269

### 270 **3.3. Total <sup>210</sup>Po deficits**

271 The vertical profiles of total <sup>210</sup>Po and <sup>210</sup>Pb activity at each station have been described in a  
272 companion article (Tang et al., 2018). Here we show the section view of the water column <sup>210</sup>Po  
273 deficit (dpm 100 L<sup>-1</sup>), which was calculated as total <sup>210</sup>Pb activity minus total <sup>210</sup>Po activity (Fig.  
274 3). There were small <sup>210</sup>Po deficits in the upper 100 m (including the majority of the depths of  
275 MLD, Z<sub>1%</sub>, PPZ, and ThEq at all stations) at stations 1, 13, and 21, whereas a relatively large  
276 excess of <sup>210</sup>Po was observed at 100 – 400 m depth. Station 60 had the highest deficits of <sup>210</sup>Po (~  
277 8 dpm 100 L<sup>-1</sup>, n = 5) at 40 – 120 m depth. A large surface deficit of <sup>210</sup>Po was found at station  
278 64 (8 dpm 100 L<sup>-1</sup>) and a surface excess was found at station 38 (-3.5 dpm 100 L<sup>-1</sup>). There were  
279 positive <sup>210</sup>Po deficits throughout most of the water column at stations in the Irminger and  
280 Labrador Basins, whereas large <sup>210</sup>Po excesses (negative deficits) below 100 m were generally  
281 seen in the Iberian Basin and Western European Basins. Such <sup>210</sup>Po excess was likely related to  
282 the Iberian upwelling, which may have provided a source of <sup>210</sup>Po activity.

283

### 284 **3.4. The <sup>210</sup>Po flux calculated from the deficit of <sup>210</sup>Po alone**

285 Using the data of total <sup>210</sup>Po and <sup>210</sup>Pb activities, the amount of <sup>210</sup>Po escaping from the  
286 surface ocean via particles (“<sup>210</sup>Po fluxes”, dpm m<sup>-2</sup> d<sup>-1</sup>) was calculated using Eq. (2) assuming  
287 steady state and ignoring advection and diffusion (Table 2, <sup>210</sup>Po/<sup>210</sup>Pb term). The <sup>210</sup>Po fluxes  
288 were negligible or very low at stations 1, 21, and 38. At the other stations the <sup>210</sup>Po fluxes  
289 averaged  $3.7 \pm 1.4$ ,  $4.6 \pm 2.6$ ,  $9.5 \pm 4.9$ , and  $14.4 \pm 12$  dpm m<sup>-2</sup> d<sup>-1</sup> at the MLD, Z<sub>1%</sub>, PPZ, and

290 ThEq, respectively. The  $^{210}\text{Po}$  fluxes tended to increase with depth at seven out of eleven stations  
291 (26, 38, 44, 60, 64, 69, and 77). At the MLD,  $Z_{1\%}$  and PPZ, the largest  $^{210}\text{Po}$  fluxes were all  
292 found in the Labrador Basin. The other 4 basins had relatively similar  $^{210}\text{Po}$  export fluxes (2.1 –  
293 2.8  $\text{dpm m}^{-2} \text{d}^{-1}$ ) at the MLD and  $Z_{1\%}$ . The West European Basin had much higher  $^{210}\text{Po}$  flux (8.7  
294  $\text{dpm m}^{-2} \text{d}^{-1}$ ) relative to that in the Iberian Basin ( $-0.1 \text{ dpm m}^{-2} \text{d}^{-1}$ ) at the PPZ. At the ThEq, on  
295 the other hand, the Irminger Sea had the highest  $^{210}\text{Po}$  fluxes followed by the West European  
296 Basin. The lowest  $^{210}\text{Po}$  fluxes at all investigated depths were generally found in the Iberian  
297 Basin.

298

### 299 **3.5. POC/ $^{210}\text{Po}$ ratios in particles**

300 Most of the ratios of POC concentration to  $^{210}\text{Po}$  activity ( $\mu\text{mol dpm}^{-1}$ ) in the large size  
301 fraction of particles (POC/ $^{210}\text{Po}$ \_LSF,  $> 53 \mu\text{m}$ ) were comparable to or higher than those in the  
302 small size fraction (POC/ $^{210}\text{Po}$ \_SSF,  $1 - 53 \mu\text{m}$ ), although a few samples at stations 13, 26, 44,  
303 64, and 77 had lower values of POC/ $^{210}\text{Po}$ \_LSF than those of POC/ $^{210}\text{Po}$ \_SSF (Table 3, Fig. 4a).  
304 The POC/ $^{210}\text{Po}$  ratio in the total particles ( $> 1 \mu\text{m}$ , the combination of small and large particles,  
305 POC/ $^{210}\text{Po}$ \_TPF) was similar to that in the small particles (SSF), within about 97% (Table 3, Fig.  
306 4b). This is because over 80% of the particulate  $^{210}\text{Po}$  activity was associated with the small size  
307 fraction (Tang et al., 2018) likely due to the large surface area of abundant small particles.  
308 Because of the possible link between small particles and export along the transect discussed in  
309 section 3.1, and the results that scavenging of  $^{210}\text{Po}$  was governed by the small particles (Tang et  
310 al., 2018), we propose to use this total particulate fraction in addition to the more commonly  
311 used large size fraction to calculate POC export along this cruise track.

312 The POC/ $^{210}\text{Po}$  in total particles (POC/ $^{210}\text{Po}$ \_TPF) varied from 19 to 1300  $\mu\text{mol dpm}^{-1}$  with a  
313 mean of  $290 \pm 320 \mu\text{mol dpm}^{-1}$  ( $n = 51$ , upper 800 m). The variability of POC/ $^{210}\text{Po}$ \_TPF ratios  
314 in this study is in line with previous observations in the Antarctic Circumpolar Current (300 -  
315 1200  $\mu\text{mol dpm}^{-1}$  for particles  $> 1 \mu\text{m}$ ) (Friedrich and Rutgers van der Loeff, 2002), and the  
316 central Arctic (90 - 1900  $\mu\text{mol dpm}^{-1}$  for particles  $> 53 \mu\text{m}$ ) (Roca-Martí et al., 2016). The  
317 average ratio of 290  $\mu\text{mol dpm}^{-1}$  is comparable to those observed in the central Equatorial Pacific  
318 ( $202 \pm 90 \mu\text{mol dpm}^{-1}$  for particles  $> 0.45 \mu\text{m}$ ) (Murray et al., 2005), the North Atlantic ( $290 \pm$   
319  $70 \mu\text{mol dpm}^{-1}$  for particles  $> 1 \mu\text{m}$ ) (Rigaud et al., 2015), and the South Atlantic ( $113 \pm 80$   
320  $\mu\text{mol dpm}^{-1}$  for particles  $> 0.7 \mu\text{m}$ ) (Sarin et al., 1999).

321 The measured POC/<sup>210</sup>Po ratios in total particles at each station and depth were grouped into  
322 the 5 basins and fitted against depth using a single power law function in each basin (Fig. 5). The  
323 fit equations were used to calculate total particulate POC/<sup>210</sup>Po ratios at the investigated depths at  
324 each station (Table 3).

325

## 326 **4. Discussion**

### 327 **4.1. Physical advection effects on <sup>210</sup>Po export fluxes**

328 In the study region, there were consistent patterns of circulation traveling through and near  
329 our sampling sites during the GEOVIDE cruise. From east to west the cruise track crossed the  
330 North Atlantic Current, the Eastern Reykjanes Ridge Current, the Irminger Current, the Irminger  
331 Gyre, the Western and Eastern Boundary Currents and the Labrador Current (Fig. 1 in García-  
332 Ibáñez et al., 2018). Additionally, short-lived eddies and fronts were also observed during the  
333 cruise, particularly in the OVIDE section from Portugal to Greenland (García-Ibáñez et al., 2018;  
334 Zunino et al., 2018). In this dynamic region advective influences may be important to include in  
335 calculations of <sup>210</sup>Po export. Despite this knowledge, we could not include horizontal advection  
336 in our model because the horizontal resolution of our sample sites was not sufficient to constrain  
337 reliable horizontal gradients of <sup>210</sup>Po activity in the study region. This assumption of negligible  
338 horizontal physical transport has been made in most <sup>210</sup>Po studies because of a similar lack of  
339 spatial resolution (e.g. Kim and Church, 2001; Stewart et al., 2010; Rigaud et al., 2015), and may  
340 be justified in some open ocean settings where horizontal gradients in <sup>210</sup>Po activities are small  
341 (e.g. Wei et al., 2011). For more dynamic regimes such as along the GA01 transect, however,  
342 this assumption needs to be carefully evaluated, and the relative importance of advective <sup>210</sup>Po  
343 flux should be assessed if possible.

