

Reply letter to Nathaniel Ostrom's second review of our manuscript bg-2018-426

We would like to thank Nathaniel Ostrom for re-reviewing our manuscript after our manuscript revisions according to his previous suggestions and according to the anonymous referee's suggestions. Below, the referee's comments (RC1) are displayed followed by the authors' response, which are highlighted in grey.

General comments:

The authors have carefully addressed the issues raised in review and overall this is an excellent manuscript with a compelling data set. I remain concerned with three points that were raised in my initial review.

RC1 Comment 1:

Reporting of isotope standards outside the range of the standards. There is no doubt that the authors have an extensive history in the development of N₂O standards and international collaboration to attain that goal. And I agree that the authors are conducting the “current best practice(s)” in the field. But this does not avoid the issue that, particularly with regard to $\delta^{18}\text{O}$, the sample values are well outside the range of the standards and, further, the range in $\delta^{18}\text{O}$ values for standards is quite small. The statement that “... the linearity of the delta scale for QCLAS measurements was demonstrated already in 2008 (Waechter et al., 2008)” is not very satisfactory as spectroscopic instruments are very susceptible to drift and require “frequent calibration” (Waechter et al., 2008). Further, linearity does not equate to accuracy. In that study, the $\delta^{18}\text{O}$ values for the standards ranged about 100 per mil vs only a few per mil in this study. As in archery, accuracy becomes much more difficult the further from the target you are. I agree that international standards are not available in this range, but Waechter et al. clearly demonstrated that working standards can be generated (although I expect that there is some uncertainty in the accuracy of those standard values). Thus, the authors are following best practices, but the standard should not be best practices, but do we have sufficient confidence in the accuracy of the sample values to publish? Calibration is far behind the applications and this is largely because of the difficulty in developing standards, lack of support from funding agencies and insufficient attention by the scientific community. I, for one, have chosen not to publish $\delta^{18}\text{O}$ values generated spectroscopically because of the limited range of values in our standards. I believe the isotope values I obtain are accurate, but the problem is that I don't know for certain. Further, the casual reader is very unlikely to be able to make this distinction. I honestly don't know the solution for this problem and have no desire to hold up publication. My leaning, as indicated, is not to publish the $\delta^{18}\text{O}$ values but, at the least, the authors should indicate that many isotope values are outside the range of the standards which can be problematic to precise calibration.

Authors' response: As also mentioned in our previous response, we do agree that calibration of $\delta^{18}\text{O}$ -N₂O data should be improved in future studies, given the availability of appropriate standard gases. As acknowledged by Nathaniel Ostrom, the two point calibration approach presented here corresponds to current best practice, while most other laboratories publish $\delta^{18}\text{O}$, but also $\delta^{15}\text{N}^{\alpha}$ and $\delta^{15}\text{N}^{\beta}$ results using a one point calibration approach based on a singular working standard. While recently available N₂O calibration standards bracket a range of approx. 0.6 ‰ (Ostrom et al., 2018) and therefore do not enable two-point calibration, the standards S1 and S2 used in this study span approx. 7 ‰. The accuracy of our $\delta^{18}\text{O}$ -N₂O measurement data for samples outside the calibrated range was demonstrated in Mohn et al. (2014) and results of our laser spectroscopic technique were comparable to IRMS performance. We therefore would expect all users of laser spectroscopic as well as mass spectrometric techniques to implement a two point calibration approach, covering all measurement data. Nonetheless we agree to add a further statement to the conclusion section.

Page 13 Line 40: “Replicate in-situ measurements of a pressurized air tank demonstrated a short term repeatability of the TREX-QCLAS system of 0.25 ‰, 0.31 ‰, 0.30 ‰ and 0.25 ppb for $\delta^{15}\text{N}^{\alpha}$, $\delta^{15}\text{N}^{\beta}$, $\delta^{18}\text{O}$ and N_2O concentration, respectively. Accuracy of results was assured using a two point calibration that entirely spanned the range of obtained $\delta^{15}\text{N}^{\alpha}$ and $\delta^{15}\text{N}^{\beta}$ values, however, did not fully cover the range of obtained $\delta^{18}\text{O}$ values. This is current best practice, as no suitable reference gases are available, but might lead to a somewhat larger uncertainty for $\delta^{18}\text{O}\text{-N}_2\text{O}$.”

RC1 Comment 2:

The “benchmark value of 10 per mil for the SP standard deviation” seems rather large given that the difference between microbial sources of N_2O is about 30-40 per mil. As long as the authors are clear about this and, perhaps, report the standard deviations the reader will have the ability to evaluate accuracy.

Authors' response: Actual standard deviations for reported SP values are given in Table 3 and range between 0.7 and 7.9 ‰, with 3.2 ± 2.2 ‰ (mean \pm 1SD). Accordingly, the highest standard deviation actually presented in our manuscript corresponds to 7.9 ‰, while most of the them are much lower. Therefore, the reader has the ability to evaluate the uncertainty of the results and no additional measures are taken.

RC1 Comment 3:

I agree that given full exchange between N_2O and water during bacterial denitrification the $\delta^{18}\text{O}$ values for N_2O should be constant. I find the word “stable” in this context to be less accurate than “constant”. But, what can we expect the $\delta^{18}\text{O}$ values to be when exchange is not 100% and how often does this happen?

Authors' response: We agree that “constant” is a better expression than “stable” in this context and replace “stable” by “constant” on page 12 line 9 and page 20 line 18.

The authors agree that the effect of oxygen exchange on the $\delta^{18}\text{O}\text{-N}_2\text{O}$ values is complex and depends on several parameters ($\delta^{18}\text{O}$ values of precipitation, $\delta^{18}\text{O}$ values of soil water, degree of oxygen exchange), which makes a quantification challenging.

Abstract

15 Nitrous oxide (N₂O) is the primary atmospheric constituent involved in stratospheric ozone depletion and contributes strongly to changes in the climate system through a positive radiative forcing mechanism. The atmospheric abundance of N₂O has increased from 270 ppb during the pre-industrial era to approx. 330 ppb in 2018. Even though it is well known that microbial processes in agricultural and natural soils are the major N₂O source, the contribution of specific soil processes is still uncertain. The relative abundance of N₂O isotopocules (¹⁴N¹⁴N¹⁶O, ¹⁴N¹⁵N¹⁶O, ¹⁵N¹⁴N¹⁶O and ¹⁴N¹⁴N¹⁸O) carries process-specific
20 information and thus can be used to trace production and consumption pathways. While isotope ratio mass spectroscopy (IRMS) was traditionally used for high-precision measurement of the isotopic composition of N₂O, quantum cascade laser absorption spectroscopy (QCLAS) has been put forward as a complementary technique with the potential for on-site analysis. In recent years, preconcentration combined with QCLAS has been presented as a technique to resolve subtle changes in ambient N₂O isotopic composition.

25 From the end of May until the beginning of August 2016, we investigated N₂O emissions from an intensively managed grassland at the study site Fendt in Southern Germany. In total, 612 measurements of ambient N₂O were taken by combining preconcentration with QCLAS analyses, yielding $\delta^{15}\text{N}^{\alpha}$, $\delta^{15}\text{N}^{\beta}$, $\delta^{18}\text{O}$ and N₂O concentration with a temporal resolution of approximately one hour and precisions of 0.46 ‰, 0.36 ‰, 0.59‰ and 1.24 ppb, respectively. Soil $\delta^{15}\text{N}\text{-NO}_3^-$ values and concentrations of NO₃⁻ and NH₄⁺ were measured to further constrain possible N₂O-emitting source processes. Furthermore,
30 the concentration footprint area of measured N₂O was determined with a Lagrangian particle dispersion model (FLEXPART-COSMO) using local wind and turbulence observations. These simulations indicated that night-time concentration observations were largely sensitive to local fluxes. While bacterial denitrification and nitrifier denitrification were identified as the primary N₂O-emitting processes, N₂O reduction to N₂ largely dictated the isotopic composition of measured N₂O. Fungal denitrification and nitrification-derived N₂O accounted for 34 - 42 % of total N₂O emissions and had a clear effect on the
35 measured isotopic source signatures. This study presents the suitability of on-site N₂O isotopocule analysis for disentangling source and sink processes in-situ and found that at the Fendt site bacterial denitrification/ nitrifier denitrification is the major source for N₂O, while N₂O reduction acted as a major sink for soil produced N₂O.

1. Introduction

Nitrous oxide (N₂O) is the third most important greenhouse gas (GHG), accounting for 6 % of the total anthropogenic radiative forcing (Myhre et al., 2013), and is thus far the dominant stratospheric ozone depleting substance emitted in the 21st century (Ravishankara et al., 2009). Its globally averaged atmospheric concentration has increased since the preindustrial era from approximately 270 ppb (parts-per-billion, 10⁻⁹ mole mole⁻¹) at an average rate of 0.2 – 0.3% yr⁻¹ and reached 328.9 ± 0.1 ppb in 2016 (Prinn, 2016; WMO and GAW, 2016). While it is well known that natural and agricultural soils are the major N₂O sources on a global scale, the relative contributions of individual microbial and abiotic N₂O production and consumption pathways remain largely uncertain because different N₂O-producing and -consuming processes are active simultaneously in a soil. Until now, there were no direct methods that allow for the attribution of an emitted amount of N₂O to a given process in the field (Solomon et al., 2007; Billings, 2008; Butterbach-Bahl et al., 2013). However, a detailed understanding of the temporal and spatial variations in N₂O emissions and controlling processes is required to develop mitigation strategies and to better achieve emission reduction targets (Nishina et al., 2012; Cavigelli et al., 2012; Herrero et al., 2016; Decock et al., 2015). Atmospheric N₂O isotopic composition provides important information about N₂O production and consumption processes because distinct microbial and abiotic process pathways exhibit characteristic isotopic signatures (Toyoda et al., 2017; Decock and Six, 2013b; Verhoeven et al., 2018; Denk et al., 2017). Apart from ¹⁴N¹⁴N¹⁶O, representing 99 % of total atmospheric N₂O, the three most abundant N₂O isotopocules are ¹⁴N¹⁵N¹⁶O (¹⁵N at central α position), ¹⁵N¹⁴N¹⁶O (¹⁵N at terminal β position) and ¹⁴N¹⁴N¹⁸O (Toyoda and Yoshida, 1999; Kato et al., 1999). Abundances of isotopocules are usually reported in the δ-notation in per mil (‰) as δ¹⁵N^α, δ¹⁵N^β, δ¹⁸O, calculated according to the equation (1):

$$\delta X = (R_{\text{sample}} - R_{\text{standard}}) / R_{\text{standard}} \quad (1)$$

where X denotes ¹⁵N^α, ¹⁵N^β or ¹⁸O and R refers to ¹⁴N¹⁵N¹⁶O / ¹⁴N¹⁴N¹⁶O, ¹⁵N¹⁴N¹⁶O / ¹⁴N¹⁴N¹⁶O or ¹⁴N¹⁴N¹⁸O / ¹⁴N¹⁴N¹⁶O, respectively, in a sample or standard (Toyoda and Yoshida, 1999; Brenninkmeijer and Röckmann, 1999; Werner and Brand, 2001). The international isotope reference scale for ¹⁵N / ¹⁴N is atmospheric N₂ (AIR-N₂) and for ¹⁸O / ¹⁶O Vienna Standard Mean Ocean Water (VSMOW). Thermal decomposition of isotopically characterized ammonium nitrate (NH₄NO₃) has been suggested as an approach to link the position-dependent nitrogen isotopic composition of N₂O to AIR-N₂ (Toyoda and Yoshida, 1999; Mohn et al., 2016). The total ¹⁵N content is usually reported as bulk ¹⁵N content (δ¹⁵N^{bulk}) according to equation (2):

$$\delta^{15}\text{N}^{\text{bulk}} = (\delta^{15}\text{N}^{\alpha} + \delta^{15}\text{N}^{\beta}) / 2 \quad (2)$$

while the site preference (SP) is used to denote the intramolecular ¹⁵N distribution according to the equation (3):

$$\text{SP} = \delta^{15}\text{N}^{\alpha} - \delta^{15}\text{N}^{\beta} \quad (3)$$

