**Abstract.** Rapid warming of Arctic ecosystems exposes soil organic matter (SOM) to accelerated microbial decomposition, potentially leading to increased emissions of carbon dioxide (CO<sub>2</sub>) and methane (CH<sub>4</sub>) that have a positive feedback on global warming. Current estimates of the magnitude and form of carbon emissions from Earth system models include significant uncertainties, partially due to the oversimplified representation of geochemical constraints on microbial decomposition. Here we coupled modeling principles developed in different disciplines, including a thermodynamically based microbial growth model for methanogenesis and iron reduction, a pool-based model to represent upstream carbon transformations, and a humic ion-binding model for dynamic pH simulation to build a more versatile carbon decomposition model framework that can be applied to soils under varying redox conditions. This new model framework was parameterized and validated using synthesized anaerobic incubation data from permafrost affected soils along a gradient of fine-scale thermal and hydrological variabilities across Arctic polygonal tundra. The model accurately simulated anaerobic CO<sub>2</sub> production and its temperature sensitivity using data on labile carbon pools and fermentations rates as model constraints. CH<sub>4</sub> production is strongly influenced by water content, pH, methanogen biomass, and presence of competing electron acceptors, resulting in high variability in its temperature sensitivity. This work provides new insights into the interactions of SOM pools, temperature increase, soil geochemical feedbacks, and resulting CO<sub>2</sub> and CH<sub>4</sub> production. The proposed anaerobic carbon decomposition framework presented here builds a mechanistic link between soil geochemistry and carbon mineralization, making it applicable over a wide range of soils under different environmental settings.

## 1 Introduction

35 The northern permafrost region contains 1400-1800 Pg soil carbon (C), which is more than twice as much C as is currently contained in the atmosphere (Tarnocai et al., 2009; McGuire et al., 2012). Persistent cold and saturated soil conditions have limited C decomposition in this reservoir. However, rapid warming and permafrost thaw exposes previously frozen organic carbon to accelerated microbial decomposition, potentially leading to emissions of carbon dioxide (CO<sub>2</sub>) and methane (CH<sub>4</sub>) that have a

positive feedback on global warming (Zimov et al., 2006; Schuur et al., 2015; Schuur et al., 2009). How quickly frozen soil organic matter (SOM) will be mineralized, and how much permafrost C will be released to the atmosphere following thaw is highly uncertain. Earth system models project 27 -508 Pg carbon release from the permafrost zone by 2100 under current climate forcing (Zhuang et al., 2006; Koven et al., 2015; MacDougall et al., 2012; Schaefer et al., 2014), varying by a factor of thirty. Understanding environmental dependencies of soil organic matter (SOM) decomposition is therefore essential for reducing model uncertainties and improving predictions of future climate change.

Disagreement in model projections for the northern permafrost region could be due to differences in model structure, model initialization, or parameters used in simulations. Despite increasingly detailed process representations in many models that simulate terrestrial CO<sub>2</sub> and CH<sub>4</sub> fluxes, important geochemical and metabolic constraints might still be poorly represented, oversimplified or missing in current biogeochemical models (Xu et al., 2016). The northern permafrost region is rapidly changing in response to the changing climate. Rising temperatures not only release more labile carbon from permafrost for decomposition, but also create thermal and hydrological heterogeneity that further affects biogeochemical processes. Here we examine two mechanisms that substantially affect SOM turnover in permafrost-affected soils. First, rising temperature alters the kinetics of biogeochemical reactions (Segers, 1998). This effect is more pronounced at subzero temperature (Bore et al., 2017), and the process rate increase is higher at lower temperature ranges (Davidson and Janssens, 2006). Microbial communities also change with temperature, compounding effects on process rates (Karhu et al., 2014). Models address this temperature effect using empirical functions and parameters (Tuomi et al., 2008; Xu et al., 2016), which might be highly biased depending on model assumptions and original curve fitting techniques, generating large uncertainties. Second, heterogeneity in permafrost thaw and related hydrological responses creates geochemical gradients in soils. Models use different levels of detail to simulate effects of water saturation (Meng et al., 2012; Xu et al., 2016). Soil moisture limits gas transport, and it is often used as an implicit control on heterotrophic respiration and methanogenesis. However, the explicit processes resulting from with soil oxygen depletion (e.g. soil redox status and pH dynamics) are not widely represented (Riley et al., 2011; Meng et al., 2012; Xu et al., 2015).