344 We did, however, have enough sampling depths at each station to assess the vertical  
345 variability in <sup>210</sup>Po activity and to estimate the impact of vertical advection on the <sup>210</sup>Po flux. The  
346 range of <sup>210</sup>Po activity flux due to vertical advection (-40 to 14 dpm m<sup>-2</sup> d<sup>-1</sup>, Table 2) was of the  
347 same magnitude as the steady state fluxes calculated from the deficit alone (-5 to 37 dpm m<sup>-2</sup> d<sup>-1</sup>,  
348 Table 2). The magnitude of the uncertainty of the <sup>210</sup>Po export flux due to vertical advection was  
349 influenced by the large variance in vertical velocity field mentioned in Sect. 3.2. When excluding  
350 the three depths at stations 13 and 21 where the monthly vertical velocity average had substantial  
351 standard deviations (an order of magnitude greater than  $w_{20}$ ), the uncertainty of the <sup>210</sup>Po export

352 flux was on average 2-fold larger than the calculated  $^{210}\text{Po}$  export flux. The largest positive  
353 vertical advective  $^{210}\text{Po}$  fluxes were at station 1 where the Iberian upwelling increased the  
354 calculated flux by 150 - 500%. The largest negative vertical advective  $^{210}\text{Po}$  fluxes were seen at  
355 station 60 where upwelling decreased the  $^{210}\text{Po}$  flux by 370 – 1100% at the depths of the MLD,  
356  $Z_{1\%}$ , and PPZ. This is because the upwelling velocity was high at those depths ( $14 - 36 \times 10^{-6} \text{ m}$   
357  $\text{s}^{-1}$ , Table 1) and the water upwelled was depleted in  $^{210}\text{Po}$  activity. The vertical advective  
358 transport was smaller at the MLD and  $Z_{1\%}$  at station 13, at the ThEq at station 21, and at the PPZ  
359 and ThEq at station 64, with contributions lower than 6% of the total  $^{210}\text{Po}$  fluxes. Including  
360 vertical advection in our flux estimates at all other depths, however, increased/decreased the  
361  $^{210}\text{Po}$  fluxes by 10 – 180%. Like with vertical advection, neglecting horizontal advection can  
362 result in either an underestimate or overestimate of  $^{210}\text{Po}$  export flux depending on whether the  
363 advected water is enriched or depleted in  $^{210}\text{Po}$ . However, because our study region was  
364 characterized by distinct water masses separated over 10s to 100s of meter in the vertical plane,  
365 whereas those same water masses covered huge distances (100s to 1000s of kilometer) in the  
366 horizontal plane (Fig. 4 in García-Ibáñez et al., 2018), vertical advection would most likely result  
367 in more change in physical and chemical parameters over the scale of sampling than horizontal  
368 advection would. Because the advective  $^{210}\text{Po}$  export flux was calculated as the product of the  
369 velocity of the water mass and the gradient of  $^{210}\text{Po}$  activity in the corresponding direction,  
370 horizontal advection would most likely contribute a much smaller range of advective  $^{210}\text{Po}$  flux  
371 estimates.

372 Overall, the influence of physical advection on  $^{210}\text{Po}$  activity may range from relatively  
373 unimportant to dominant depending on study area. In this study, we observed physical processes  
374 influencing  $^{210}\text{Po}$  fluxes, in particular at stations 1 and 60. For future studies of  $^{210}\text{Po}$  and  $^{210}\text{Pb}$   
375 activity in regions of established upwelling or ocean margins, we suggest designing the sampling  
376 plan so that the magnitude and variability of these processes may be incorporated into  $^{210}\text{Po}$   
377 export models. At ocean margins, in particular, more water samples should be taken to improve  
378 the resolution of horizontal features.

379

#### 380 **4.2. Non-steady state effects on $^{210}\text{Po}$ export fluxes**

381 To our knowledge, three time-series studies of  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  activities have been conducted  
382 to date and have assessed the NSS effects on  $^{210}\text{Po}$  fluxes. First, in the upper 500 m of the

383 Sargasso Sea, Kim and Church, (2001) found that the SS model may have overestimated and  
384 underestimated the  $^{210}\text{Po}$  export fluxes in May and July 1997, respectively. Second, at the  
385 DYFAMED site of the northwestern Mediterranean Sea, the  $\partial Po/\partial t$  term accounted for  $\sim 50\%$   
386 of  $^{210}\text{Po}$  flux estimated by using the SS model (Stewart et al., 2007). Last, in the South China Sea,  
387 the  $^{210}\text{Po}$  export fluxes at 1000 m calculated from the SS and NSS models had similar values  
388 within the uncertainties (Wei et al., 2014). In fact, the SS model generally results in an  
389 underestimation of the  $^{210}\text{Po}$  flux under conditions of decreasing  $^{210}\text{Po}$  activities in the water  
390 column (i.e. when blooms switch from the productive phase to the export phase) whereas the SS  
391 model overestimates the flux for conditions of increasing  $^{210}\text{Po}$  activities (i.e. high atmospheric  
392 deposition).

393 Atmospheric aerosol deposition along the GA01 transect was reportedly low, without  
394 significant influence of the Saharan plume (Shelley et al., 2017). The influence of atmospheric  
395 deposition on the SS estimates obtained in this study, therefore, can be ignored. However, it is  
396 important to assess the  $\partial Po/\partial t$  term that was associated with the site-specific bloom events  
397 during the cruise. Satellite estimates of net primary production (VGPM model) for the eight 8-  
398 day periods prior to the sampling date ( $\sim 2$  months) were calculated at each station (Fig. 6). Two  
399 months' NPP data is needed because such a time scale could ensure the sensitivity for NSS  
400 estimates (Friedrich and Rutgers van der Loeff, 2002; Stewart et al., 2007). NPP for the two-  
401 month period were in the ranges of 51 – 184, 39 – 403, 22 – 131, 18 – 204, 16 – 210  $\text{mmol C m}^{-2}$   
402  $\text{d}^{-1}$  in the Iberian Basin, the West European Basin, the Iceland Basin, the Irminger Basin, and the  
403 Labrador Basin, respectively, indicating the occurrence of blooms during this time period along  
404 the transect that might have influenced the  $^{210}\text{Po}$  fluxes derived from Eq. (1).

405 Assuming SS may have underestimated the  $^{210}\text{Po}$  export along the GA01 transect depending  
406 on the stage of the bloom before sampling. For example, at station 21 the largest NPP peak (403  
407  $\text{mmol C m}^{-2} \text{d}^{-1}$ ) occurred 2 weeks before our sampling date and diminished rapidly ( $\sim 100 \text{mmol}$   
408  $\text{C m}^{-2} \text{d}^{-1}$  at sampling time). The combination of high phytoplankton export and sudden decrease  
409 in NPP may have significantly lowered the  $^{210}\text{Po}$  activity in the upper waters, resulting in a  
410 negative  $\partial Po/\partial t$ , and thus the SS model may have underestimated the true  $^{210}\text{Po}$  flux. Temporal  
411 variations were also seen in the time-series phytoplankton community composition, in particular  
412 at stations 1 and 13 (Fig. 2). Both stations were dominated ( $> 60\%$ ) by coccolithophores between  
413 October 2013 – July 2014, but appeared to have a diatom bloom in April 2014 before sampling.

414 Polonium-210 and  $^{210}\text{Pb}$  tend to bind to specific biopolymeric functional groups, leading to  
415 fractionation during their sorption onto particles (Quigley et al., 2002; Chuang et al., 2013; Yang  
416 et al., 2013). The temporal variation of phytoplankton composition could therefore also lead to  
417 non-steady state effects on the overall  $^{210}\text{Po}$  activity balance, which are difficult to assess but  
418 deserve more attention.

419 The NSS effect on the  $^{234}\text{Th}$  fluxes at the ThEq were evaluated during the same cruise along  
420 the GA01 transect in Lemaitre et al., (2018) by using the NSS model developed in Savoye et al.,  
421 (2006). Because the cruise plan did not allow an opportunity to reoccupy the study areas over  
422 time, the authors made the assumption that  $^{234}\text{Th}$  activity was in equilibrium with  $^{238}\text{U}$  activity at  
423 the starting date of the bloom. Their results suggested that the NSS  $^{234}\text{Th}$  fluxes were about 1.1  
424 to 1.3 times higher than the SS estimates in the Iberian and West European Basins, and 1.4 to 2.1  
425 times higher in the Iceland, Irminger, and the Labrador Basins. We did not attempt to apply the  
426 same technique to estimate NSS  $^{210}\text{Po}$  fluxes in this study because the assumption of equilibrium  
427 between  $^{210}\text{Po}$  activity and  $^{210}\text{Pb}$  activity at the starting date of the bloom may be inappropriate  
428 and the  $^{210}\text{Po}$  deficit integrates over a longer time period (months) than a typical bloom event  
429 (days/weeks).