The established technique for the analysis of N₂O isotopic composition is isotope-ratio mass-spectrometry (IRMS) (Toyoda and Yoshida, 1999), which is very sensitive and capable of providing highly precise analytical results (Toyoda and Yoshida, 2016). However, IRMS instruments are usually not suitable for field deployment. Recently, quantum cascade laser absorption spectroscopy (QCLAS) (Waechter et al., 2008; McManus et al., 2015), cavity ring-down spectroscopy (CRDS, Erler et al., 2015), and off-axis cavity output spectroscopy (OA-ICOS, Wassenaar et al., 2018) were introduced as alternatives for greenhouse gas (GHG) stable isotope analysis, with the capability for real-time, on-site analysis even at remote locations (Tuzson et al., 2011; Wolf et al., 2015; Eyer et al., 2016; Röckmann et al., 2016). Another advantage of spectroscopic techniques is their ability for direct selective analysis of intra-molecular isotopic isomers (isotopomers) such as ¹⁴N¹⁵N¹⁶O and ¹⁵N¹⁴N¹⁶O, while the determination of the SP using IRMS is only possible via a detour of measuring δ¹⁵N-NO⁺ in combination with δ¹⁵N^{bulk} and a correcting for scrambling (Toyoda et al., 1999). Several studies have successfully applied QCLAS and CRDS for N₂O isotope analysis in laboratory and field incubation experiments (Koster et al., 2013; Yamamoto et al., 2014;

Erler et al., 2015; Mohn et al., 2013; Winther et al., 2018), and more recently to analyse diurnal and seasonal isotopic variations in ambient N₂O (Mohn et al., 2012; Toyoda et al., 2013; Wolf et al., 2015; Harris et al., 2017). The isotopic composition of N₂O emitted from soils can be extracted from ambient air measurements using traditional two end-member mixing models, i.e. the “Keeling plot” approach (Keeling, 1961) or the Miller–Tans approach. While the Keeling plot approach requires stable background conditions, the Miller-Tans approach is also applicable if the stable background requirement is violated (Miller and Tans, 2003). However, the spatial attribution of the extracted N₂O isotopic composition has to date been neglected because atmospheric transport and turbulence needs to be considered.

The bulk isotopic composition of N₂O produced by biogeochemical source processes, i.e. $\delta^{15}\text{N}^{\text{bulk}}$ and $\delta^{18}\text{O}$, is controlled by fractionation during N₂O production, the isotopic composition of N₂O precursors (i.e., NH₄⁺, NO₂⁻, NO₃⁻ and H₂O), and N₂O reduction. In contrast, the difference in ¹⁵N substitution between the central and terminal position within the N₂O molecule (SP) is independent of the precursor's isotopic composition and characteristic for specific reaction mechanisms or enzymatic pathways (Sutka et al., 2006). Therefore, SP provides distinct process information, which can be determined by pure culture studies and chemical reactions under laboratory conditions (Heil et al., 2014; Wei et al., 2017b; Toyoda et al., 2005). Decock and Six (2013a) and Toyoda et al. (2017) summarized that N₂O from hydroxylamine (NH₂OH) oxidation, fungal denitrification and abiotic N₂O production on the one hand and N₂O originating from nitrifier-denitrification and denitrification on the other hand display distinct SP values of $32.8 \pm 4.0 \text{ ‰}$ and $-1.6 \pm 3.8 \text{ ‰}$, respectively. Accordingly, SP values of N₂O from mixed microbial communities/ abiotic processes, may display large variations depending on the prominent reaction pathway and the respective study conditions.

With this study, we aim to improve the understanding of the temporal dynamics of N₂O isotopic composition, and to identify the relative contribution of the dominant N₂O producing and consuming microbial processes under field conditions. To achieve this, we i) applied a revised coupled TRace gas EXtractor (TREX) and a QCLAS-based instrumentation (TREX-QCLAS, Ibraim et al., 2018) for the first time during a field campaign for in-situ analysis of N₂O isotopocules from ambient air samples, ii) compared two approaches for the calculation of the isotopic composition of N₂O emitted from soils, namely the Keeling plot versus the Miller-Tans approach, iii) include the isotopic composition of a N₂O precursor, nitrate (NO₃⁻), to support the identification of dominant processes and iv) use local turbulence and wind profile measurements to outline the spatial extent for which the determined isotopic compositions of soil emitted N₂O are representative.

2. Material and Methods

2.1 Characterization of the research site Fendt

2.1.1 Study site

The TERENO-preAlpine Observatory (Kiese et al., 2018) research site Fendt (De-Fen), a typical montane grassland south of Munich (Germany) is situated at 595 m a.s.l. and has an annual mean temperature of 8.9 °C with 960 mm mean annual precipitation. The site is intensively managed, which includes up to five times of cutting per year for fodder production followed by manure application as well as occasional cattle grazing (Zeeman et al., 2017). Soil characteristics of the site are given in Table 1. These measurements were carried out between 29 May and 03 August 2016 as part of the ScaleX 2016 campaign (Wolf et al., 2017; <https://scalex.imk-ifu.kit.edu/>). During the measurement period, management activities included one cut (04 July 2016) and one manure application event (12 July 2016) with a load of 43.7 kg N ha⁻¹, of which 20 and 23.7 kg were in the form of organic and ammonium-N, respectively (Raiffeisen Laborservice, Ormont, Germany). The average footprint area for N₂O flux and isotope measurements is given in Figure 7

2.1.2 Environmental conditions

Rainfall was determined using four precipitation gauges (Rain collector, Davis instruments, Hayward, CA) as indicated in Figure 1 with triangles. The soil temperature was monitored at three locations across De-Fen (red squares in Figure 1) at three depths (5 cm, 10 cm and 15 cm) using PT100 sensors (IMKO, Ettlingen, Germany). Soil water content was determined within the area (locations are indicated by the dashed square in Figure 1) with five ThetaML2x probes (Delta-T Devices, Cambridge, UK), which integrate soil water content over a soil depth of 0 - 6 cm. Water filled pore space (WFPS) was calculated based on measured volumetric water contents and soil characteristics (Kiese et al., 2018). The atmospheric turbulence statistics were determined using the permanently installed micrometeorological instrumentation (Kiese et al 2018) and additional sonic anemometers installed at 6 m and 9 m above the ground. Vertical wind profiles were determined up to 1000 m above the ground in 20 m intervals using Doppler wind-lidar systems (StreamLine, Halo Photonics, Worcestershire, United Kingdom).

2.1.3 Concentrations of soil extracted NH_4^+ and NO_3^- and $\delta^{15}\text{N}-\text{NO}_3^-$

Soil samples (approx. 150 g, 2-7 cm depth) were collected twice per week in a sampling grid (mesh size 70 m) spanning the whole measuring area at the De-Fen site (dashed square Fig. 1; Wolf et al., 2017), extracted with 1M potassium chloride (KCl, Merck KGaA, Darmstadt, Germany) and stored at -18 °C. After the manure application, sampling was increased to daily time intervals (12 July 2016 – 15 July 2016), followed by further sampling on 19, 21 and 27 July 2016. The concentrations of NH_4^+ and NO_3^- were determined colorimetrically using a spectrophotometer (AGROLAB Agrarzentrum GmbH, Germany). For 116 out of 298 soil extracts described above, $\delta^{15}\text{N}-\text{NO}_3^-$ was also analysed. This subset of samples was collected at the sampling nodes in the vicinity of the flux chambers and the TREX-QCLAS sample inlet. Soil extracts and 14 KCl blanks were analysed for $\delta^{15}\text{N}-\text{NO}_3^-$ at the Stable Isotope Facility of the University of California Davis, USA using the bacterial denitrification assay (Sigman et al., 2001; Casciotti et al., 2002). The reference materials USGS 32, USGS 34, and USGS 35, as supplied by NIST (National Institute of Standards and Technology, Gaithersburg, MD) were used for data correction and additional laboratory reference materials were included to monitor and correct for instrumental drift and linearity. The standard deviation for repeated measurements of reference material was < 0.2 ‰.

2.2 Measurements of soil N_2O fluxes

Soil N_2O flux rates ($f(\text{N}_2\text{O})$) were obtained using five replicated opaque static flux chambers coupled with a gas chromatograph with an electron capture detector (GC-ECD) and operated according to a pre-defined schedule. A detailed description of the method can be found for example in Rosenkranz et al. (2006). The chambers were alternately closed and opened for 60 minutes, and each chamber was sampled every 15 minutes, resulting in 4 headspace air measurements per chamber closure time. The chamber dimensions were $50 \times 50 \text{ cm}^2$ and either 15 or 50 cm in height, depending on vegetation height. All flux chambers were deployed south of the mobile laboratory within the dashed square in Figure 1. N_2O fluxes were calculated from the concentration increase over time according to Rosenkranz et al. (2006), taking into account local air pressure and the chamber headspace temperature.

2.3 Analysis of N_2O isotopocule by TREX-QCLAS

2.3.1 Analytical procedure

The TREX-QCLAS setup used in this study for the N_2O isotope measurements was developed and described in detail by Ibraim et al. (2018), based on a previous system developed for CH_4 isotope analysis by Eyer et al. (2014, 2016). In brief, N_2O from 5 L of ambient air is extracted using the TREX device and purged into the multi-pass (76 m) cell of the spectrometer (CW-QC-TILDAS-76-CS; Aerodyne Research Inc., Billerica, USA) by means of a low flow of synthetic air (20.5 % O_2 , 79.5

% N₂, Messer Schweiz AG, Switzerland). This approach is capable of measuring the four most abundant N₂O isotopic species (¹⁴N¹⁴N¹⁶O, ¹⁴N¹⁵N¹⁶O, ¹⁵N¹⁴N¹⁶O and ¹⁴N¹⁴N¹⁸O) at approx. 90 ppm with an Allan deviation of < 0.1 ‰.

The TREX-QCLAS was operated in an air-conditioned mobile laboratory (22 - 30 °C) situated at the north end of De-Fen (Figure 1). Ambient air was continuously sampled with a flow rate of approx. 900 mL min⁻¹ from 2 m above the ground at the Eddy Covariance (EC) tower and transported to the mobile laboratory using a SERTOflex tube (~ 20 m length, 6 mm OD, SERTO AG, Switzerland). Then the sample gas was dried using a nafion drier (PermaPure Inc., USA) and subsequently pressurized to 4.5 bars using a membrane pump (PM25032-022, KNF Neuberger, Switzerland). Downstream of the pump the air was passed through a chemical trap for carbon dioxide (CO₂) and residual H₂O removal. After this pre-treatment, the air was passed into the TREX device for N₂O pre-concentration following the procedure as described in Ibrahim et al. (2018).

Maintenance demand during field application was minimized by successively using a multi-position valve (Valco Instruments Inc., Switzerland) to switch between eight chemical traps for CO₂ and H₂O removal (Figure 2). Each of the traps consisted of a stainless steel tube (12 mm OD, 350 mm length) filled with 12 g Ascarite (10 - 35 mesh, Fluka, Switzerland), bracketed with magnesium perchlorate (Mg(ClO₄)₂, 2 × 1.5 g, Fluka, Switzerland) and silane-treated glass wool (Sigma-Aldrich Chemie GmbH, Switzerland). The CO₂ extraction capacity of the Ascarite traps was found to be sufficient for > 500 L at ambient CO₂ concentrations (unpublished). To avoid CO₂ breakthrough and particularly clogging of the trap under varying CO₂ and residual H₂O concentrations, the chemical trap was changed every day.