The extent of SOM decomposition and gas emissions depends upon soil geochemical characteristics beyond temperature and O<sub>2</sub> availability. Among the wide range of environmental variables, pH emerges as a primary control on decomposition by regulating both microbial communities and microbial metabolic activities (Zhalnina et al., 2015; Bethke et al., 2011; Jin and Kirk, 2018). pH affects microbial metabolism by modulating the thermodynamics and kinetics of redox reactions. Redox reactions produce or consume protons, and thus, their free energy yields vary with pH (Bethke et al., 2011; Jin and Bethke, 2007). The Gibbs free energy available to anaerobic microorganisms that degrade simple organic molecules generally increases (becomes less favorable) with increasing pH (Bethke et al., 2011). Notably, iron [Fe(III)] reduction is highly proton consuming and becomes less favorable at higher pH (Figure S1). Previous studies identified iron reduction as a major process in anoxic Arctic soils (Lipson et al., 2010; Lipson et al., 2013), which increases local pH and might favor co-occurring methanogenesis (Tang et al., 2016; Wagner et al., 2017). However, the influence of iron reduction on methanogenesis rates in different soils is rarely investigated. The reactivity of iron and its pH-feedback impose additional complexity on the controls of SOM decomposition and associated CH<sub>4</sub> production.

Despite the importance of pH in controlling redox reactions and resulting C emissions, pH change is not explicitly represented in biogeochemical models. Most of the current biogeochemical models apply a single initial pH value for redox reactions without considering proton production and consumption during the processes. Traditional decomposition models use landscape position, soil moisture content, or other proxies for O<sub>2</sub> concentration to determine the form of C release. Scalars on aerobic respiration (Riley et al., 2011; Lawrence et al., 2015) or empirical ratios of CO<sub>2</sub> and CH<sub>4</sub> (Koven et al., 2015) are often used to inform the extent of C decomposition and partitioning of CO<sub>2</sub> and CH<sub>4</sub> production. Reactions that produce or consume protons and the resulting pH

changes or ion exchange reactions are not considered in these empirical models. Some process-rich models explicitly include details of methanogen populations and their interactions with substrates and other environmental factors, but these models still lack the capability to simulate pH changes during long-term carbon decomposition. Instead, constant pH is often assumed within bell-shaped pH response functions (Meng et al., 2012; Tian et al., 2010; Xu et al., 2015). Without underlying proton exchange and pH buffering mechanisms, a significant error may occur when rate calculations depend heavily upon the initial choice of a single optimal pH value for various reactions.

In this study we developed a new anaerobic carbon decomposition model framework with explicit representation of aqueous phase geochemistry to allow pH and thermodynamic calculations. By coupling three different models, including a thermodynamically based microbial growth model, a substrate pool-based model, and a humic ion-binding model, we built a process-rich carbon decomposition model that allows simultaneous thermodynamic and pH calculations. Results from anoxic incubations of permafrost affected soils along a hydrological gradient were synthesized to parameterize and validate this new model framework. The main objectives of this study were to (i) examine the role of soil geochemical variables in controlling anaerobic carbon decomposition and carbon release (as both CO<sub>2</sub> and CH<sub>4</sub>); (ii) develop a common set of parameters in the new anaerobic carbon decomposition framework to capture variabilities in CO<sub>2</sub> and CH<sub>4</sub> production; and (iii) evaluate model uncertainties in responses to both soil heterogeneity and model parameterization, emphasizing effects of soil saturation, pH and temperature response.

## 2 Materials and methods

### 2.1 Anaerobic carbon decomposition model

The anaerobic carbon decomposition framework was developed with explicit representation of fermentation, methanogenesis and iron reduction, which were identified as key mechanisms for anaerobic CO<sub>2</sub> and CH<sub>4</sub> production (Roy Chowdhury et al., 2015; Yang et al., 2016; Zheng et al., 2018b). The main structure of this framework included two major components: a simplified CLM-CN decomposition cascade (Converging Trophic Cascade, or CTC) (Thornton and Rosenbloom, 2005) to facilitate parameterization of the upstream carbon flow entering the aqueous phase dissolved organic carbon (DOC) pool (Figure 1, process 1), and an aqueous phase to facilitate calculations of thermodynamics and redox-reaction associated acid-base chemistry. An empirical approach was used to represent non-aqueous phase SOC decomposition. Additionally, mechanistic representations of methanogenesis and iron reduction were developed in this work based on aqueous phase thermodynamic calculations.

The simplified CTC cascade included 4 SOM pools to represent bulk SOC with different levels of complexity. Changes of these SOM pools followed modified first-order-decay (see Supplementary Material for details). We modified the original respiration fraction (Thornton and Rosenbloom, 2005; Koven et al., 2013) into direct and indirect fractions. Thus for each SOM pool, the direct respiration fraction represented CO<sub>2</sub> lost as originally defined, while the indirect respiration fraction was labile C produced from bulk C entering the aqueous phase carbon pool (DOC pool, Figure 1).