430

### 431 **4.3. POC flux calculated from $^{210}\text{Po}$ flux**

432 The POC export fluxes were calculated by multiplying both the  $^{210}\text{Po}$  export fluxes  
433 calculated from the deficit alone (SS without advection) and the total  $^{210}\text{Po}$  fluxes (sum of the  
434 fluxes calculated from the  $^{210}\text{Po}$  deficit and vertical advection) by the total particulate ( $> 1 \mu\text{m}$ )  
435 POC/ $^{210}\text{Po}$  ratios at the corresponding depths (Table 2, Fig. 7). The POC fluxes calculated from  
436 only the deficit term and the total term ranged from negligible to  $7 \text{ mmol C m}^{-2} \text{ d}^{-1}$  and from  
437 negative to  $10 \text{ mmol C m}^{-2} \text{ d}^{-1}$ , respectively. This is in good agreement with the SS fluxes  
438 derived via the  $^{210}\text{Po}/^{210}\text{Pb}$  method ignoring advection in other regions of the world ocean  
439 (negligible to  $8.5 \text{ mmol C m}^{-2} \text{ d}^{-1}$ ) (e.g. Shimmiel et al., 1995; Sarin et al., 1999; Kim and  
440 Church, 2001; Stewart et al., 2007; Verdeny et al., 2008; Roca-Martí et al., 2016; Subha Anand  
441 et al., 2017).

442 The highest estimated POC fluxes (Table 2) along the transect were observed at most of the  
443 investigated depths in the Labrador Sea and at the Greenland Shelf, whereas the lowest export  
444 was in the Iberian and West European Basins. An exception to this pattern was found at station

445 26 where POC flux was actually similar in magnitude to the flux at stations 64 and 69. Station 26  
446 was located in the middle of the Subarctic Front (SAF), a cold and fresh anomaly originating  
447 from subpolar water (Zunino et al., 2018). The hydrographic properties associated with the SAF  
448 appear to promote high primary production ( $174 \pm 19 \text{ mmol C m}^{-2} \text{ d}^{-1}$ , Table 1) and subsequently  
449 high carbon export (Kemp et al., 2006; Rivière and Pondaven, 2006; Guidi et al., 2007; Waite et  
450 al., 2016). While stations on the Greenland Shelf (stations 60 and 64) had the greatest estimated  
451 carbon export at the depth of ThEq ( $5 - 10 \text{ mmol C m}^{-2} \text{ d}^{-1}$ ), station 60 at the depth of  $Z_{1\%}$  had  
452 the lowest POC flux ( $-12.5$  to  $-8.4 \text{ mmol C m}^{-2} \text{ d}^{-1}$ ).

453 The negligible deficit of  $^{210}\text{Po}$  at the MLD and  $Z_{1\%}$  seen at stations 21, 38 and 44 leads to  
454 negligible  $^{210}\text{Po}$ -derived POC fluxes at those depths and stations (Table 2, Fig. 67). The  
455 relatively low POC export (negligible –  $1.7 \text{ mmol C m}^{-2} \text{ d}^{-1}$ ) at stations 1 and 13, on the other  
456 hand, resulted from low particulate POC/ $^{210}\text{Po}$  ratios (Table 2). In fact, the Iberian Basin had the  
457 lowest measurements of particulate POC/ $^{210}\text{Po}$  ratios in both the small and large size fractions  
458 relative to the other four basins along the transect (Fig. 4). This basin was also the only region  
459 along the transect where the phytoplankton community was not dominated by diatoms but by  
460 smaller phytoplankton, in particular coccolithophores. Smaller phytoplankton cells could  
461 scavenge more  $^{210}\text{Po}$  (higher particulate  $^{210}\text{Po}$  activity relative to the large particles) due to larger  
462 surface area per unit of volume, lowering their ratio of POC concentration to  $^{210}\text{Po}$  activity.

463

#### 464 **4.4. POC export efficiency**

465 The POC export flux calculated from the total  $^{210}\text{Po}$  flux at the depth of the PPZ was  
466 compared to the satellite-derived NPP over  $\sim 138$  days (see section 2.5) at each station, and the  
467 ratio was reported as the POC export efficiency.

468 The export efficiencies in this study were below 10% at 10 out of 11 stations, averaging  $6 \pm 4\%$   
469 ( $n = 10$ , excluding the negative value at station 60, Fig. 8). Export efficiencies  $< 10\%$  observed  
470 here were similar to those found in the Equatorial Pacific, the Arabian Sea, and at the BATS site  
471 (Buesseler, 1998; Subha Anand et al., 2017), but lower than those reported at high latitude sites  
472 ( $> 25\%$ ) such as the Arctic (Gustafsson and Andersson, 2012; Moran et al., 1997; Roca-Martí et  
473 al., 2016), the Bellingshausen Sea (Shimmield et al., 1995), and the Antarctic Polar Front  
474 (Rutgers van der Loeff et al., 1997).

475 Export efficiencies ranged from 0.5 to 2.5% in the Iberian Basin, while the values in the  
476 Irminger Basin ( $3 \pm 3\%$ , excluding station 60) were similar to the export efficiencies in the  
477 Western European Basin ( $5 \pm 5\%$ ) and in the Iceland Basin ( $6 \pm 6\%$ ). The export efficiencies, in  
478 contrast, were larger in the Labrador Basin ( $10 \pm 3\%$ ). The lowest export efficiencies observed in  
479 the Iberian Basin were consistent with the dominance of smaller phytoplankton species there  
480 (coccolithophores and cyanobacteria; Fig. 2). Indeed, small cells are usually slow-sinking  
481 particles that are likely more prone to degradation (Villa-Alfageme et al., 2016), leading to lower  
482 export efficiencies. Conversely, the higher export efficiencies at other stations, all generally  
483 dominated by diatoms (Fig. 2), support the idea that diatoms may be more efficient in exporting  
484 POC than smaller phytoplankton (Buesseler, 1998). Differences in export efficiencies between  
485 the basins dominated by diatoms suggest that other factors may also play some role (e.g.,  
486 temporal decoupling between production and export).

487 The POC export efficiency could also vary widely within the same basin. Taking the two  
488 stations in the Western European Basin for instance, export efficiency at station 26 was  $\sim 5$ -fold  
489 greater than that estimated at station 21, likely consistent with a lower contribution of diatoms  
490 and a higher contribution of smaller phytoplankton at station 21 relative to those at station 26  
491 (Fig. 2). But overall the time-series composition of the phytoplankton community at the two  
492 stations was similar (Fig. 2). The site-specific environment may have impacted the export of the  
493 same cell type to different degrees (Durkin et al., 2016). Station 26 was in the middle of the SAF,  
494 and the mesoscale physical processes (i.e. turbulence and mixing) at the front can introduce  
495 nutrients into the local euphotic zone (Lévy et al., 2012). Large phytoplankton species generally  
496 dominate in these nutrients-rich waters and can promote massive episodic particle export (e.g.  
497 Kemp et al., 2006; Guidi et al., 2007; Waite et al., 2016).

498

#### 499 **4.5. Comparison of $^{210}\text{Po}$ and $^{234}\text{Th}$ derived POC fluxes**

500 The measurements of  $^{234}\text{Th}/^{238}\text{U}$  disequilibrium to estimate POC export flux were  
501 simultaneously carried out during the GEOVIDE cruise (Lemaitre et al., 2018). The authors  
502 discussed the influence of vertical advection on  $^{234}\text{Th}$  export flux and concluded it can be  
503 neglected. In the present study, estimates of  $^{234}\text{Th}$ -derived POC ( $^{234}\text{Th}$ -POC) flux were compared  
504 to  $^{210}\text{Po}$ -derived POC ( $^{210}\text{Po}$ -POC) flux. To avoid discrepancies, both the  $^{234}\text{Th}$ -POC and  $^{210}\text{Po}$ -  
505 POC flux estimates were calculated at the depth of ThEq using the POC/radionuclide ratio in

506 total particles  $> 1 \mu\text{m}$  (TPF) and large particles  $> 53 \mu\text{m}$  (LSF), and both methods ignored  
507 physical transport and assumed steady state, where any deviation from secular equilibrium was  
508 created by sinking particles with an adsorbed and/or absorbed excess of the short-lived daughter  
509 isotope.