2.3.2 Calibration strategy and data processing

The isotopic composition of ambient air was referenced against a set of standard gases (Table 2) that were periodically measured (Figure 2) to ensure long-term repeatability. The measurement routine was implemented using a customized LabVIEW programme. Initially, two standard gases (S1, S2) were analysed for a two-point delta calibration and a target (T) gas was measured to monitor the data quality (Table 2). While S1 and S2 cover the range of $\delta^{15}\text{N}^{\alpha}$ and $\delta^{15}\text{N}^{\beta}$ values of the sample gas, for $\delta^{18}\text{O}$ this is currently confined by the non-availability of suitable standard gases. Nonetheless, the implemented calibration procedure presents current best practice in particular as the linearity of the delta scale for QCLAS measurements was demonstrated already in 2008 (Waechter et al., 2008). This phase was followed by a series of four alternating S1 and ambient air sample (S) measurements. A full analytical cycle yielded 13 measurements, including four ambient air analyses, and required approx. four hours, corresponding to a measurement frequency of approx. 1 ambient air sample per hour.

Data processing was conducted as previously described by Harris et al. (2017) using Matlab (MathWorks, Inc., USA). Abundances of the four isotopocules (¹⁴N¹⁴N¹⁶O, ¹⁴N¹⁵N¹⁶O, ¹⁵N¹⁴N¹⁶O and ¹⁴N¹⁴N¹⁸O) were obtained with TDL Wintel (Aerodyne Research Inc., Billerica, USA), and isotope ratios were drift-corrected for changes observed in S1. Specifically, the isotope ratios of S1 were linearly fitted to cell pressure, cell temperature and to the goodness-of-the-TDL-fit. If this linear fit was significant (p-value < 0.05) the correction was applied to all data. These corrections were always relatively small and within the range of 0.05 – 0.2 ‰. In addition, a concentration correction was performed using a linear regression curve determined with S1 diluted in synthetic air. The concentration corrections were -0.20, 0.32 and -0.24 ‰ ppm⁻¹ for $\delta^{15}\text{N}^{\alpha}$, $\delta^{15}\text{N}^{\beta}$ and $\delta^{18}\text{O}$, respectively. Finally, delta values were calculated from isotope ratios using the two-point delta calibration based on S1 and S2. Since no international standards were available for N₂O isotopes, S1 and S2 were analysed against N₂O standards for which the isotopic composition was assigned at Tokyo Institute of Technology (Tokyo Tech) according to Toyoda and Yoshida (1999). In addition, past and ongoing inter-laboratory comparison measurements on pressurized air indicated a very good agreement with Tokyo Tech results (Mohn et al., 2014; Ostrom et al., 2018).

2.4 Source signatures of soil emitted N₂O

Source signatures of soil-emitted N₂O were interpreted using the Keeling plot approach (Keeling, 1958). Each analysis started at 7 pm on day *n* and lasted until 6 am on the consecutive day *n+1* local time (UTC +1). This procedure yielded 30 Keeling

plot derived source signatures. The uncertainty of the source signatures was assessed based on the measured isotope delta values and N₂O concentrations using a Monte-Carlo model with 200 iterations. A benchmark value of 10 ‰ for the SP standard deviation was chosen as a criterion to distinguish valid measurements, finally leading to 12 N₂O accumulation events.

For comparison, the source signatures were also calculated with the Miller and Tans (2003) approach. An in-depth description of the implementation of the Miller-Tans method is provided by Harris et al. (2017). In brief, first, a baseline is determined by averaging the data points in the lowest 5 % of the diurnal N₂O concentrations with a 5-day moving window (see SI Figure 3). The same measurement points are also used to find the baseline of the isotope delta values – isotope values are not used to flag the baseline since deviations can be both positive and negative. Subsequently, the Miller-Tans equation (eq. 2 in Harris et al. (2017)) is used to derive the source isotope signatures based on a simple linear regression within a 24-hour moving window. The uncertainty in source isotopic composition is calculated by first propagating measurement errors into all terms used in the Miller-Tans equation and then running 200 iterations assuming a normal distribution of error in all terms.

2.5 Footprint analysis with FLEXPART – COSMO simulations

The Lagrangian Particle Dispersion Model FLEXPART (Stohl et al., 2005) was adapted for input from the numerical weather prediction model COSMO (Brunner et al., 2012, Oney et al., 2015 and Henne et al., 2016) and was used on a site-scale to determine the concentration footprint of our observations. For this purpose the model was adapted by locally nudging wind profiles and micro-meteorological observations at De-Fen into the COSMO model output. The latter was taken from the operation analysis and forecast runs by MeteoSwiss with a spatial resolution of approximately 1 km × 1 km. Into these model fields observed profiles of the wind vector (composite of 2.5 m and 9 m sonic anemometer) were locally nudged using a tricubic nudging kernel with a width of 3 km, hence influencing approximately 3 grid cells around the observational site (further related information is provided by Wolf et al. (2017)). Turbulence statistics (friction velocity, Monin-Obukhov length) required by FLEXPART were taken from the observations and locally replaced the COSMO-simulated values. The effect of the nudging procedure was strongest at night and under stable boundary layer conditions, which COSMO often fails to reproduce correctly. FLEXPART was run in backward mode, tracing released model particles 24 h and generating hourly surface source sensitivities (τ_{50} (s m³ kg⁻¹); also called concentration footprint) for the location of the N₂O isotope observations. Source sensitivities were calculated on a regular longitude-latitude grid around the De-Fen site (47.825 – 47.845 °N and 11.50 – 11.51 °E) with a resolution of approximately 50 m × 50 m and for model particles from the surface to 50 m above the ground, the latter of which was also the defined minimum of the model boundary layer height. Multiplication of the source sensitivities with a surface flux and summation over the whole model domain and time of the backward integration yields the concentration increment during the period of simulation. The map of source sensitivities was used as an indicator of the extent of the observed N₂O source. Average source sensitivities were calculated for the 12 accumulation events between 6 pm and 6 am the next day.

3. Results

3.1 N₂O fluxes and soil parameters

The initial phase of the measurement campaign (10 May 2016 – 21 June 2016) was characterized by low ambient air and soil temperatures (13.5 and 15.6 °C, respectively) along with high precipitation and high WFPS values (> 5 mm d⁻¹ and > 95 %, respectively, between 10 – 21 June; Figure 3). Soil extracted NH₄⁺ and NO₃⁻ values in this period were 0.27 to 8.32 mg N l⁻¹ and 0.12 to 3.15 mg N l⁻¹, respectively. This period was also characterized by the lowest N₂O flux rates ($f(\text{N}_2\text{O})$), i.e. the mean $f(\text{N}_2\text{O})$ of all five chambers was below 70 µg N m⁻² h⁻¹. After 21 June the N₂O fluxes increased, reaching a maximum of approx. 450 µg N m⁻² h⁻¹ on 24 and 25 June. $f(\text{N}_2\text{O})$ followed a diurnal pattern with slightly higher emissions during the day but also higher nocturnal $f(\text{N}_2\text{O})$ values compared to the initial phase of the campaign. Thereafter $f(\text{N}_2\text{O})$ decreased to around 200 µg N m⁻² h⁻¹ on 29 June, before it began to steadily rise from 30 June to 12 July. After the cutting event on 4 July, NO₃⁻

concentrations increased, while NH_4^+ remained unaffected. In contrast, after the manure application on 12 July, the concentration of NH_4^+ increased immediately, while NO_3^- only accumulated slowly over the course of the following week. In this period N_2O daytime emissions also peaked at $> 900 \mu\text{g N m}^{-2} \text{ h}^{-1}$ followed by a period of variable N_2O fluxes with very low but also very high emission rates, for example 17 July and 24 July at 290 and 2400 $\mu\text{g N m}^{-2} \text{ h}^{-1}$, respectively. Two weeks after the manure application the concentrations of NH_4^+ and NO_3^- and N_2O fluxes were comparable to the period prior to manure application and cutting.

3.2 Ambient N_2O concentrations and isotopic variations

Figure 4 shows N_2O concentrations and isotopic composition ($\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$, $\delta^{18}\text{O}$) analysed between 9 June and 23 July in ambient air 2 m above the ground. In total, 612 air sample measurements (S), 150 target gas (T), 1783 anchor gas (S1) and 164 calibration gas (S2) measurements were performed (concentrations and isotopic composition of T, S1 and S2 are given in Table 2). The data gap between 27 June and 8 July was caused by a hard disk failure of the system computer. The standard deviation for repeated in-situ T measurements (undergoing identical treatment compared to S) was 0.46 ‰, 0.36 ‰, 0.59 ‰ and 1.24 ppb, for $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$, $\delta^{18}\text{O}$ and N_2O concentrations, respectively.

Apart from a small nocturnal N_2O concentration increase on 11 June, no clear variations in ambient N_2O were observed in the first three weeks of the campaign, which is in accordance with the lowest soil N_2O fluxes, as described above. On 21 June the onset of a diurnal pattern with nocturnally enhanced N_2O concentrations accompanied by co-varying $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$ and $\delta^{18}\text{O}$ values was observed. Mean N_2O concentrations were 331.62 ± 1.41 ppb during the day and elevated at night with a maximum of 429 ppb observed on 23 June. During the day, mixed surface-layer isotopic compositions of N_2O were 15.22 ± 0.42 ‰, -2.78 ± 0.34 ‰, and 45.88 ± 0.43 ‰ for $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$ and $\delta^{18}\text{O}$, respectively, thus yielding SP and $\delta^{15}\text{N}^{\text{bulk}}$ values of 17.95 ± 0.15 ‰ and 6.28 ± 0.30 ‰, respectively.

The nocturnal increase of N_2O concentrations was accompanied by a decrease in $\delta^{15}\text{N}^\alpha$ and $\delta^{15}\text{N}^\beta$, while $\delta^{18}\text{O}$ values generally increased at higher N_2O concentrations, but also showed the opposite behaviour for some events. The most extreme δ -values were 8.98 ‰, -9.66 ‰ and 50.61 ‰ for $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$ and $\delta^{18}\text{O}$. Compared to the background values, this results in a difference of 6.24 ‰, 6.88 ‰ and 4.73 ‰ for $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$ and $\delta^{18}\text{O}$, respectively.

3.3 Source signature of soil emitted N_2O and precursors

Source signatures of soil-emitted N_2O at De-Fen were calculated using the Keeling plot method (Keeling 1961, 1958) and the Miller-Tans method (Miller and Tans 2003), as shown in Figure 5. For periods complying with the quality criteria defined for the Keeling plot analysis, results of the two independent techniques agreed reasonably well, as shown in the correlation diagrams in Figure 5. Keeling plot-derived $\delta^{15}\text{N}^{\text{bulk}}$, $\delta^{18}\text{O}$ and SP values varied between -32.5 ‰ and -1.2 ‰, 38.0 ‰ and 65.0 ‰, and 8.4 and 36.8 ‰, respectively; the Miller-Tans analysis resulted in similar source signatures of -29.6 ‰ to 20.3 ‰ ($\delta^{15}\text{N}^{\text{bulk}}$), 40.7 ‰ to 84.9 ‰ ($\delta^{18}\text{O}$) and 5.1 ‰ to 35.0 ‰ (SP) for the same period. The results of the Miller-Tans method were rather scattered for periods when small changes in N_2O concentrations and N_2O isotopic composition precluded Keeling plot analysis (i.e. prior to 22 June). Values of individual Keeling plot derived source signatures can be found in Table 3.

The $\delta^{15}\text{N}-\text{NO}_3^-$ values ranged from 0.13 to 11.42 ‰. Spatial variations of $\delta^{15}\text{N}-\text{NO}_3^-$ across the De-Fen site were relatively large (Figure 5). In the first week of June $\delta^{15}\text{N}-\text{NO}_3^-$ was rather variable with very low values on 9 June but higher $\delta^{15}\text{N}-\text{NO}_3^-$ in the second week. Thereafter it decreased slowly from approx. 10 ‰ to values close to 0 ‰. After the manure application on 12 July a continuous increase of $\delta^{15}\text{N}-\text{NO}_3^-$ was observed, reaching a maximum of approx. 8 ‰ around 24 July.