The large biomolecules in the DOC pool went through multiple hydrolysis and fermentation steps to produce low molecular weight organic acids that would further respire into CO<sub>2</sub> and CH<sub>4</sub> (Boye et al., 2017; Zheng and Graham, 2018; Yang et al., 2016; Roy Chowdhury et al., 2015). Under anoxic conditions, hydrolysis of polysaccharides was considered the rate-limiting step for downstream methanogenesis (Glissmann and Conrad, 2002). Polysaccharide hydrolysis has a favorable free energy, due to increased entropy, but cannot be readily coupled to biological energy transduction outside of the cell. We previously measured a rapid decrease in reducing sugar concentrations in pore water during tundra soil incubations, which indicated that hydrolysis limits

decomposition (Yang et al., 2016). At low temperature (below 15 °C), the microbial degradation of cellulose was considerably diminished while other polymers, such as starch or proteins, were degraded much faster at low temperature, resulting in the accumulation of organic acids, primarily acetic, propionic and butyric acids (Kotsyurbenko, 2005; Yang et al., 2016). These low molecular weight organic acids further fueled microbial mineralization reactions that led to production of CH<sub>4</sub> and CO<sub>2</sub>. Given that most anaerobic lignocellulose degraders also fermented sugars following hydrolysis (Blumer-Schuette et al., 2014), we assumed the turnover of DOC into low molecular weight organic acids was a single lumped fermentation process (Figure 1, process 2), in which labile DOC (C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>) was fermented into acetate, H<sub>2</sub> and CO<sub>2</sub> (Appendix A, reaction A1 and Table S1). This assumption gave a fixed stoichiometry ratio: 1/3 of the fermented carbon was oxidized to CO<sub>2</sub>.

Redox reactions including methanogenesis and iron reduction were represented using a thermodynamically-based approach (Istok et al., 2010), with unique microbial growth kinetics incorporated into energy yielding redox reactions. In this thermodynamically based approach, the growth equations of methanogens and iron reducers were derived from paired electron donor (acetate or H<sub>2</sub>) and electron acceptor half reactions and a biomass synthesis equation (Istok et al., 2010). Using a constant molecular formula as biomass (C<sub>5</sub>H<sub>7</sub>O<sub>2</sub>N), and ammonium (NH<sub>4</sub><sup>+</sup>) as the nitrogen source for biosynthesis, we derived the growth equations for methanogenesis and iron reduction (Appendix A, equation A2-A5). Rate calculations followed the generalized Monod rate law (Jin and Bethke, 2007) with an additional thermodynamic factor representing the thermodynamic driving force. The thermodynamic factor  $f(G)$  is calculated using equation 1 (Jin and Bethke, 2003):

$$f(G) = 1 - \exp\left(-\frac{-\Delta G - m\Delta G_p}{\chi RT}\right) \quad (1)$$

where  $\Delta G$  [kJ (mol reaction)<sup>-1</sup>] is the free energy change of the redox reaction.  $\Delta G$  depends on the standard Gibbs free energy change ( $\Delta G^0$ ) and the concentrations of chemical species involved in the reaction.  $\Delta G_p$  is the phosphorylation potential, i.e., the energy required to synthesize ATP to ADP and dihydrogen phosphate in cell's cytoplasm.  $\Delta G_p$  is about 45 kJ (mol ATP)<sup>-1</sup> (Jin and Kirk, 2018).  $m$  is the number of ATP molecules synthesized per redox reaction.  $\chi$  is the average stoichiometric number (Jin and Kirk, 2018),  $R$  is the gas constant (kJ mol<sup>-1</sup> K<sup>-1</sup>), and  $T$  is the absolute temperature (K). This factor  $f(G)$  ranges from 0 to 1, where the reaction is thermodynamically favorable when  $f(G) > 0$ .

Both methanogenesis and iron reduction contribute to pH change. Reactions such as ferrihydrite reduction substantially increase alkalinity (Appendix A, Reaction A4, A6). Furthermore, the solubility of CO<sub>2</sub> and the composition of dissolved CO<sub>2</sub> and bicarbonate vary significantly over typical soil pH values, affecting all C mineralization processes. In the organic-rich soils modeled here, SOM rather than minerals provides most buffering capacity. Therefore, we used the humic ion-binding model to describe pH buffering during carbon decomposition. A simplified parameterization of proton binding is available in the Windermere Humic Aqueous Model (WHAM, (Tipping, 1994; Tipping, 1998)), which has been extensively calibrated to represent the acid-base chemistry of "average" humic and fulvic acids, and benchmarked with heterogeneous natural organic matter (Atalay et al., 2009). We adopted the WHAM parameterization to represent proton binding characteristics (pH buffering) provided by SOM (Tang et al., 2016). Using representative binding constants provided by WHAM, the pH buffering capacity can be directly adjusted by altering the number of proton binding sites, which is assumed to be linearly correlated with the total amount of SOM (see Supplementary Material for details).