510

#### 511 **4.5.1. $^{210}\text{Po}$ flux vs. $^{234}\text{Th}$ flux**

512 The integrated  $^{210}\text{Po}$  and  $^{234}\text{Th}$  fluxes at the depth of ThEq were compared (Fig. 9). There  
513 was a spatial trend of  $^{234}\text{Th}$  flux, but not  $^{210}\text{Po}$  flux along the transect;  $^{234}\text{Th}$  fluxes at stations 1 to  
514 38 (eastern section,  $1580 \pm 430 \text{ dpm m}^{-2} \text{ d}^{-1}$ ) were significantly greater (Wilcoxon rank sum test,  
515  $p\text{-value} < 0.002$ ) than the fluxes at stations 44 to 77 (western section,  $710 \pm 230 \text{ dpm m}^{-2} \text{ d}^{-1}$ ).  
516 The means of the  $^{210}\text{Po}$  fluxes in the western and eastern sections were not statistically different  
517 from each other (Wilcoxon rank sum test,  $p\text{-value} = 0.3$ ). However, the flux of  $^{210}\text{Po}$  and  $^{234}\text{Th}$   
518 correlated with each other better in the western ( $n = 5$ ,  $R^2 = 0.6$ ) than in the eastern ( $n = 6$ ,  $R^2 =$   
519  $0.01$ ) sections.

520 These relationships may be related to both the stage of the bloom and different half-lives of  
521 the two isotopes. Indeed,  $^{234}\text{Th}$  fluxes integrate the conditions that occurred days to weeks prior  
522 to the sampling date while the  $^{210}\text{Po}$  method integrates the flux over the past few months. Within  
523 the Iberian Basin, stations 1 and 13 were sampled weeks to months after the bloom development  
524 (Fig. 6). The moderate to relatively high  $^{234}\text{Th}$  fluxes are thus surprising. Lemaitre et al., (2018)  
525 argue that the greater fluxes there might be related to the proximity of the Iberian margin, where  
526 particle dynamics were intense and lithogenic particles were numerous (Gourain et al., 2018). A  
527 temporal decoupling between production and export could be an alternative possibility. The  
528 Western European and Icelandic Basins were sampled during bloom development, and the NPP  
529 peaks occurring just before sampling may have promoted the high fluxes. In fact, these basins  
530 have been characterized by the presence of fast-sinking particles during the bloom (Villa-  
531 Alfageme et al., 2016), likely also explaining the high export. In contrast, the lower export  
532 observed in the western section may be due to the fact that the sampling occurred during the  
533 decline of the bloom, probably with a decoupling between production and export in the  
534 Labrador Basin, or during a particle retention event in the Irminger Basin.

535 Unlike the observations of higher  $^{234}\text{Th}$  export flux in the eastern than western sections, there  
536 were no significant differences in  $^{210}\text{Po}$  export flux between the two sections. This observation

537 supports the argument that the  $^{210}\text{Po}$  deficit tends to smooth out episodic events due to  
538 integration over longer time periods. The  $^{210}\text{Po}$  deficit records seasonal changes in export fluxes,  
539 whereas the  $^{234}\text{Th}$  deficit represents more recent changes in the water column (Verdeny et al.,  
540 2009; Hayes et al., 2018). Indeed, the  $^{210}\text{Po}$  deficit integrates the flux over months that include a  
541 period of lower flux prior to the bloom along the GA01 transect, whereas the  $^{234}\text{Th}$  deficit  
542 integrates the flux only over weeks that include the bloom itself at most of the stations (Fig. 6).  
543 Therefore, the specific stage of the bloom shortly prior to the sampling date appears to have less  
544 influence on the  $^{210}\text{Po}$ -derived than the  $^{234}\text{Th}$ -derived export flux along this transect.

545

#### 546 **4.5.2. POC/ $^{210}\text{Po}$ vs. POC/ $^{234}\text{Th}$ ratio**

547 In order to calculate POC export flux, one needs both the export of the daughter nuclide at a  
548 defined depth as well as the particulate POC/radionuclide ratio on the sinking particles. In situ  
549 pump filtered particles, either operationally defined as small (1-53  $\mu\text{m}$ , SSF), large ( $> 53 \mu\text{m}$ ,  
550 LSF), or total ( $> 1 \mu\text{m}$ , TPF) particles, may all represent a combination of sinking and non-  
551 sinking particles. In the present study, the particulate POC/radionuclide ratio on the TPF and  
552 LSF were examined and used to calculate POC export flux. The POC/ $^{210}\text{Po}$  and POC/ $^{234}\text{Th}$  ratios  
553 in the particles at the depths of ThEq were derived from the power law functions in each basin  
554 (POC/ $^{210}\text{Po}$  in Table 2, POC/ $^{234}\text{Th}$  in Lemaitre et al., (2018)). The TPF POC/ $^{210}\text{Po}$  and TPF  
555 POC/ $^{234}\text{Th}$  ratios had very similar spatial trends ( $n = 11$ ,  $R^2 = 0.8$ ,  $p\text{-value} < 0.0001$ ) along the  
556 transect, with the lowest POC/radionuclide ratios in the Iberian and Western European Basins  
557 and the highest ratios in the Labrador Sea. In contrast, the LSF POC/ $^{210}\text{Po}$  ratios were not  
558 correlated with LSF POC/ $^{234}\text{Th}$  ratios ( $n = 11$ ,  $R^2 = 0.3$ ,  $p\text{-value} = 0.07$ ). The correlation of values  
559 within the TPF but not the LSF suggests that the composition of large particles was different  
560 from that of the total particles, and that the difference in particle association between POC and  
561  $^{210}\text{Po}$  and  $^{234}\text{Th}$  was greater in large than total particles.

562

#### 563 **4.5.3. $^{210}\text{Po}$ -derived POC vs. $^{234}\text{Th}$ -derived POC**

564 When the radionuclide fluxes were multiplied by the POC/radionuclide values, the range of  
565 the calculated POC fluxes were negligible to 7  $\text{mmol C m}^{-2} \text{d}^{-1}$  and negligible to 12  $\text{mmol C m}^{-2}$   
566  $\text{d}^{-1}$  via the  $^{210}\text{Po}$  method using the TPF and LSF POC/ $^{210}\text{Po}$  ratios, respectively; and from 2.5 to  
567 13  $\text{mmol C m}^{-2} \text{d}^{-1}$  and from 1 to 12  $\text{mmol C m}^{-2} \text{d}^{-1}$  via the  $^{234}\text{Th}$  method using the TPF and LSF

568 POC/<sup>234</sup>Th ratios, respectively (Fig. 10). The <sup>234</sup>Th-POC and <sup>210</sup>Po-POC fluxes agreed within a  
569 factor of 3 along the transect, with higher POC estimates derived from the <sup>234</sup>Th method in 9 out  
570 of 11 stations. This was consistent with previous studies that have typically found higher  
571 estimated POC flux via the <sup>234</sup>Th method (e.g. Shimmield et al., 1995; Stewart et al., 2007;  
572 Verdeny et al., 2009).

573 When using the total particle POC/radionuclide ratios, only stations 26 and 60 were  
574 characterized by slightly higher <sup>210</sup>Po-derived POC flux estimates than <sup>234</sup>Th-derived estimates  
575 (0.2 and 1.5-fold, respectively). In contrast, at station 1 the difference between the methods was  
576 greatest, with the <sup>210</sup>Po-derived POC flux negligible and the <sup>234</sup>Th-POC flux of about 7 mmol C  
577 m<sup>-2</sup> d<sup>-1</sup>. At stations 13, 21, and 44, the <sup>234</sup>Th-POC fluxes were greater than <sup>210</sup>Po-POC estimates  
578 by almost 1-fold. Whereas in the Iceland and Labrador Basins, the <sup>234</sup>Th-POC fluxes were larger  
579 than <sup>210</sup>Po-POC estimates by 3- and 2-fold, respectively. When using the large particle  
580 POC/radionuclide ratios, only in the Irminger Basin was there higher <sup>210</sup>Po-derived POC flux  
581 than <sup>234</sup>Th-derived POC flux (> 0.2 to 3-fold). In the Iberian Basin, the greatest difference  
582 between the methods was found at station 1 where <sup>210</sup>Po-derived POC flux was negligible while  
583 <sup>234</sup>Th-derived POC flux was the highest along the transect but with a large uncertainty (12 ± 22  
584 mmol C m<sup>-2</sup> d<sup>-1</sup>), and at station 13 the <sup>234</sup>Th-POC flux was greater than the <sup>210</sup>Po-POC estimate  
585 by 4-fold. In the Western European, Iceland, and Labrador Basins, the <sup>234</sup>Th-POC fluxes were  
586 larger than <sup>210</sup>Po-POC estimates by 5, 4, and 2-fold, respectively.