4. Discussion

4.1 N₂O fluxes and WFPS

Throughout the measurement campaign, the N₂O flux rates were between 70 and 2400 µg N m⁻² h⁻¹ at De-Fen, and thus of a similar order of magnitude as reported earlier for other intensively fertilized grasslands (Merbold et al., 2014; Wolf et al., 2015; Schäfer et al., 2012). $f(\text{N}_2\text{O})$ showed a clear dependence on the soil water content, with maximum emissions at 90 % WFPS (Figure 6). While for drier soils (WFPS < 60 %) lower but still substantial N₂O fluxes were detected, fluxes declined to their lowest values near water saturation, i.e. when WFPS was close to 100%. The observed relationship between $f(\text{N}_2\text{O})$ and WFPS ($R^2 = 0.92$) can be best described with an exponential function with two terms as given by equation 4:

$$(\text{N}_2\text{O})_{\text{Fitted}} = a \cdot \exp(b \cdot \text{WFPS}) + c \cdot \exp(d \cdot \text{WFPS}) \quad (4)$$

where the coefficients are best approximated by $a = -5.09\text{e-}06$, $b = 0.19$, $c = 15.86$ and $d = 0.04$. This relationship is a strong indicator that the activity of the main source process increases with the soil water content, which is characteristic for denitrification and nitrifier-denitrification (Wrage et al., 2001; Decock and Six, 2013a). Furthermore, the decline of N₂O fluxes at very high WFPS values is in line with this interpretation, because the last step of the denitrification pathway, N₂O reduction to N₂, is only active under anoxic conditions. This shift from nitrification-dominated to denitrification-dominated N₂O production with increasing WFPS should be reflected in the isotopic signature of the residual N₂O. Indeed, there is a tendency towards high SP values under low (indicating higher nitrification contribution) and high WFPS values (indicating higher N₂O reduction to N₂ rates) (Figure 6). The peak $f(\text{N}_2\text{O})$ was observed on 23 July, a day after a severe precipitation event. The N₂O emission rate of this peak event was 2415 µg N m⁻² h⁻¹ (average of five replicate flux chambers). Unfortunately, this event cannot be discussed in terms of N₂O isotopocules due to termination of TREX-QCLAS measurements after 22 July 2016.

4.2 On-site performance of TREX-QCLAS

The short term repeatability over 10 target gas (T) measurements was 0.25 ‰, 0.31 ‰, 0.30 ‰ and 0.25 ppb for $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$, $\delta^{18}\text{O}$ and N₂O concentration, respectively. This is sufficient to track changes in ambient N₂O close to emission sources as described in this study and superior to most IRMS and laser spectrometer systems (Mohn et al., 2014), but slightly inferior to laboratory experiments using the same system (Ibraim et al., 2018) or earlier versions of preconcentration – QCLAS based approaches (Mohn et al., 2012; Harris et al., 2014; Wolf et al., 2015). The slightly lower repeatability was due to a more compact spectrometer design, which allowed for the integration of the system in a 19-inch rack at the cost of a higher optical noise level and larger drifts due to the harsher conditions in the mobile lab, i.e. higher temperature variations and vibrations.

4.3 Variability of N₂O concentrations and isotopic composition above De-Fen

During the day, the atmospheric boundary layer (ABL) and the lowest part of the ABL (surface layer) are well mixed due to turbulence arising from buoyancy and wind shear (Ibbetson, 1994). At night, stable stratification attenuates vertical mixing processes, also leading to generally lower horizontal wind speeds. Both entail accumulation of local soil-emitted N₂O in the surface layer. For this reason, daytime N₂O concentrations and isotopic composition mostly reflect the atmospheric background, while the nighttime accumulation reflects the influence of soil-emitted N₂O.

Variations in N₂O, SP, $\delta^{15}\text{N}^{\text{bulk}}$ and $\delta^{18}\text{O}$ follow a diurnal pattern that is in agreement with the variations of N₂O concentrations depicted in Figure 4. Accordingly, average daytime N₂O concentrations, $\delta^{15}\text{N}^{\text{bulk}}$, SP and $\delta^{18}\text{O}$ of 331.6 ± 1.41 ppb, 6.28 ± 0.30 ‰, 17.95 ± 0.15 ‰ and 45.54 ± 0.27 ‰, respectively, are in agreement with background measurements at other sites, such as Dübendorf, Switzerland (N₂O: 325.8 ± 3.3 ppb, $\delta^{15}\text{N}^{\text{bulk}}$: 6.53 ± 0.14 ‰, SP: 17.95 ± 0.40 ‰, $\delta^{18}\text{O}$: 44.41 ± 0.13 ‰ (Harris et al., 2017)), or Hateruma Island, Japan (decadal mean values for the northern hemisphere of $\delta^{15}\text{N}^{\text{bulk}}$: 6.65 ‰, SP: 18.44 ‰, $\delta^{18}\text{O}$: 44.21 ‰ (Toyoda et al., 2013)). Observed changes in N₂O concentrations and isotopic composition at night are within

the range of previous studies from agricultural sites (Wolf et al., 2015; Toyoda et al., 2011), but clearly higher than variations measured at 13 m or 95 m above ground in an urban or suburban environment (Harris et al., 2014; Harris et al., 2017).

4.3.1 N₂O footprints

At night, within a stable nocturnal boundary layer, vertical wind speeds and hence tracer transport are low, while lateral wind speeds can be high and constituents like N₂O can be transported over larger distances. As a result, N₂O emissions from other land uses or land cover have contributed to the observed N₂O isotopic composition. To assess the influence of other land use / land cover, the concentration footprint calculated with FLEXPART-COSMO was assessed for periods where the Keeling plot and Miller-Tans approaches were applied. The FLEXPART-COSMO simulations indicate that between 15 % and 45 % of the source sensitivity originates from areas within approximately 300 m to 700 m distance to the sample inlet, respectively (isolines in Figure 7). Highest source sensitivities which amounted to 30% of the total sensitivity were calculated for areas predominately covered by grassland or pasture. Although sources outside this local area contributed more than half of the total emissions and included other land cover such as arable land and forest, the impact of individual source areas was smaller by several orders of magnitude, hence having much less impact on the isotopic source signature. While more than 95 % of the area covered by the 15 % isopleth (bold isolines in Figure 7) corresponds to grasslands, the residual 5 % belongs to a wetland to the northeast of the De-Fen (Figure 7). Furthermore, the 30 and 45 % isopleth's surfaces include approximately 20 % of mixed forest and 5 % wetland along with around 75 % under grassland, underlining further that sensitivities were highest for grassland emitted N₂O.

In addition to the N₂O footprint, the temporal trend of the N₂O concentration at the sampling point was simulated using individual source sensitivities and assuming a homogeneous N₂O flux identical to measured local N₂O fluxes (see section 2.2). Simulated N₂O concentrations were in very good agreement with N₂O concentrations measured by the TREX-QCLAS (SI Figure 10), indicating that the simulated footprint, attributing a substantial part of the emissions to the De-Fen grassland, is representative of the measurement site. Furthermore, N₂O concentration measurements obtained with TREX-QCLAS were in a good agreement with the local N₂O flux measurements (SI Figure 2).

4.4 N₂O source signatures and implicated processes

4.4.1 Comparison Miller–Tans and Keeling plot techniques

Figure 5 shows the temporal trends of the N₂O source signatures, illustrating the potential of this quasi-continuous dataset to identify process changes induced by management events or changing environmental parameters. The dataset also enables a direct comparison of two approaches for extracting the isotopic composition of N₂O emitted from soils based on surface layer measurements, namely the Keeling plot and the Miller-Tans approach. In the first three weeks of the campaign, i.e. under conditions of low N₂O fluxes, the Keeling plot results did not pass the quality criterion, and the source signatures, i.e., the calculated isotopic composition of N₂O emitted from soil ($\delta^{15}\text{N}^{\text{bulk}}$, SP, $\delta^{18}\text{O}$) derived from the Miller-Tans method showed relatively large uncertainties and amounted to 2.8 – 9.8 ‰, 2.3 – 10.6 ‰ and 4.6 – 12.9 ‰, respectively (shaded areas in Figure 5). Thereafter, N₂O source signatures as estimated with the Keeling plot and Miller–Tans approaches show a comparable trend and mostly agree within the indicated uncertainties without systematic deviations. Overall, the agreement (R^2 value) between the Miller–Tans and Keeling plot results is best for $\delta^{15}\text{N}^{\text{bulk}}$ (0.84), intermediate for SP (0.57) and weakest for $\delta^{18}\text{O}$ (0.39) (Figure 5). The weaker correlation for $\delta^{18}\text{O}$ -N₂O can be explained by a lower analytical data quality as compared to $\delta^{15}\text{N}^{\text{bulk}}$ and SP, exemplified by a higher standard deviation for repeated measurements of the target gas (0.59 ‰ for $\delta^{18}\text{O}$ and 0.41 ‰ for $\delta^{15}\text{N}^{\text{bulk}}$ and SP). The reasoning behind this effect might be that the calibrated range of $\delta^{18}\text{O}$ values (S1, S2) does not cover the isotopic composition of the target and sample gases, because no suitable calibration gas was available. A difference of 7

‰ in $\delta^{18}\text{O}$ between the two calibration gases is rather small, leading to a relatively high uncertainty in the respective calibration factors.

The base calculation for both the Keeling plot and Miller-Tans is identical and the two methods would yield identical results if every term was known perfectly. However, the uncertainty term is treated differently in the two approaches. The Miller-Tans approach calculates source signatures for individual sample gas measurements (SI Figure 3) and, thus, may be the better choice when the source process or the background N_2O isotopic composition changes rapidly, i.e. during a 24 hour period. However, the large fluctuations of the source signatures (up to 100 ‰, Figure 5) extracted by the Miller-Tans approach prior to 22 June indicate that the uncertainty estimated for the Miller-Tans approach is too optimistic and needs to be reassessed. In addition, it is noteworthy that the Keeling plot approach as presented here, implicitly considers changes in background N_2O concentration from day to day, since one Keeling plot (comprising both N_2O background and N_2O variations) was carried out per day. Therefore, we conclude that the Keeling plot method remains a robust way of estimating source signatures of N_2O emitted from a predominantly agricultural landscape as the one presented here, where variations in background N_2O compared to source contributions can be neglected and changes in source processes generally occur only on long timescales as a response to changes in environmental conditions (e.g. WFPS).

4.4.2 Range of N_2O source signatures

Typical source signatures of biologically produced N_2O are approx. $-40 - 0$ ‰ and $0 - 40$ ‰ for $\delta^{15}\text{N}^{\text{bulk}}$ and SP, respectively, while $\delta^{18}\text{O}-\text{N}_2\text{O}$ are around 40 ‰ and 70 ‰ for N_2O emitted through grasslands or wetlands, respectively (Toyoda et al., 2017). Accordingly, the $\delta^{15}\text{N}^{\text{bulk}}$ values found in our study are well within literature values of grassland emitted N_2O , while the SP values are rather high. Interestingly, the obtained $\delta^{18}\text{O}$ values were strongly elevated on some occasions and close to those found by Ostrom et al. (2007) in a pure culture experiment in which approx. 80 % of produced N_2O was reduced to N_2 . A correlated increase of the SP, $\delta^{15}\text{N}^{\text{bulk}}$ and $\delta^{18}\text{O}$ values, with SP values potentially larger than the endmember value of 32.8 ± 4 ‰, can be explained by N_2O reduction to N_2 , which is particularly active under wet and anaerobic soil conditions (Wrage et al., 2004; Lewicka-Szczebak et al., 2017). Thus, isotopic fractionation during partial N_2O reduction must be taken into account in order to apportion isotopic source signatures of soil-emitted N_2O (Lewicka-Szczebak et al., 2017; Verhoeven et al., 2018). The fractionation factors $\epsilon^{18}\text{O}/\epsilon^{15}\text{N}^{\text{bulk}}$, $\epsilon^{18}\text{O}/\epsilon\text{SP}$ and $\epsilon^{15}\text{N}^{\text{bulk}}/\epsilon\text{SP}$ have been determined in a number of incubation experiments and it has been suggested that their ratios (2.4, 2.8 and 1.2, respectively) may be indicators for N_2O reduction (Koba et al., 2009). It has to be mentioned, however, that fractionation factors may deviate depending on environmental conditions (Koster et al., 2013) or even over the course of a single experiment due to multiple reaction steps involved (Haslun et al., 2018). Furthermore, $\delta^{18}\text{O}-\text{N}_2\text{O}$ of denitrification is affected by oxygen exchange between reaction intermediates (NO_3^- , NO_2^-) and soil water as a function of WFPS (Well et al., 2008; Kool et al., 2011).