## 2.2 Model implementation and initialization

The above model structure was implemented using the open source geochemical program PHREEQC 3.0 (Charlton and Parkhurst, 2011) with a new database describing SOC decomposition cascade, redox reaction kinetics and pH buffering (*redox.dat*, available at <https://github.com/jianqiuz/decomposition>). This model assumed thermodynamic equilibrium of aqueous chemical speciation, mineral dissolution/precipitation, and ion sorption/desorption based on the updated PHREEQC thermodynamic database (*phreeqc.dat*, (Charlton and Parkhurst, 2011)). The database was modified to include WHAM pH buffering and reaction kinetics for SOM pools decay and reaction kinetics for fermentation, methanogenesis and iron reduction. The kinetic rate constants and microbial biomass growth and decay rates were adopted from former thermodynamically based studies (Istok et al., 2010) and previously tested with low-center polygon Arctic soils (Tang et al., 2016).

The model initialization was based on both the incubation conditions and soil geochemical characterizations (Figure S2). The initial partitioning of SOM pools was assumed to be at fixed ratios due to the limitation of short-term incubation data. Under the experimental conditions, we assumed SOM1 and SOM2 pools with relatively shorter turnover rates ( $\tau = 14$  days and 70 days, respectively) were most relevant in the model. On the other hand, SOM3 and SOM4 pools were relatively inert ( $\tau > 2$  years for both pools). We started with the relative fractions of SOM pools at approximately 10%, 40%, 10% and 40% of SOC in organic and mineral soils for SOM1-4. We further assessed the bias of this assumption with sensitivity analysis. Sizes of SOM1 and SOM2 pools were reduced by 90% for permafrost to better account for the overall low levels of carbon degradation.

All other variables required were initialized using measurements based upon 10 to 15 g of wet soil incubated in 60 to 70-mL sealed bottles. Total soil organic carbon (SOC), total water (TOTW), total organic acid carbon (TOAC), pH and the initial concentration of Fe(II) were specified in the model based on measurements (Table S2). The DOC pool in the model was initialized using the measured water extractable organic carbon (WEOC) expressed as a fraction of SOC ( $f_{doc}$ ). On average, WEOC accounts for approximately 2% of SOC based on our synthesized data (see section 3.1). This value is consistent with previous long-term incubations, which suggested less than 5% of SOC was fast decomposing carbon in permafrost affected soils at a standardized temperature of 4-5 °C (Knoblauch et al., 2013; Schädel et al., 2014). The starting biomass of methanogens and iron reducers was assumed to be within the range of  $10^{-3}$  to  $10^{-5}$  gC/gSOC for organic soils,  $10^{-4}$  to  $10^{-6}$  gC/gSOC for mineral soils, and  $10^{-7}$  to  $10^{-9}$  gC/gSOC for permafrost (Table S2). This stratified microbial biomass distribution was used to represent the vertical gradient in the relative abundance of microbial communities (Yang et al., 2017).

The lumped fermentation process was the rate-limiting step in the model and was fitted individually with data from each soil microcosm. Based upon reaction stoichiometry, the fermentative conversion of each mole of labile C led to 2/3 mole of organic acids and 1/3 mole of CO<sub>2</sub>. Organic acids were mineralized via methanogenesis or iron reduction to convert approximately 49% to 88% of C in organic acids into CO<sub>2</sub>. This estimation was based on reaction stoichiometry of A2 and A4, and a fraction of the C was incorporated into microbial biomass. Therefore, the percentage of respired C would be less than 100% even if all organic acids were respired as CO<sub>2</sub>. If we assume all fermentation products were mineralized into CH<sub>4</sub> and CO<sub>2</sub>, we could estimate the fermentation rate ( $R_{fer}$ ) from measured CO<sub>2</sub> production. Thus,  $R_{fer}$  was estimated using the initial CO<sub>2</sub> production rate in the incubation data, and further optimized using the least squares method by fitting with observed CO<sub>2</sub> production values (Table S3).