587 Wilcoxon rank sum tests revealed that the <sup>234</sup>Th-POC estimates were significantly greater  
588 than <sup>210</sup>Po-derived POC export at the stations from the Iberian Basin to the Iceland Basin (n = 6,  
589 TPF: p-value < 0.01, LSF: p-value < 0.02), but not at the stations from the Irminger Basin to the  
590 Labrador Basin (n = 5, TPF: p-value > 0.1, LSF: p-value = 1). Since the ratios of POC to  
591 radionuclides on total particles had very similar spatial trends along the transect, the discrepancy  
592 between TPF <sup>234</sup>Th-POC and TPF <sup>210</sup>Po-POC flux estimates must be driven primarily by the  
593 discrepancy between the SS estimates of <sup>234</sup>Th and <sup>210</sup>Po fluxes, discussed in section 4.5.1. In  
594 contrast, the discrepancy between the POC to isotope ratios in the large particle may have led to  
595 some degree of discrepancy between the LSF <sup>234</sup>Th-POC and LSF <sup>210</sup>Po-POC flux estimates.

596

## 597 5. Conclusions

598 This study used the water column  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  activity data to constrain the  $^{210}\text{Po}$   
599 particulate flux from the mixed layer depth, the base of the euphotic zone and primary  
600 production zone, and the  $^{234}\text{Th}$ - $^{238}\text{U}$  equilibrium depth. The ratios of POC concentration to  $^{210}\text{Po}$   
601 activity on the total particulate ( $> 1 \mu\text{m}$ ) fraction and large particulate fraction ( $> 53 \mu\text{m}$ ) were  
602 used to estimate POC export fluxes. We have been able to include vertical advection into a  
603 steady-state model to calculate the  $^{210}\text{Po}$  flux along the transect. The scale of  $^{210}\text{Po}$  fluxes due to  
604 vertical advection were of the same magnitude as the steady state fluxes calculated from the  
605  $^{210}\text{Po}$  deficit alone. The  $^{210}\text{Po}$ -derived POC export fluxes varied spatially, ranging from  
606 negligible to  $10 \text{ mmol C m}^{-2} \text{ d}^{-1}$  along the transect, with the highest export fluxes in the Labrador  
607 Sea. POC export efficiencies (flux relative to production) also showed regional differences,  
608 ranging from negligible to 13% along the transect. Higher export efficiencies were seen in the  
609 basins where diatoms dominated the phytoplankton community. The low export efficiencies  
610 recorded in the Iberian Basin, on the other hand, may be associated with the dominance of  
611 smaller phytoplankton, such as coccolithophores. POC export fluxes estimated from the water  
612 column  $^{210}\text{Po}/^{210}\text{Pb}$  and  $^{234}\text{Th}/^{238}\text{U}$  disequilibria agreed within a factor of 3 across our study  
613 region, with higher POC estimates generally derived from the  $^{234}\text{Th}$  method. The differences  
614 were attributed to integration timescales and the history of bloom events.

615

## 616 **Acknowledgements**

617 We thank the captain (Gilles Ferrand) and crew of the *R/V Pourquoi Pas?* and the chief  
618 scientists (Géraldine Sarthou and Pascale Lherminier) of the GEOVIDE cruise. We also thank  
619 Pierre Branellec, Floriane Desprez de Gésincourt, Michel Hamon, Catherine Kermabon, Philippe  
620 Le Bot, Stéphane Leizour, Olivier Ménage, Fabien Pérault, and Emmanuel de Saint-Léger for  
621 their technical support during the GEOVIDE expedition, Catherine Schmechtig for the  
622 GEOVIDE database management, and Phoebe Lam for providing two modified McLane in-situ  
623 pumps, Frédéric Planchon, Virginie Sanial, and Catherine Jeandel for their assistance with pump  
624 deployments and particulate sample collection. The authors also thank Arnout Roukaerts,  
625 Debany Fonseca-Batista, Florian Deman, and Frank Dehairs for providing primary production  
626 data. Funding for the GEOVIDE cruise was provided by the French National Research Agency  
627 (ANR-13-BS06-0014, ANR-12-PDOC-0025-01), the French National Center for Scientific  
628 Research (CNRS-LEFE-CYBER), the LabexMER (anr-10-LABX-19), and Ifremer. Gillian

629 Stewart and Yi Tang were supported by NSF award #OCE 1237108. The Generalitat de  
630 Catalunya also helped through its grant 2017 SGR-1588. This work is contributing to the ICTA  
631 ‘Unit of Excellence’ (MinECo, MDM2015-0552). Maxi Castrillejo and Montserrat Roca-Martí  
632 were funded by an FPU PhD studentship (AP-2012-2901 and AP2010-2510, respectively) from  
633 the Ministerio de Educación, Cultura y Deporte of Spain. Maxi Castrillejo was also supported by  
634 the ETH Zurich Postdoctoral Fellowship Program (17-2 FEL-30), co-funded by the Marie Curie  
635 Actions for People COFUND Program. We also thank Gary Hemming (Queens College) and  
636 Troy Rasbury (Stony Brook University) for laboratory assistance with the ICP-MS analyses.  
637 Finally, we thank the Associate Editor and the anonymous reviewers for their helpful comments  
638 on how to improve the manuscript.

893 Table 1. The mixed layer depth (MLD, defined as a change in potential density of  $0.03 \text{ kg m}^{-3}$  relative to the potential density at 10 m),  
894 the depth of the euphotic zone ( $Z_{1\%}$ , defined as the depth where photosynthetic available radiation was 1% of its surface value), the  
895 primary production zone (PPZ, at which the fluorescence reaches 10% of its maximum), and the  $^{234}\text{Th}$ - $^{238}\text{U}$  equilibrium depth (ThEq)  
896 at each station along the GA01 transect. Together with the 30-day (30 days prior to the sampling date) average vertical velocity within  
897 the 20 m under the corresponding depths ( $w_{20}$ ,  $10^{-6} \text{ m s}^{-1}$ , downwards as positive direction). Primary production (PP) and net primary  
898 production (NPP) rates derived from 24-hour bottle incubations (Fonseca-Batista et al., 2018; Lemaitre et al., 2018) and from the  
899 VGPM products, respectively, are also presented. Note the NPP rates were averaged for the previous 138 days ( $^{210}\text{Po}$  half-life) prior to  
900 the sampling date.

901

St.	Sampling date	Basin	Integration Depth (m)				$w_{20}$ ( $10^{-6} \text{ m s}^{-1}$ )				Production ( $\text{mmol C m}^{-2} \text{ d}^{-1}$ )			
			MLD	$Z_{1\%}$	PPZ	ThEq	MLD	$Z_{1\%}$	PPZ	ThEq	PP	$\pm$	NPP	$\pm$

902 Table 2. The total  $^{210}\text{Po}$  flux as the sum of the flux calculated from the deficit and vertical advection, together with POC/ $^{210}\text{Po}$  ratios in  
 903 particles  $> 1 \mu\text{m}$  (derived from the power law function in Fig. 5) and POC fluxes derived from  $^{210}\text{Po}$  at the corresponding depths. The  
 904 uncertainties of  $^{210}\text{Po}$  export flux are associated with the activity uncertainty of the radionuclides. The error for the calculated  
 905 particulate POC/ $^{210}\text{Po}$  ratio in each basin is the standard error of regression. The uncertainties of the  $^{210}\text{Po}$ -derived POC flux were  
 906 estimated based on the propagation of error. (Editors/Reviewers please NB: This is a table with 53 columns that has been divided into  
 907 3 pieces for review purposes, but which should be published as one long table.)