4.4.3 N_2O source partitioning using SP and $\Delta\delta^{15}\text{N}^{\text{bulk}}$

An SP-versus- $\Delta\delta^{15}\text{N}^{\text{bulk}}$ (Figure 8(a)) mapping approach as originally presented by Koba et al. (2009) was used to interpret the Keeling plot-derived source signatures with respect to the possible underlying N_2O producing and consuming processes. Here, $\Delta\delta^{15}\text{N}^{\text{bulk}}$ denotes the $\delta^{15}\text{N}$ difference between the product N_2O and its substrate (NO_3^-). While Koba et al. (2009) applied this approach in the framework of a groundwater study where NO_3^- was the only available N_2O substrate, the grassland research site De-Fen showed rather high NH_4^+ concentrations (Figure 3(b)). Therefore, the N_2O substrate at De-Fen might be either NH_4^+ for N_2O emitted by nitrification (N) and nitrifier-denitrification (ND) or NO_3^- from fungal denitrification (FD) and bacterial denitrification (BD). Within the framework of this study, it was assumed that $\delta^{15}\text{N}-\text{NH}_4^+$ and $\delta^{15}\text{N}-\text{NO}_3^-$ values were in a similar range, i.e. approx. $0 - 15$ ‰, in agreement with the literature (Mook, 2002; Holland, 2011). We thus used only the $\delta^{15}\text{N}-\text{NO}_3^-$ values for the substrate isotopic composition. For periods where N_2O emissions were present but no $\delta^{15}\text{N}-\text{NO}_3^-$

values were obtained, the $\delta^{15}\text{N}-\text{NO}_3^-$ values were approximated by linear interpolation. In addition, the concept of Koba et al. (2009) was modified for the two N_2O -emitting domains FD/N and BD/ND using literature values as provided in Table 4. For simplicity, in the remaining part of this section the flux-weighted average values of SP and $\Delta\delta^{15}\text{N}^{\text{bulk}}$ are discussed, while values of individual events can be found in Table 4. Plotting SP vs. $\Delta\delta^{15}\text{N}^{\text{bulk}}$ revealed that there was a trend of increasing SP with decreasing $\Delta\delta^{15}\text{N}^{\text{bulk}}$ values. As indicated in Figure 8 with orange crosses, the flux-averaged SP, $\Delta\delta^{15}\text{N}^{\text{bulk}}$ and $\delta^{18}\text{O}$ values were 23.4, 19.0 and 62.3 ‰, respectively. The slope of the SP-versus- $\Delta\delta^{15}\text{N}^{\text{bulk}}$ linear regression line of -0.85 (solid red arrow in Figure 8(a)) is in agreement with literature values (-0.83 and -1.1) given by Koba et al. (2009) and Toyoda et al. (2017) for partial N_2O -to- N_2 reduction. This observed negative slope, which is in contrast to the grey shaded area anticipated for mixing of N_2O produced by BD/ND and FD/N indicates a major contribution of BD/ND and N_2O reduction to N_2 , the final reaction step in the anoxic reduction of NO_3^- to N_2 . The suspected predominance of denitrification agrees with previous field studies presented by Opdyke et al. (2009), Wolf et al. (2015) and Mohn et al. (2012). SI Figure 9 illustrates contributions of FD/N on the total N_2O emissions for individual accumulation events.

A semi-quantitative source partitioning can be calculated assuming average SP (-0.9 ‰) and $\Delta\delta^{15}\text{N}^{\text{bulk}}$ (18.5 ‰) values for N_2O production by BD/ND and a fixed SP/ $\Delta\delta^{15}\text{N}^{\text{bulk}}$ ratio of -0.83 for N_2O reduction to N_2 (Figure 8(a)). Correspondingly, the simultaneous SP increase and $\Delta\delta^{15}\text{N}^{\text{bulk}}$ decrease during N_2O reduction to N_2 can be interpreted in terms of the $\text{N}_2\text{O}/(\text{N}_2\text{O}+\text{N}_2)$ product ratio using the Rayleigh fractionation approach of Mariotti et al. (1981). Accordingly, a 90 % reduction of N_2O translates into an increase in SP by 13.6 ‰ assuming an SP fractionation factor (ϵ_{SP}) of -5.9 ‰ in accordance with Ostrom et al. (2007). Using a single ϵ_{SP} value is a simplification, however, as fractionation factors might vary e.g. depending on WFPS (Jinuntuya-Nortman et al, 2010) and $\text{N}_2\text{O}/(\text{N}_2+\text{N}_2\text{O})$ product ratio (Lewicka-Szczebak et al., 2015). A deviation of source signatures from the SP/ $\Delta\delta^{15}\text{N}^{\text{bulk}}$ line can then be interpreted in terms of addition of N_2O produced by additional processes, e.g. FD/N. This interpretation is supported by the relationship between SP and WFPS (Figure 6). Accordingly, the lowest SP values were found at intermediate to high soil water contents (80 – 90 % WFPS) along with maximum N_2O fluxes, while SP values increased towards lower WFPS values, due to the increasing contribution of nitrification, and towards higher WFPS values, due to increasing N_2O reduction to N_2 . Furthermore, the fraction of FD/N-derived N_2O increased with NH_4^+ fertilization, also in agreement with the literature (Toyoda et al., 2011; Koster et al., 2011).

A semi-quantitative interpretation of isotope signatures can be done assuming average source signature values (SP and $\Delta\delta^{15}\text{N}^{\text{bulk}}$) and considering two scenarios (see also SI Figure 4): in scenario 1, BD/ND-produced N_2O is partially reduced to N_2 and the residual N_2O (rN_2O ; remaining N_2O after N_2O reduction to N_2) is then mixed with N_2O derived from FD/N (path of solid arrows in Figure 8(a)). In scenario 2, N_2O from BD/ND is mixed with FD/N-derived N_2O before a part of the mixed N_2O is reduced to N_2 (path of dashed arrows in Figure 8(a)). While these scenarios result in equal source signatures, they assign a different relative contributions of the processes involved. The respective N_2O to N_2 reduction rates can be calculated based on the associated shift in SP, which corresponds to the y component of each of the red arrows in Figure 8(a). For convenience, here we only discuss the reduction rates and source partitioning of the two scenarios for flux-averaged SP and $\Delta\delta^{15}\text{N}^{\text{bulk}}$ values (23.4 and 19.0, respectively), while those of individual events could be estimated analogously (related results given in Table 3). Assuming scenario 1, the SP shift caused by N_2O reduction is equal to 18.0 ‰; resulting in a reduction rate of approx. 95 % assuming $\epsilon_{\text{SP}} = -5.9$ ‰. The remaining 5.4 ‰ SP shift can be explained as the result of mixing the rN_2O with FD/N-derived N_2O . A 5.4 ‰ SP shift corresponds to approx. 38 % contribution of FD/N-derived N_2O with the residual N_2O emitted by BD/ND. Note that the FD/N contribution is less than 1 % when accounting for the total N_2O production, i.e. the N_2O before partial reduction to N_2 . In contrast, in scenario 2, the FD/N-derived N_2O is mixed with BD/ND-derived N_2O first. This mixing induces a SP shift of approx. 13.0 ‰, which is given by the y-coordinate of the intersection of the mixing-line and the reduction line of the mean source signatures. However, since no N_2O reduction to N_2 has occurred yet at this point,

this shift corresponds to 39 % contribution of FD/N to total N₂O production. The remaining 10.4 ‰ SP shift is then subject to reduction of N₂O to N₂, corresponding to approx. 83 % reduction of N₂O to N₂.

4.4.4 N₂O source partitioning using SP and $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$

Identification of the processes producing and consuming N₂O was also done using an adapted SP-versus- $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ mapping approach (Figure 8(b)) as previously presented by Lewicka-Szczebak et al. (2017). This approach was suggested because the values of $\delta^{18}\text{O}$ -N₂O from BD/ND and FD/N are less variable than those of $\delta^{15}\text{N}$ -N₂O. The lower variability is indicated by the smaller BD/ND and FD/N boxes in Figure 8(b) compared to Figure 8(a); thus, using this approach reduces the uncertainty of the calculated relative contributions of the different processes as the boxes are used to span the mixing line. $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ for denitrification is considered to be **relatively stable constant** (Lewicka-Szczebak et al., 2016), in particular under high WFPS associated with close to 100 % oxygen exchange between soil water and reaction intermediates (Kool et al., 2011). The approach was slightly modified using the values presented in Table 4 to match the FD/N and the BD/ND domains according to Figure 8(a) with regard to SP values. In this approach, $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ represents the difference between the $\delta^{18}\text{O}$ values of the product (N₂O) and the substrate (H₂O). Since no measurements for $\delta^{18}\text{O}$ -H₂O were available, we used a value of -8 ‰ in accordance with Xiahong et al. (2009). Values obtained for $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ were clearly higher than previously observed in grassland soils (Wrage et al., 2004; Wolf et al., 2015; Snider et al., 2012) but particularly close to $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ values from studies related to wetland ecosystems (Toyoda et al., 2017; Snider et al., 2009), likely reflecting the fact that the study site was in the vicinity of a wetland (see section 4.3.1 and Wolf et al., 2017) and often flooded due to extraordinary precipitation events throughout the measurement period.

In the mapping approach suggested by Lewicka-Szczebak et al. (2017), two scenarios are considered to estimate the shift in N₂O isotopic composition due to N₂O reduction to N₂. In Figure 8(b), the y-component of the red arrows represents the SP shift that was caused by N₂O reduction to N₂. Knowledge of the degree to which SP has been changed due to fractionation during N₂O reduction is a prerequisite for determining the relative contributions of the process groups BD/ND and FD/N using a simple mixing model and the SP values given in Table 4. Scenario 1 assumes that BD/ND-derived N₂O is partly reduced to N₂ before mixing with N₂O originating from FD/N, while scenario 2 assumes the reverse order (i.e. first mixing, then N₂O reduction). The two scenarios yield different reduction rates and proportions of BD/ND- versus FD/N-derived N₂O, although final N₂O source signatures are identical. A quantitative estimate of source contributions was conducted for the flux averaged mean values of 23.4 and 62.3 ‰ for SP and $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ as follows: using scenario 1 (depicted with solid arrows in Figure 8(b)), N₂O reduction to N₂ has led to an SP shift of approx. 17.3 ‰, which corresponds to approx. 95 % N₂O reduction. The residual SP shift of 6.1 ‰ would be caused by the mixing of FD/N-derived N₂O with the rN₂O, corresponding to approx. 19 % FD/N-derived N₂O compared to BD/ND. The 19 % mentioned here only accounts for the mixing with the rN₂O but not for the initially produced N₂O. Taking into account that 95 % of the N₂O initially produced was reduced to N₂ reveals that the FD/N contribution to total N₂O production was below 1 %. In contrast, in scenario 2, the FD/N-derived N₂O is mixed into the N₂O pool before N₂O reduction to N₂ has occurred. Therefore, approx. 29 % FD/N-derived N₂O is needed to account for a 16 ‰ SP shift in the produced N₂O. In this case, the residual SP shift of 9 ‰ is due to N₂O reduction, corresponding to a 79 % reduction rate with $\epsilon_{\text{SP}} = -5.9$ ‰.