Temperature and pH response functions were used to further constrain model simulations (Figure S2). A temperature effect was parameterized using the CLM-CN temperature response function (Appendix B, equation B1). Additional temperature response functions were evaluated by sensitivity analysis (see section 2.4). The effect of pH on biological reaction rates is modulated by bell-shaped pH response functions (Tang et al., 2016; Xu et al., 2016). Here we used the Dynamic Land Ecosystem Model (DLEM) pH response function (Appendix B, equation B5), since it generated the least variation in parameter perturbation tests (Tang et al.,

2016).

### 2.3 Incubation data synthesis for model validation

5 Incubation data from Utqiagvik (Barrow) Alaska soil cores that represent the microtopographic heterogeneity of polygona tundra were synthesized to validate the new anaerobic carbon decomposition model. The selected datasets represent fine scale variabilities in thermal and hydrological regimes across the gradient of soil microtopographic positions (Herndon et al., 2015). The synthesized data contains complete sets of soil geochemical descriptions for organic, mineral, transition zone (if identified) and permafrost layers from each microtopographic feature (see Supplementary Material for details). Levels of total soil organic carbon, WEOC, and TOAC were available before and after soil incubation. Besides CH<sub>4</sub> and CO<sub>2</sub> production during low temperature soil decomposition, data on Fe(II) concentrations and pH changes were also available for model initialization and validation.

### 2.4 Model parameter uncertainty

15 This model was designed as a generic framework to simulate anaerobic carbon decomposition across a range of soil physiochemical conditions. Two types of sensitivity analysis were conducted to evaluate model performance. First, possible bias and variations associated with model initialization variables (soil geochemical attributes) were assessed using perturbation simulations. Variations of  $\pm 25\%$  and  $\pm 50\%$  ( $+100\%$  and  $200\%$  for some variables) were applied to these variables, and the resulting changes in cumulative CO<sub>2</sub> and CH<sub>4</sub> production were evaluated by comparing with reference simulations. This evaluation helps to identify critical measurements needed for initializing the model. Second, parameters specifically benchmarked in this study and parameters adopted from empirical relationships were also evaluated with perturbation simulations. This test helps to apportion the model prediction uncertainties into different sources, including model input, parameters, or model structure.

## 20 3 Results

### 3.1 Meta-analysis to validate model assumptions

25 Incubation data used in this study were generated from soils representing different microtopographic features with a wide range of moisture and SOC contents and reported elsewhere (Roy Chowdhury et al., 2015; Zheng et al., 2018b). Correlation analysis revealed a close relationship between soil moisture and organic carbon pools (measured as SOC, WEOC and TOAC) among examined soil microtopographic features and across soil depth ( $p < 0.01$ , Table S4). All these soil properties significantly correlated with cumulative CO<sub>2</sub> and CH<sub>4</sub> production ( $p < 0.05$ ), suggesting the important role of initial soil geochemical properties in controlling carbon degradation.

30 Although various levels of carbon mineralization were measured as CO<sub>2</sub> and CH<sub>4</sub> production during incubations, changes in WEOC and TOAC were consistent among treatments with distinct patterns. WEOC represents 0.3% to 2.6% of total SOC among all test soils, and this ratio remained constant before and after anoxic incubations (Figure S3). On the other hand, TOAC showed much more dynamic changes among different soils and different incubation temperatures. TOAC generally increased in soils from organic layer, transition zone and permafrost. In contrast, TOAC drastically decreased by up to 90% in mineral soils. These results indicate that WEOC was in a steady state among examined soils, while TOAC varied substantially due to microbial mineralization processes, supporting the model assumption of lumped fermentation (the conversion of WEOC to TOAC) as the rate limiting step.

Both CO<sub>2</sub> and CH<sub>4</sub> production rates responded strongly to rising incubation temperature ( $p=0.02$  and  $p=0.04$ , respectively, Figure S4, Tables S5 and S6). The estimated Q<sub>10</sub> values of CO<sub>2</sub> production showed a relatively narrow range while methanogenesis had much larger variation in estimated Q<sub>10</sub> values ranging from 1.6 to 48.1. Using Q<sub>10</sub> values to simulate the temperature dependence of processes might work for CO<sub>2</sub> production, but could generate significant errors in predicting CH<sub>4</sub> production.