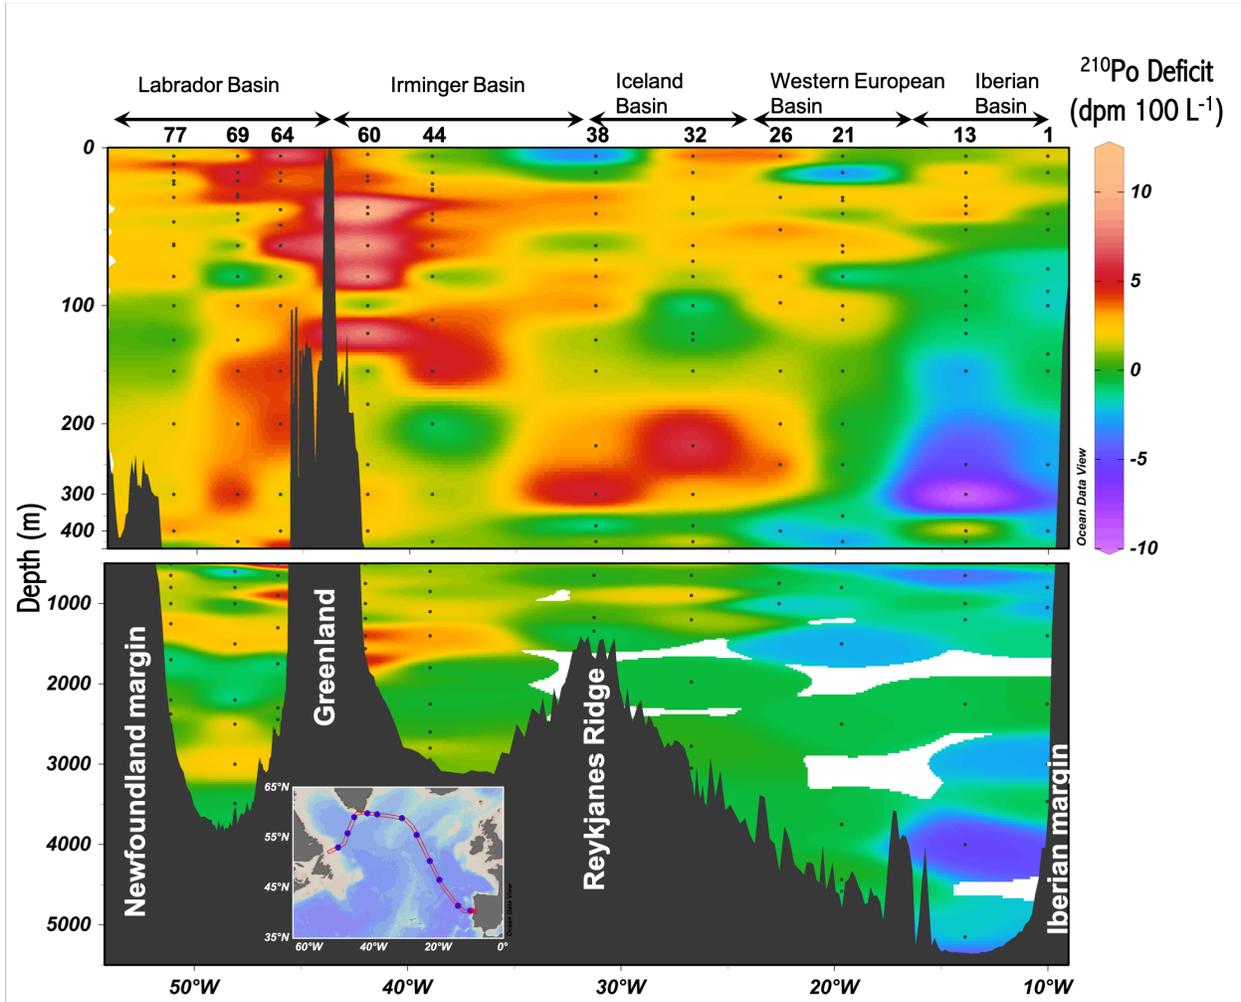

Fig. 1. Map of stations occupied during the GA01 transect in the North Atlantic. The red squares indicate the stations where  $^{210}\text{Po}$  and  $^{210}\text{Pb}$  activities were measured discussed in this study. The transect is divided into the Iberian Basin (stations 1, 13), the Western European Basin (stations 21, 26), the Iceland Basin (stations 32, 38), the Irminger Basin (stations 44, 60), and the Labrador Basin (stations 64, 69, 77).

948  
949

950 Fig. 3. Section plots of water column  $^{210}\text{Po}$  deficits (dpm 100 L<sup>-1</sup>, total  $^{210}\text{Pb}$  activity minus total  
951  $^{210}\text{Po}$  activity) across the GA01 transect. Upper panel is the upper 500 m. Lower panel is 500 –  
952 5500 m. Station numbers and basins are shown on the top of the upper panel.

953

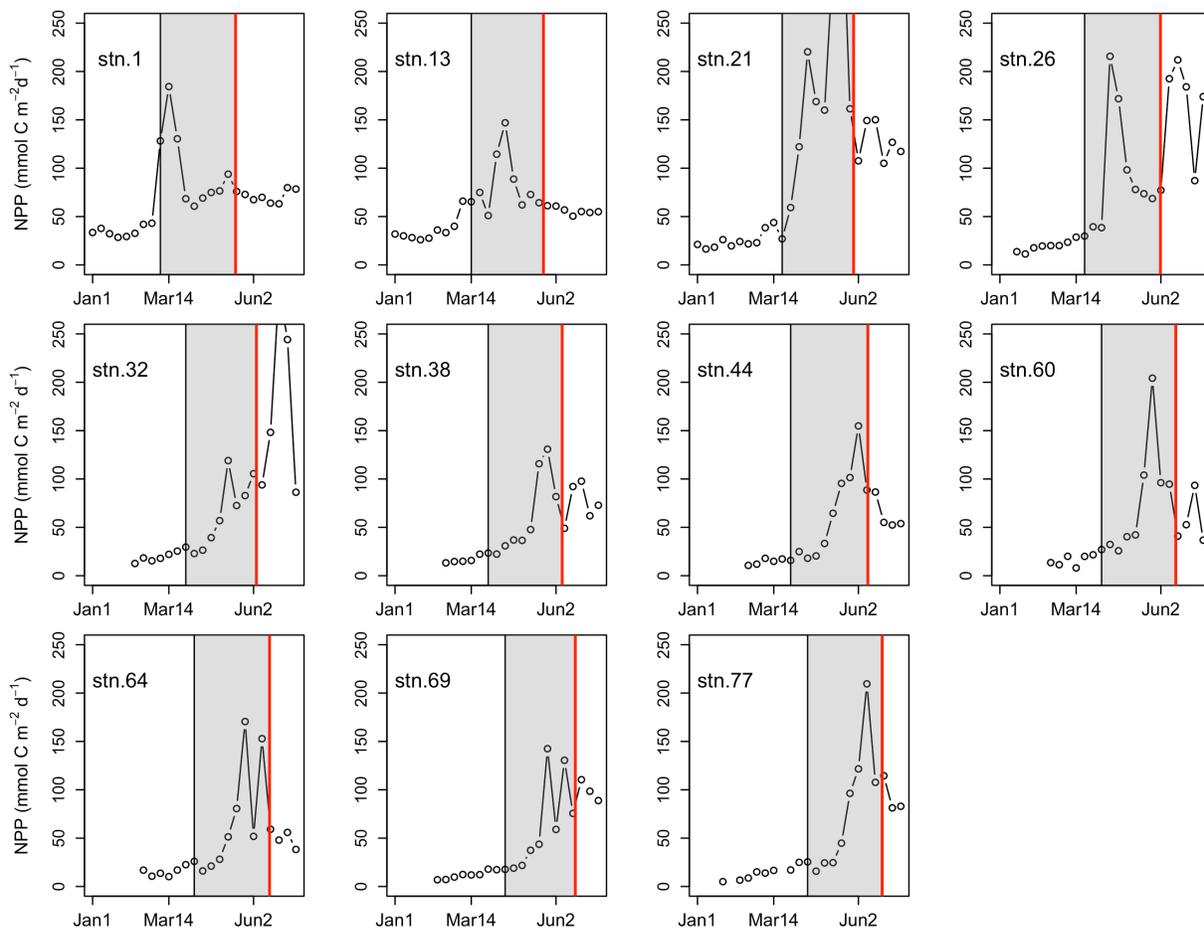

954 Fig. 4. Plots of the ratios of POC concentration to  $^{210}\text{Po}$  activity in: (a) the large (> 53  $\mu\text{m}$ )  
 955 particles (POC/ $^{210}\text{Po}$ \_LSF) against the small (1-53  $\mu\text{m}$ ) particles (POC/ $^{210}\text{Po}$ \_SSF), and in (b) the  
 956 total (> 1  $\mu\text{m}$ ) particles (POC/ $^{210}\text{Po}$ \_TPF) against the small particles. The black lines indicate the  
 957 1:1 line.

958

959

960 Fig. 5. The ratios of POC concentration to  $^{210}\text{Po}$  activity in the total particles vs. depth in each  
 961 basin along the GA01 transect. Power law regression (red line) was fitted for  $\text{POC}/^{210}\text{Po}$  against  
 962 depth in each plot: the Iberian Basin (stations 1, 13), West European Basin (stations 21, 26),  
 963 Iceland Basin (stations 32, 38), Irminger Basin (stations 44, 60), and Labrador Basin (stations 64,  
 964 69, 77). The data points denoted as filled black circles were outliers (points at a distance greater  
 965 than 1.5 standard deviations from the power law model) and excluded from the power law  
 966 regression.