4.4.5 Comparison of the results obtained with the SP-vs.- $\Delta\delta^{15}\text{N}^{\text{bulk}}$ and SP-vs.- $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ approaches

In summary, the two scenarios lead to different calculated relative amounts of N₂O produced by BD/ND and FD/N as well as the emissions ratio of N₂O to N₂. The average contribution of FD/N to the N₂O emissions was 42 and 34 % according to the SP-vs.- $\Delta\delta^{15}\text{N}^{\text{bulk}}$ and SP-vs.- $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ approaches, respectively (distributions given in SI Figure 8, temporal trend given in SI Figure 9). However, regardless of the approach and scenario, the obtained rN₂O values were very low, indicating

that N₂O reduction played a major role. The median of the rN₂O values obtained with the SP-vs.- $\Delta\delta^{15}\text{N}(\text{NO}_3^-/\text{N}_2\text{O})$ approach was 0.02 for scenario 1 and 0.10 for scenario 2. Utilizing the SP-vs.- $\Delta\delta^{18}\text{O}(\text{N}_2\text{O}/\text{H}_2\text{O})$ approach, those values were even slightly lower and corresponded to 0.01 in scenario 1 and 0.02 in scenario 2 (SI Figure 5). Interestingly, the two rN₂O values calculated for scenario 1 with the two approaches were highly correlated, while those for scenario 2 were not correlated (SI Figure 5). This indicates that scenario 1 more likely occurred at our site.

The rN₂O values were also compared to the WFPS (SI Figure 6) and to the ambient temperature (SI Figure 7). A positive correlation should be expected between WFPS and the N₂O reduction rates, resulting in a negative correlation between WFPS and rN₂O values. However, observed rN₂O values did not reflect this hypothesis. Similarly, one could expect a positive correlation between rNit (the fraction of measured N₂O originating from fungal denitrification or nitrification, therefore with high SP values) and rN₂O, since the contributions of fungal denitrification and nitrification should be higher under conditions that are disadvantageous for N₂O reduction. However, also this hypothesis was refuted by these results.

Our findings confirm that natural abundance isotope studies of N₂O provide a way to trace N₂O production / destruction pathways, in particular when combined with supportive parameters or isotope modelling approaches (Denk et al., 2017). However, the complexity of N₂O production pathways could not be fully accounted for, in particular abiotic processes; for example, N₂O production by NH₂OH oxidation (Heil et al., 2014) or NO₂ reduction (Wei et al., 2017a) were not considered. These reactions yield N₂O with high (34 – 35 ‰) or variable (8 – 12 ‰) SP and might therefore be falsely interpreted as nitrification-derived N₂O. In addition, the approach cannot resolve individual processes with high SP, i.e. fungal denitrification versus nitrification, or low SP, i.e. heterotrophic versus nitrifier denitrification, due to overlapping source signature regions. Furthermore, nitrite (NO₂⁻) and nitric oxide (NO) could have acted as the substrate instead of NO₃⁻, leading to different fractionation factors from those incorporated for NO₃⁻.

4.4.6 Effect of manure application on the source signatures

In addition to the mapping approaches discussed above, N₂O source signatures can be interpreted with respect to management events. After the manure application on 12 July and rainfall events in the days thereafter a strong shift to lower SP and $\delta^{15}\text{N}^{\text{bulk}}$ values was observed (Figure 5). The negative shift in $\delta^{15}\text{N}^{\text{bulk}}$ might be explained by changes in the isotopic composition of the applied precursors, by an enhanced fractionation due to higher substrate availability or changes in process conditions (e.g. WFPS, see sections above). However, since SP is considered to be process-specific and substrate-independent (Yoshida and Toyoda, 2000), it should not change as a response to a change in the substrate isotopic composition or by enhanced fractionation. There are two alternative explanations for the lower SP and $\delta^{15}\text{N}^{\text{bulk}}$ values. The increase in NH₄⁺ concentration after manure application was followed by an increase of NO₃⁻ concentration. This indicates a stimulation of nitrification. An increase of N₂O production due to nitrification would be associated with higher SP values. However, the nitrate produced during nitrification may have been used as substrate for denitrification, given the increase in WFPS due to intensive rainfall events. While N₂O is an obligatory product of denitrification, and only a by-product of nitrification, the N₂O yield of denitrification may have been higher, and the increase of SP due to nitrification may have been outweighed by the decrease of SP due to denitrification. Secondly, N₂O reduction to N₂ could be slightly reduced due to an elevated NO₃⁻ availability (Wang et al., 2013). A parallel increase in WFPS and N₂O flux rates after the manure application combined with low FD/N fraction in the period 17 July to 22 July supports the hypothesis that both effects might have contributed to a decrease in SP values.

5. Conclusions

Real-time and in-situ N₂O concentration and isotope measurements were successfully performed at a temperate humid grassland site in Southern Germany with a coupled preconcentration technique and quantum cascade laser absorption spectroscopy (TRES-QCLAS) based method in a two-month period between June and July 2016. **Replicate in-situ**

measurements of a pressurized air tank demonstrated a short term repeatability of the TREX-QCLAS system of 0.25 ‰, 0.31 ‰, 0.30 ‰ and 0.25 ppb for $\delta^{15}\text{N}^{\alpha}$, $\delta^{15}\text{N}^{\beta}$, $\delta^{18}\text{O}$ and N_2O concentration, respectively. Accuracy of results was assured using a two point calibration that entirely spanned the range of obtained $\delta^{15}\text{N}^{\alpha}$ and $\delta^{15}\text{N}^{\beta}$ values, however, did not fully cover the range of obtained $\delta^{18}\text{O}$ values. This is current best practice, as no suitable reference gases are available, but might lead to a somewhat

5 larger uncertainty for $\delta^{18}\text{O}\text{-N}_2\text{O}$. Concentrations of soil-extracted NH_4^+ , NO_3^- and $\delta^{15}\text{N}\text{-NO}_3^-$ values were taken into account to interpret the N_2O measurements. This study provides new insights into the isotopic composition of grassland-emitted N_2O under changing soil environmental and management conditions. Our results support previous observations that bacterial denitrification/ nitrifier denitrification (BD/ND) is the dominant N_2O -emitting source in permanent grassland soils. The measured N_2O isotopic composition, in particular the intramolecular isotopic composition, or site preference (SP), can be
10 explained by taking into account partial N_2O reduction to N_2 . Two distinct approaches were used to estimate the relative contributions of BD/ND and FD/N as well as the N_2O reduction rates. The average FD/N contribution to the total N_2O emissions was 42 and 34 % with the SP-vs.- $\Delta\delta^{15}\text{N}^{\text{bulk}}$ and SP-vs.- $\Delta\delta^{18}\text{O}$ approaches, respectively, indicating that denitrification dominated the N_2O emissions. N_2O reduction rates were estimated by calculating the residual N_2O fractions (rN_2O), i.e. the fraction of remaining N_2O after N_2O reduction to N_2 has occurred. Two distinct scenarios were considered for each of the two
15 approaches, resulting in the four rN_2O values of 0.02, 0.10, 0.02 and 0.01. The low values underline both the dominant role of denitrification in N_2O production at the grassland site and the large extent to which N_2O reduction occurred during the measurement period.

This study demonstrates the suitability of the TREX-QCLAS for in-situ analysis of the isotopic composition of soil-emitted N_2O in terrestrial ecosystems. While the observations presented here integrate N_2O fluxes and thus source processes at the plot
20 scale, the interpretation of source processes in future studies will be resolved at smaller spatial scales, for example by a combination of TREX-QCLAS with static flux chambers and the implementation of an isotopic biogeochemical soil model. In particular, an approach based on the combination of the TREX-QCLAS method with static flux chambers would allow us to distinguish between the two scenarios (reduction then mixing vs. mixing then reduction) discussed in this study.

Notes: i) 29.8 and 34.5 refer to the 0.25 and 0.75 quantiles of all values compiled by Denk et al. (2017) in Table S12 for the indices 1 – 3. iii) Lowest absolute isotope effect (η) of NO_3^- reduction to N_2O by fungal denitrification as found by Rohe et al. (2014). iv) Taken from Koba et al. (2009) (referring to Yoshida (1988))

7.3 List of figure captions

Figure 1 Map of research site De-Fen with nearby farm buildings (yellow), streets and country lanes (grey) , ditches (blue), the mobile laboratory (filled red square), 2-m sample inlet for TREX-QCLAS measurements, (red dot), area of flux chambers and soil water content measurements (dashed red square), precipitation gauges (open triangles) and location of PT-100 sensors (open squares)..... 19

Figure 2 Instrumental setup for semi-continuous analysis of N_2O isotopes by coupled preconcentration laser spectroscopy (TREX-QCLAS) (Ibraim et al., 2018), including peripherals for the conditioning of the sample gas. Consecutive sample gas treatments include dehumidification by permeation drying, adjustment of sample gas pressure with a pressure release valve after the membrane pump, and CO_2 / H_2O removal using Ascarite / $\text{Mg}(\text{ClO}_4)_2$ traps and filtering for particles using a sintered metal filter. An automatized multiposition valve enables us to switch between eight different Ascarite traps and thus reduces the maintenance effort to one visit per eight days. The indicated gases are: target gas (T), synthetic air (SA), standard gas 1 (S1) and standard gas 2 (S2). CO is removed from the analyte gases using a Sofnocat catalyst (type 423, Molecular Products LTD). At the top right, a full measurement cycle is given. Letters on the y axis correspond to different gas types: standard 1 (S1), standard 2 (S2) sample (S) and target (T) gases. The x axis gives the elapsed time in minutes. The full measurement cycle lasts approx. four hours, which results in a frequency of approx. 1 hr^{-1} for ambient air measurements. 19

Figure 3 (a) Average N_2O flux ($f(\text{N}_2\text{O})$) as measured by five replicate flux chambers coupled to a GC-ECD. (b) Concentration of $\text{NH}_4^+ - \text{N}$ and $\text{NO}_3^- - \text{N}$. Up to 8 nodes across the De-Fen site were sampled twice per week, except in the week of fertilization, when sampling frequency was increased. Therefore, variability within a sampled day refers to spatial variability across the De-Fen site on the given day. (c) Observed WFPS (red) and precipitation (blue). (d) Observed ambient (2 m above ground) and soil (2 - 6 cm below ground) temperature. The blue dashed line indicates a cutting event and the red line indicates a manure application. 20

Figure 4 Time series of N_2O concentrations (a), $\delta^{15}\text{N}^\alpha$ (b), $\delta^{15}\text{N}^\beta$ (c) and $\delta^{18}\text{O}$ (d), respectively. The left axes give concentrations and isotope delta values on the respective scales, while the right axes depict the difference to background values ($\Delta X = X_{\text{measured}} - X_{\text{background}}$, where X refers to N_2O , $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$ or $\delta^{18}\text{O}$, respectively). At the top right, histogram plots of the four quantities are given. Coloured symbols indicate ambient air samples (S) from 2 m above ground, and black symbols refer to the corresponding measurements of the target gas (T, Table 2). Shaded areas indicate one standard deviation (σ) as calculated for three consecutive measurements of T. Standard deviations for the complete measurement period are given on the right, in coloured font for S and in black for T. The vertical blue dashed lines indicates a cutting event on 04 July 2016, while the red dashed line indicates a manure application on 12 July 2016. 21

Figure 5 Temporal trend of $\delta^{15}\text{N}$ of soil-extracted NO_3^- at eight different nodes (N1-N8) near the N_2O flux and isotope measurements at De-Fen, indicating large spatial variability. In (a), concentration-weighted average values (red filled symbols)

and their uncertainty (one standard deviation) are given. Source signatures (b) $\delta^{15}\text{N}^{\text{bulk}}$, (c) SP and (d) $\delta^{18}\text{O}$ of soil-emitted N_2O derived from the Miller and Tans (2003) approach (red crosses) and the Keeling (1961, 1958) plot approach (blue filled symbols) are given. Uncertainties are indicated as pale red shaded areas for the Miller-Tans approach and error bars for the Keeling plot approach (one standard deviation with a Monte Carlo model). The blue dashed line shows the cutting event, while