### 5 3.2 Modeled CO<sub>2</sub> and CH<sub>4</sub> production using observed parameters

The model performed well in simulating CO<sub>2</sub> and CH<sub>4</sub> dynamics across a range of moisture and SOC gradients and among different soil types (Figures S5 and S6). Variations in gas production among different conditions, including microtopographic features, soil layers, and different incubation temperatures were well captured (Figure S7). The comparisons between modeled and observed CO<sub>2</sub> and CH<sub>4</sub> production are shown in Figure 2. The model slightly underestimates CO<sub>2</sub> production towards the end of the incubations, but still maintains a good agreement between modeled and observed CO<sub>2</sub> production ( $R^2=0.89$ ). The underestimation of CO<sub>2</sub> production is likely due to substrate limitations caused by the initial distribution of different carbon pools. Model-predicted CH<sub>4</sub> production also showed good agreement with observations ( $R^2=0.79$ ). More variation between modeled and observed CH<sub>4</sub> production suggests a systematic pattern in the model parameterization of methanogenesis: the model underestimates CH<sub>4</sub> production at 4 and 8 °C, and overestimates CH<sub>4</sub> production at -2 °C.

To assess the model sensitivity to initial model inputs, we compared model predictions in response to varying initial model inputs via perturbation simulations. First, we examined the influence of the partitioning of different carbon pools. Significant changes in model predictions of CO<sub>2</sub> and CH<sub>4</sub> were observed in response to perturbations of initial input of SOC, WEOC, but not TOAC (Figure 3). SOC determines the size of different carbon pools in the model, and it further influences the predictions of WEOC, TOAC, CO<sub>2</sub> and CH<sub>4</sub>. For example, predicted CO<sub>2</sub> and CH<sub>4</sub> production increased by about 200% when +200% changes were applied to initial SOC input. This trend is consistent with correlation analysis of incubation results, described above (Table S4). Perturbations in initial WEOC strongly altered the predictions of TOAC and CO<sub>2</sub>, consistent with the model assumption of the conversion of WEOC to TOAC (fermentation process) as the rate-limiting step. The model also predicted increases in CH<sub>4</sub> and Fe(II) accumulation in response to lower WEOC. Lower WEOC significantly reduced organic acid accumulation, and thus increased system pH and accelerated rates of both methanogenesis and iron reduction. The starting level of TOAC showed minimal influence on model predictions of CO<sub>2</sub> and CH<sub>4</sub>, suggesting other factors rather than substrate availability were limiting carbon mineralization. The initial sizes of SOM1 and SOM2 pools showed very slight changes in model predictions of WEOC and CO<sub>2</sub>, and minimal influence on CH<sub>4</sub> prediction, further supporting the assumption that downstream fermentation is the rate-limiting step in the model. Additional soil geochemical factors, including soil moisture, Fe(II) and pH also significantly influence model output. In particular, initial soil pH showed a dramatic effect on predicted CO<sub>2</sub> and CH<sub>4</sub> production. With initial soil pH increased from 5 (reference simulation) to 6, the model predicted 160% and 308% increase in CO<sub>2</sub> and CH<sub>4</sub> production, respectively. Perturbations in initial soil pH had the strongest effect on the prediction of CH<sub>4</sub> by assigning different values in  $f_{pH}$  that were directly proportional to the methanogenesis rates. The above results of perturbation simulations demonstrated high sensitivity of this model in response to varying soil geochemical properties.

### 3.3 Model sensitivity to parameterization uncertainties

To further validate the model, we performed additional sensitivity analysis to justify model assumptions and estimate the uncertainties generated from model parameterizations. One major assumption of this modeling framework is to lump multiple fermentation processes into one reaction stoichiometry, controlled by one reaction rate constant. It is critical to evaluate how this

simplified structure influences model performance and contributes to model output uncertainties. The model parameter sensitivity analysis indicated the TOAC pool was most sensitive to changes in the fermentation rate ( $R_{fer}$ ) and reaction stoichiometry (Figure 4). Downstream reactions were less affected by the uncertainties of the two tested parameters. These results supported our assumption of lumped fermentation with fixed stoichiometry, indicating the robustness of the model structure presented here.

5

The selection of temperature response functions represents one of the major sources of model uncertainties. A sensitivity analysis was performed by comparing four different temperature response functions (Appendix B). In our simulations, the quadratic temperature response function proposed by Ratkowsky et al. predicted much higher CO<sub>2</sub> and CH<sub>4</sub> production rates at higher temperature, and the lowest rates of both CO<sub>2</sub> and CH<sub>4</sub> at temperatures below 0 °C, giving the highest temperature response among tested response functions (Figure 5). In contrast, the Arrhenius equation predicted much lower temperature response for both CO<sub>2</sub> and CH<sub>4</sub>. Empirical functions used in CLM-CN and CENTURY models gave similar temperature responses for both CO<sub>2</sub> and CH<sub>4</sub>. Variations in low temperature CO<sub>2</sub> production are well constrained by established temperature response functions, while CH<sub>4</sub> production at -2 °C showed a much wider range of temperature response, and the median value is best simulated using the Ratkowsky function. This sensitivity analysis is consistent with model output of CO<sub>2</sub> and CH<sub>4</sub> production, where CO<sub>2</sub> is well constrained by the model, but CH<sub>4</sub> is significantly overestimated at -2 °C using the CLM-CN temperature response function. A unified temperature response function for all reactions under different biotic or abiotic constraints substantially contributes to the disagreement between model output and observations.