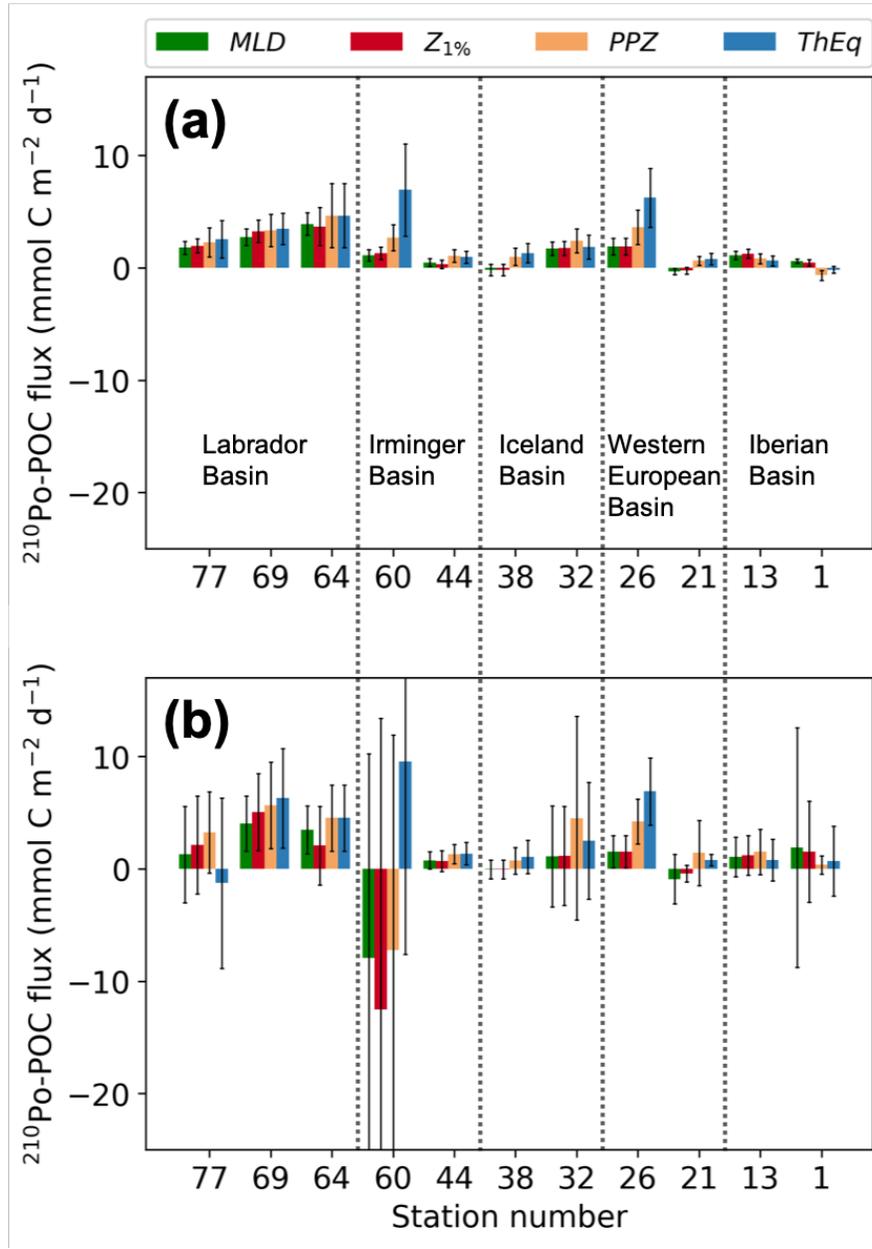

967

968

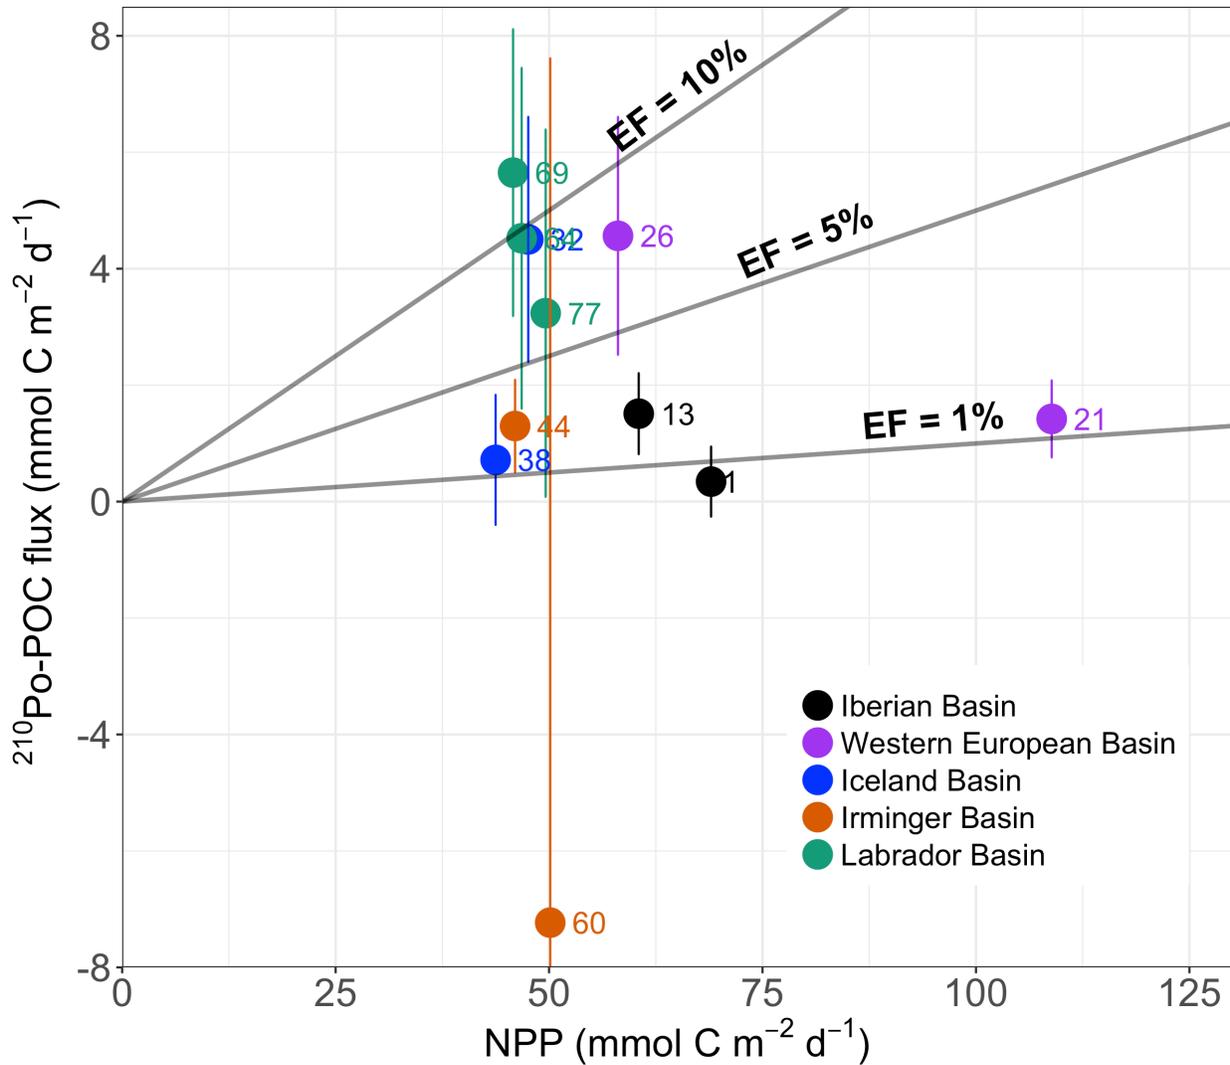

969 Fig. 6. Time-series (January 1- July 12, 2014) satellite estimates of net primary production (NPP)  
 970 between January 1 and July 12 in 2014 at each station along the GA01 transect (NPP, VPGM  
 971 algorithm, <http://www.science.oregonstate.edu/ocean.productivity/>). The shading rectangle in  
 972 each plot denotes NPP for about 2 months prior to the sampling date. Two months NPP data is  
 973 needed because such a time scale could ensure the sensitivity for NSS estimates (Friedrich and  
 974 Rutgers van der Loeff, 2002; Stewart et al., 2007). The vertical red line in each plot indicates the  
 975 sampling date at each station.