5 the red dashed line indicates the manure application. Three panels on the right: correlation diagram of results derived from the Miller and Tans (2003) and the Keeling (1961, 1958) plot approaches. The dashed line corresponds to the 1:1 slope. 22

Figure 6 (a) Noon-to-noon average N_2O flux rates $f(\text{N}_2\text{O})$ versus water filled pore space (WFPS) from the grassland site De-Fen. Indicated uncertainties represent variations of $f(\text{N}_2\text{O})$ and WFPS within one day. Results for individual chambers are given in SI Figure 1. N_2O fluxes were highest at 85 – 92 % WFPS. The red dashed line corresponds to a two-term exponential

10 fit of the data shown here. (b) SP as a function of WFPS. Lowest SP values were found in the range of 85 – 95 % WFPS, which corresponds to the highest N_2O fluxes. The red dashed line depicts a double exponential fit of the data shown here (this fit was not significant). The model used to fit the data corresponds to $y = a \cdot \exp(b \cdot x) + c \cdot \exp(d \cdot x)$ (coefficients a , b , c and d are given in the main text). 22

Figure 7 The average footprint area as calculated by the FLEXPART-COSMO model. The model was driven with local wind

15 vectors and observed N_2O flux rates, and indicates a major contribution of soils south-west of the ambient air inlet. The source sensitivities Tau (τ) are given as the product of residence time (in seconds) and inverse atmospheric density (in $\text{m}^3 \cdot \text{kg}^{-1}$). Isolines enclose the areas of largest source sensitivities summing up to 15, 30 and 45 % (decreasing thickness of lines) of the total simulated source sensitivity. The dashed rectangle indicates the area depicted in Figure 1. Individual source signatures for the 12 events are provided in the supplements (SI Figure 11). 23

20 Figure 8 Source signatures of soil-emitted N_2O for 22 to 24 June (stars 1-3), July 9 to 12 (squares 6, 9, 11 and 12) and July 17 to 21 (hexagons 4, 5, 7, 8 and 10). The colour coding of the symbols refers to WFPS, where blue corresponds to high and red corresponds to low WFPS (exact values in Table 3). The source signatures of fungal denitrification- and nitrification-derived N_2O (FD/N) and bacterial denitrification- and nitrifier denitrification-derived N_2O (BD/ND) are highlighted with rectangles according to the values given in Table 4, and the shaded area represents the mixing region of the two domains. The orange

25 cross indicates the flux averaged values of the respective source signatures. Red arrows denote the path of partial N_2O reduction to N_2 , while black arrows indicate the direction of mixing with FD/N-derived N_2O . Solid arrows indicate scenario 1 (first reduction, then mixing), while dashed arrows indicate scenario 2 (first mixing, then reduction). (a) SP versus $\Delta\delta^{15}\text{N}$ map according to Koba et al. (2009), where $\Delta\delta^{15}\text{N} = \delta^{15}\text{N}-\text{NO}_3^- - \delta^{15}\text{N}-\text{N}_2\text{O}$ (b) SP versus $\Delta\delta^{18}\text{O}$ of soil-emitted N_2O according to Lewicka-Szczebak et al. (2017), where $\Delta\delta^{18}\text{O} = \delta^{18}\text{O}-\text{N}_2\text{O} - \delta^{18}\text{O}-\text{H}_2\text{O}$, the isotope effect between soil water and formed N_2O .

30 $\Delta\delta^{18}\text{O}$ for BD/ND is considered to be **relatively stable constant**, because of the high oxygen exchange between soil water and reaction intermediates at high WFPS. An exemplary illustration is provided in the supplementary (SI Figure 4). 23

7.4 Figures

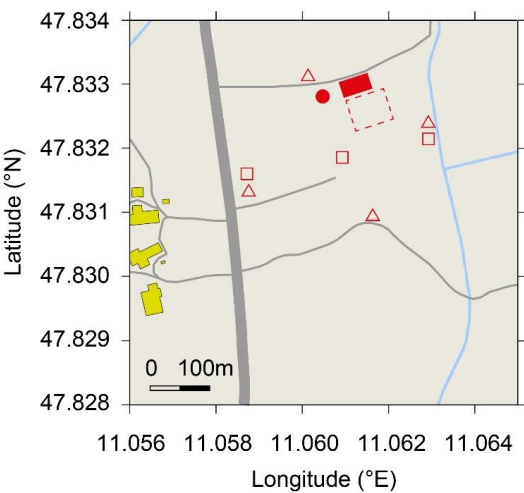

Figure 1 Map of research site De-Fen with nearby farm buildings (yellow), streets and country lanes (grey), ditches (blue), the mobile laboratory (filled red square), 2-m sample inlet for TREX-QCLAS measurements, (red dot), area of flux chambers and soil water content measurements (dashed red square), precipitation gauges (open triangles) and location of PT-100 sensors (open squares).

Figure 2 Instrumental setup for semi-continuous analysis of N₂O isotopes by coupled preconcentration laser spectroscopy (TREX-QCLAS) (Ibraim et al., 2018), including peripherals for the conditioning of the sample gas. Consecutive sample gas treatments include dehumidification by permeation drying, adjustment of sample gas pressure with a pressure release valve after the membrane pump, and CO₂ / H₂O removal using Ascarite / Mg(ClO₄)₂ traps and filtering for particles using a sintered metal filter. An automatized multiposition valve enables us to switch between eight different Ascarite traps and thus reduces the maintenance effort to one visit per eight days. The indicated gases are: target gas (T), synthetic air (SA), standard gas 1 (S1) and standard gas 2 (S2). CO is removed from the analyte gases using a Sofnocat catalyst (type 423, Molecular Products LTD). At the top right, a full measurement cycle is given. Letters on the y axis correspond to different gas types: standard 1 (S1), standard 2 (S2) sample (S) and target (T) gases. The x axis gives the elapsed time in minutes. The full measurement cycle lasts approx. four hours, which results in a frequency of approx. 1 hr⁻¹ for ambient air measurements.

Figure 3 (a) Average N_2O flux ($f(\text{N}_2\text{O})$) as measured by five replicate flux chambers coupled to a GC-ECD. (b) Concentration of $\text{NH}_4^+ - \text{N}$ and $\text{NO}_3^- - \text{N}$. Up to 8 nodes across the De-Fen site were sampled twice per week, except in the week of fertilization, when sampling frequency was increased. Therefore, variability within a sampled day refers to spatial variability across the De-Fen site on the given day. (c) Observed WFPS (red) and precipitation (blue). (d) Observed ambient (2 m above ground) and soil (2 - 6 cm below ground) temperature. The blue dashed line indicates a cutting event and the red line indicates a manure application.