Redox reactions contribute to proton production or consumption, and the resulting pH alters the value of the pH response function ( $f_{pH}$ ) that directly controls reaction kinetic functions, creating a feedback loop. pH buffering capacity (BC) provided by SOM with proton binding sites and  $f_{pH}$  represent two major sources of uncertainties in this feedback loop. Thus, we performed perturbation simulations to characterize the sensitivity of model output to variations in BC and  $f_{pH}$  (Figure 6). Higher BC stabilized system pH during prolonged incubations, while lower BC permitted a pH increase by up to 0.71 pH unit compared to the reference simulation. This 14% pH increase led to a 123% increase in  $f_{pH}$ , accelerating both methanogenesis and Fe(III) reduction rates substantially. Perturbations on the pH response function were directly reflected in the slopes of pH response curves (Figure S8). We found up to 372% change in the value of  $f_{pH}$  during a 60-day simulation, as a steeper increase in  $f_{pH}$  accelerated both methanogenesis and iron reduction (equation A2-A5), which contributed to pH rise that further accelerated  $f_{pH}$  increase. Correspondingly, both CH<sub>4</sub> and Fe(II) increased by more than 100% after the simulation. While BC is an important factor controlling both redox reactions and pH fluctuations, a unified  $f_{pH}$  for all reactions may impose significant variations in model output.

30

BC is an intrinsic soil property simulated with a simplified linear relationship to soil SOM. However, it generates a strong nonlinear response in the simulations of methanogenesis and Fe(III) reduction (Figure 7a). Simulations with varying soil BC revealed dynamic pH change at lower BC (Figures 8 and 9, with BC=1 as reference simulation) and stabilized pH at higher BC. At constant temperature, rates of both methanogenesis and Fe(III) reduction increased significantly at lower BC due to pH control. At lower BC when pH change is not well buffered, higher pH accelerated CH<sub>4</sub> and Fe(II) production rates (Figure 7), giving much higher apparent temperature responses, while at higher BC with stabilized pH in the system, apparent temperature responses of these redox processes were significantly lower than the reference simulation (BC=1). Variations in pH buffering capacity generated large variations in apparent temperature responses of methanogenesis and Fe(III) reduction due to this pH feedback loop.

## 4 Discussion

### 4.1 Synthesized soil geochemistry and model validation

40

Soil geochemical characteristics represent important abiotic controls on anaerobic carbon decomposition and subsequent CO<sub>2</sub> and CH<sub>4</sub> production. SOC content, soil pH, water table position, C:N ratio, and landscape position were all suggested to contribute to the variability in anaerobic CO<sub>2</sub> and CH<sub>4</sub> production (Lee et al., 2012; Schädel et al., 2014; Treat et al., 2015). We synthesized incubation data for gelisol soils from different pedons and soil moisture regimes representing heterogeneity across the Barrow Environmental Observatory (BEO). This coordinated data set allowed us to focus on individual factors and their roles in relation to anaerobic CO<sub>2</sub> and CH<sub>4</sub> production.

Carbon released as CO<sub>2</sub> and CH<sub>4</sub> during anoxic incubations decreased with depth. Permafrost was associated with low levels of CO<sub>2</sub> production and very low CH<sub>4</sub> production, consistent with a previous synthesis (Treat et al., 2015). Nevertheless, permafrost TOAC, WEOC, and SOC concentrations were all comparable to organic soils, suggesting high substrate availability but low microbial activity. This trend is consistent with previous studies (Walz et al., 2017; Treat et al., 2015), where highest microbial abundance and diversity were observed in surface soil, and permafrost contained low microbial abundance (Treat et al., 2014; Waldrop et al., 2010). Among surface soils, higher moisture in low-centered polygon soils significantly promoted CO<sub>2</sub> and CH<sub>4</sub> production and the accumulation of fermentation products (measured as TOAC), emphasizing the importance of soil SOC content and moisture as strong environmental drivers for carbon decomposition. Given the bias in correlation analysis created by the skewed distribution of CO<sub>2</sub> and CH<sub>4</sub> production in our dataset, additional cluster analysis was performed based on data similarity rather than correlations. High similarity of soil attributes (depth, moisture, pH, C:N ratio, SOC, TOAC) with CH<sub>4</sub> production (Figure 8a) was found, suggesting methanogenesis is potentially controlled by a set of soil geochemical characteristics in the local microenvironment.