976

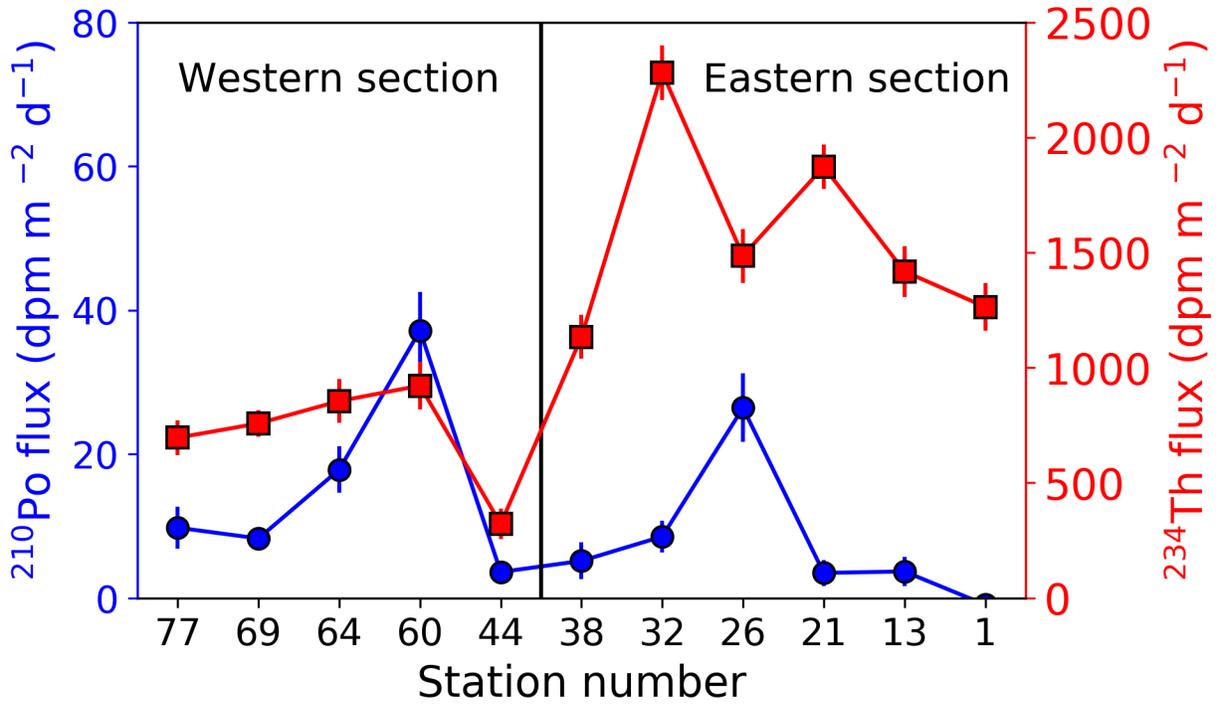

977

978 Fig. 7. POC fluxes derived from  $^{210}\text{Po}$  for the mixed layer depth (MLD), the base of the euphotic  
 979 zone ( $Z_{1\%}$ ), the base of the primary production zone (PPZ), and the  $^{234}\text{Th}$ - $^{238}\text{U}$  equilibrium depth  
 980 (ThEq). (a) POC fluxes derived from the  $^{210}\text{Po}$  fluxes that were calculated from the deficit alone;  
 981 (b) POC fluxes derived from the sum of the  $^{210}\text{Po}$  fluxes that were calculated from the  $^{210}\text{Po}$   
 982 deficit and vertical advective flux. Note that the  $> 1 \mu\text{m}$  particles were used to calculate the  
 983  $\text{POC}/^{210}\text{Po}$  ratios. The stations were plotted from west to east.

984  
 985 Fig. 8. Plot of POC export flux derived from  $^{210}\text{Po}$  method ( $^{210}\text{Po}$ -POC) versus satellite estimates  
 986 of net primary production (NPP). The NPP values were averaged for the previous 138 days  
 987 ( $^{210}\text{Po}$  half-life) prior to the sampling date. The sum of the  $^{210}\text{Po}$  fluxes calculated from the  $^{210}\text{Po}$   
 988 deficit and vertical advective flux, and the POC/ $^{210}\text{Po}$  ratios in the  $> 1 \mu\text{m}$  particles were used to  
 989 derive POC fluxes. The  $^{210}\text{Po}$ -POC fluxes were integrated within the primary production zone  
 990 (PPZ). Lines of export efficiency (EF) of 10%, 5%, and 1% are drawn in the plot. The numbers  
 991 in the plot are labelled as station numbers. The color codes of the stations correspond to the  
 992 basins.

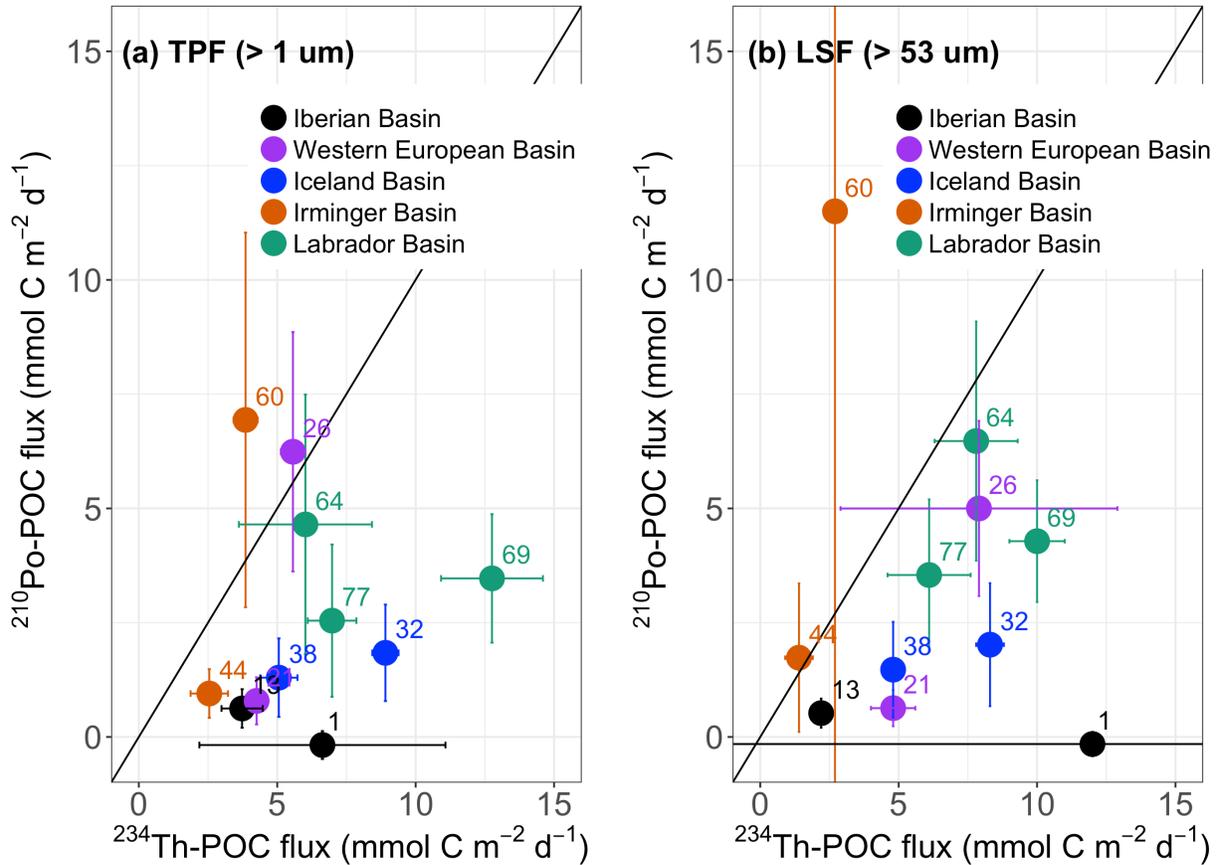

Canada ← Greenland ← Portugal

993

994

995 Fig. 9. Sinking fluxes of  $^{210}\text{Po}$  (blue circles) and  $^{234}\text{Th}$  (red squares) integrated to the depth  
 996 where  $^{234}\text{Th}$  activity returned to equilibrium with  $^{238}\text{U}$  activity (ThEq) assuming steady state and  
 997 negligible physical transport along the GA01 transect. Note that the stations are plotted from  
 998 west to east, and the transect was separated into the western (stations 44 - 77) and eastern  
 999 (stations 1 - 38) sections.

1000

1001

1002 Fig. 10. Plot of the POC flux derived from  $^{210}\text{Po}$  ( $^{210}\text{Po}$ -POC) versus the POC flux derived from  
 1003  $^{234}\text{Th}$  ( $^{234}\text{Th}$ -POC) at 11 stations along the GA01 transect. Both the fluxes of  $^{210}\text{Po}$  and  $^{234}\text{Th}$   
 1004 were calculated from the deficit term alone assuming steady state and negligible physical  
 1005 transport. The POC/radionuclide ratios on (a) total particulate fraction (TPF, > 1  $\mu\text{m}$ ) and (b)  
 1006 large size fraction (LSF, > 53  $\mu\text{m}$ ) were used to calculate the POC flux. The fluxes were  
 1007 integrated down to the depth where  $^{234}\text{Th}$  activity returned to equilibrium with  $^{238}\text{U}$  activity  
 1008 (ThEq). The numbers in the plot are station numbers. The color codes of the stations correspond  
 1009 to the basins.

1010