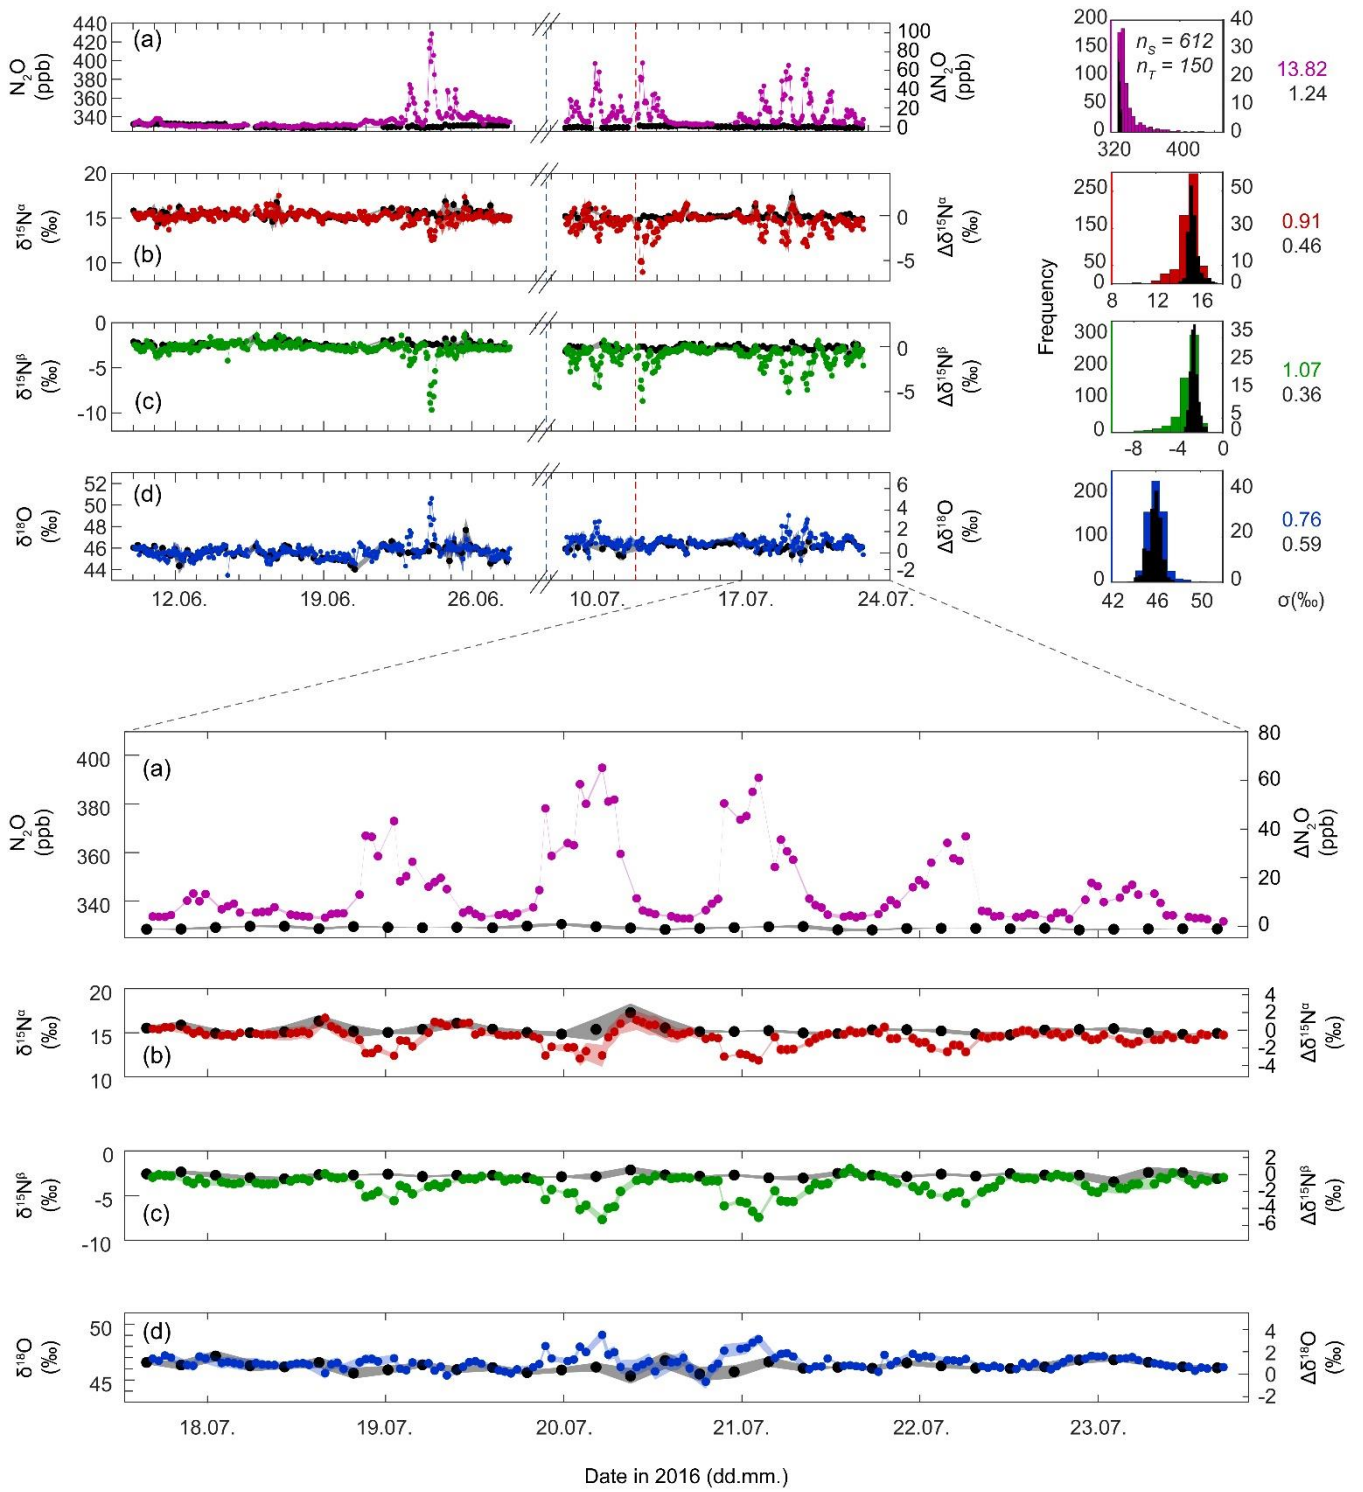

Figure 4 Time series of N_2O concentrations (a), $\delta^{15}\text{N}^\alpha$ (b), $\delta^{15}\text{N}^\beta$ (c) and $\delta^{18}\text{O}$ (d), respectively. The left axes give concentrations and isotope delta values on the respective scales, while the right axes depict the difference to background values ($\Delta X = X_{\text{measured}} - X_{\text{background}}$, where X refers to N_2O , $\delta^{15}\text{N}^\alpha$, $\delta^{15}\text{N}^\beta$ or $\delta^{18}\text{O}$, respectively). At the top right, histogram plots of the four quantities are given. Coloured symbols indicate ambient air samples (S) from 2 m above ground, and black symbols refer to the corresponding measurements of the target gas (T, Table 2). Shaded areas indicate one standard deviation (σ) as calculated for three consecutive measurements of T. Standard deviations for the complete measurement period are given on the right, in coloured font for S and in black for T. The vertical blue dashed line indicates a cutting event on 04 July 2016, while the red dashed line indicates a manure application on 12 July 2016.

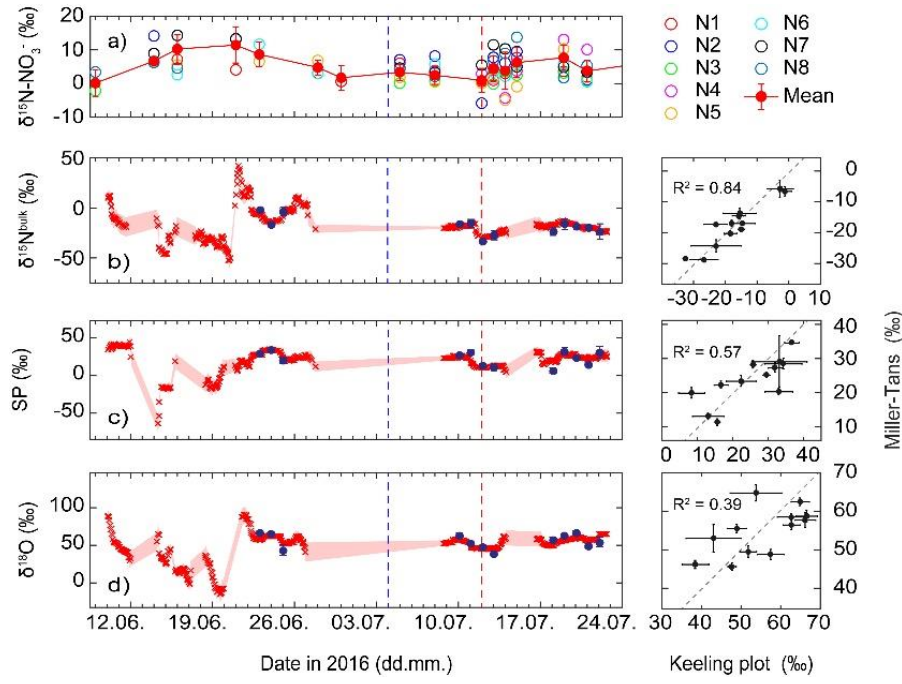

Figure 5 Temporal trend of $\delta^{15}\text{N}$ of soil-extracted NO_3^- at eight different nodes (N1-N8) near the N_2O flux and isotope measurements at De-Fen, indicating large spatial variability. In (a), concentration-weighted average values (red filled symbols) and their uncertainty (one standard deviation) are given. Source signatures (b) $\delta^{15}\text{N}^{\text{bulk}}$, (c) SP and (d) $\delta^{18}\text{O}$ of soil-emitted N_2O derived from the Miller and Tans (2003) approach (red crosses) and the Keeling (1961, 1958) plot approach (blue filled symbols) are given. Uncertainties are indicated as pale red shaded areas for the Miller-Tans approach and error bars for the Keeling plot approach (one standard deviation with a Monte Carlo model). The blue dashed line shows the cutting event, while the red dashed line indicates the manure application. Three panels on the right: correlation diagram of results derived from the Miller and Tans (2003) and the Keeling (1961, 1958) plot approaches. The dashed line corresponds to the 1:1 slope.

Figure 6 (a) Noon-to-noon average N_2O flux rates $f(\text{N}_2\text{O})$ versus water filled pore space (WFPS) from the grassland site De-Fen. Indicated uncertainties represent variations of $f(\text{N}_2\text{O})$ and WFPS within one day. Results for individual chambers are given in SI Figure 1. N_2O fluxes were highest at 85 – 92 % WFPS. The red dashed line corresponds to a two-term exponential fit of the data shown here. (b) SP as a function of WFPS. Lowest SP values were found in the range of 85 – 95 % WFPS, which corresponds to the highest N_2O fluxes. The red dashed line depicts a double exponential fit of the data shown here (this fit was not significant). The model used to fit the data corresponds to $y = a \cdot \exp(b \cdot x) + c \cdot \exp(d \cdot x)$ (coefficients a , b , c and d are given in the main text).

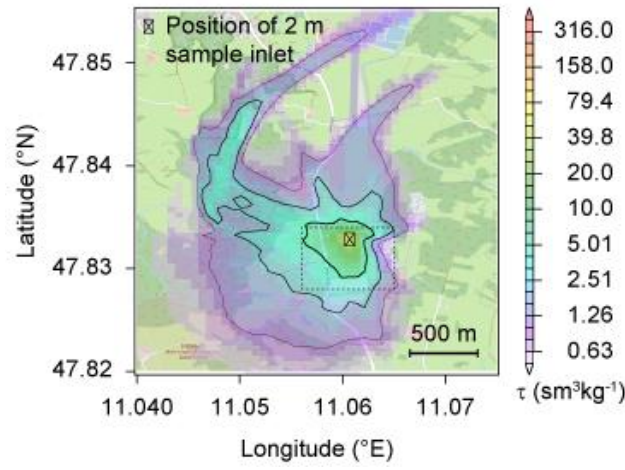

Figure 7 The average footprint area as calculated by the FLEXPART-COSMO model. The model was driven with local wind vectors and observed N₂O flux rates, and indicates a major contribution of soils south-west of the ambient air inlet. The source sensitivities Tau (τ) are given as the product of residence time (in seconds) and inverse atmospheric density (in m³*kg⁻¹). Isolines enclose the areas of largest source sensitivities summing up to 15, 30 and 45 % (decreasing thickness of lines) of the total simulated source sensitivity. The dashed rectangle indicates the area depicted in Figure 1. Individual source signatures for the 12 events are provided in the supplements (SI Figure 11).

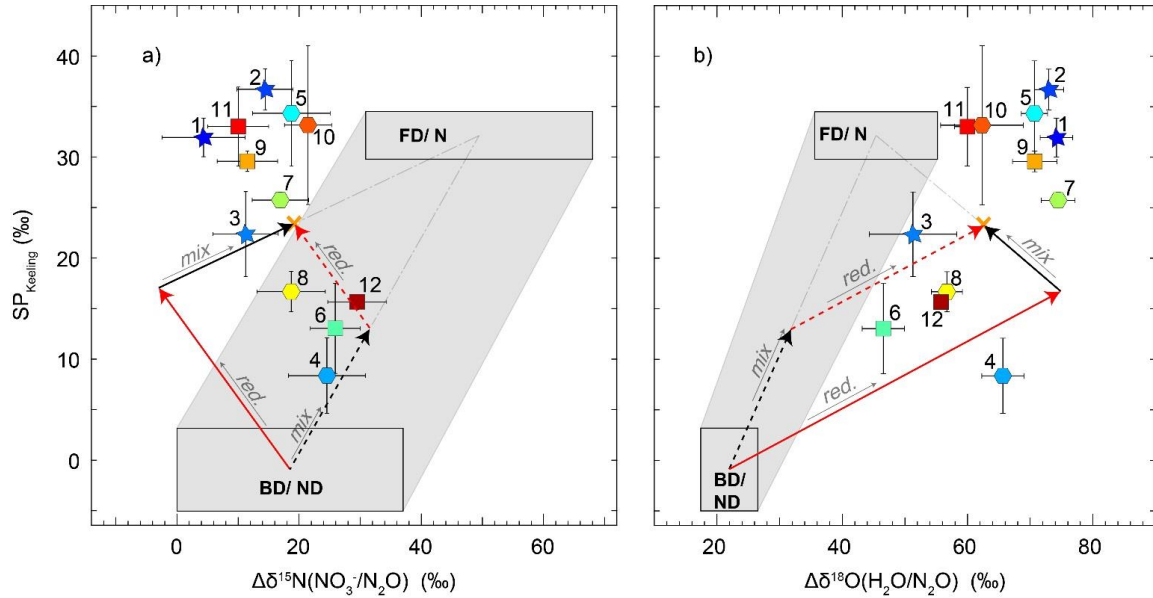

Figure 8 Source signatures of soil-emitted N₂O for 22 to 24 June (stars 1-3), July 9 to 12 (squares 6, 9, 11 and 12) and July 17 to 21 (hexagons 4, 5, 7, 8 and 10). The colour coding of the symbols refers to WFPS, where blue corresponds to high and red corresponds to low WFPS (exact values in Table 3). The source signatures of fungal denitrification- and nitrification-derived N₂O (FD/N) and bacterial denitrification- and nitrifier denitrification-derived N₂O (BD/ND) are highlighted with rectangles according to the values given in Table 4, and the shaded area represents the mixing region of the two domains. The orange cross indicates the flux averaged values of the respective source signatures. Red arrows denote the path of partial N₂O reduction to N₂, while black arrows indicate the direction of mixing with FD/N-derived N₂O. Solid arrows indicate scenario 1 (first reduction, then mixing), while dashed arrows indicate scenario 2 (first mixing, then reduction). (a) SP versus $\Delta\delta^{15}\text{N}$ map according to Koba et al. (2009), where $\Delta\delta^{15}\text{N} = \delta^{15}\text{N}\text{-NO}_3^- - \delta^{15}\text{N}\text{-N}_2\text{O}$ (b) SP versus $\Delta\delta^{18}\text{O}$ of soil-emitted N₂O according to Lewicka-Szczebak et al. (2017), where $\Delta\delta^{18}\text{O} = \delta^{18}\text{O}\text{-N}_2\text{O} - \delta^{18}\text{O}\text{-H}_2\text{O}$, the isotope effect between soil water and formed N₂O. $\Delta\delta^{18}\text{O}$ for BD/ND is considered to be **relatively stable constant**, because of the high oxygen exchange between soil water and reaction intermediates at high WFPS. An exemplary illustration is provided in the supplementary (SI Figure 4).