These synthesized observations support the major assumptions of our model development: (1) the coupled hydrolysis and fermentation processes converting macromolecular SOM into low molecular weight organic acids is the rate limiting step; and (2) different rates of CO<sub>2</sub> and CH<sub>4</sub> production from different soil layers can be attributed to variations in microbial activity manifested as differences in initial microbial biomass or growth rates. Additional observations of substantial Fe(III) reduction and associated pH increases during anaerobic decomposition (Figure S9) confirmed the need to simulate pH variations associated with redox reactions and corresponding microbial responses. This anaerobic carbon decomposition framework adequately modulated the involved biotic and abiotic interactions by splitting the carbon flow to different redox reactions and simulating pH buffering capacity to mediate associated changes in acidity or alkalinity.

The model presented here identified fermentation, acetoclastic methanogenesis and acetotrophic iron reduction as key mechanisms for anaerobic CO<sub>2</sub> and CH<sub>4</sub> production (Vaughn et al., 2016; Lipson et al., 2010). Although denitrification, ammonification and sulfate reduction are all thermodynamically more favorable, low nitrate and sulfate concentrations in BEO soils limit flux through these pathways (Newman et al., 2015). We performed another cluster analysis on the model output (Figure 8b), where we not only simulated fermentation, methanogenesis and iron reduction rates and associated pH changes, but also tracked the biomass of methanogens (M\_Meb) and iron reducers (M\_Feb). A dendrogram depicting data similarity showed four distinct clusters consisting of WEOC, CO<sub>2</sub> (CO<sub>2</sub> prediction), Ferrous (Fe(II) prediction), and CH<sub>4</sub> (CH<sub>4</sub> prediction) that closely associated with soil geochemical properties and incubation temperature. This result is similar to the cluster analysis of synthesized data, demonstrating that the proposed model structure captured major relationships between carbon mineralization and soil geochemical attributes. Predicted CH<sub>4</sub> production is strongly influenced by incubation temperature, soil pH, soil moisture, and depth that determine the size of the methanogen population. This model prediction is consistent with previous studies on the vertical distribution of methanogen population (Waldrop et al., 2010). Environmental factors, such as labile organic matter, water table depth, and soil redox status, soil alkalinity and salinity (Wachinger et al., 2000; Rivkina et al., 2007; Høj et al., 2006; Yang et al., 2017) are all

likely to contribute to the variabilities in the distribution and abundance of methanogens and subsequent methane production.

#### 4.2 Temperature and pH response of anaerobic carbon decomposition

Rising temperature promotes anaerobic carbon decomposition, resulting in increased rates of anaerobic CO<sub>2</sub> and CH<sub>4</sub> production (Treat et al., 2014; Lupascu et al., 2012). It is widely recognized that methanogenesis is more sensitive to temperature than respiration (Yvon-Durocher et al., 2014; Yvon-Durocher et al., 2012), and it is usually associated with large variations. Segers estimated the Q<sub>10</sub> value of methanogenesis ranged from 1.5 to 28 among 1043 incubation experiments using wetland soils (Segers, 1998). Our data synthesis revealed higher temperature sensitivity than other reported values. High estimated temperature sensitivity across the freezing point of water has previously been documented (Waldrop et al., 2010) and further attributed to limited water availability for microbial activities at sub-zero temperature (Tilston et al., 2010). Ratkowsky et al. proposed a quadratic relationship for the temperature dependence of microbial growth rates that modeled low-temperature growth better than the Arrhenius Law (Ratkowsky et al., 1982). Our simulations suggest better prediction of methanogenesis with this temperature response function, possibly due to a more suitable representation of growth limitation of methanogens at sub-zero temperature. Methanogenesis rates are also influenced by the availability of alternative electron acceptors and carbon source. Processes contributing to the accumulation or consumption of carbon substrates and competing electron acceptors may respond differently to temperature change, which could further complicate the temperature sensitivity of methanogenesis. Current modeling approaches heavily depend upon empirical temperature response functions, which may be associated with large uncertainties due to variations in the selection of data and curve fitting methods. Extrapolation of carbon decomposition rates, particularly methanogenesis rates, into a future warmer climate remains uncertain. More accurate simulations will require additional information on geochemical properties that contribute to the variations of methanogens distribution and methanogenesis activity.

pH values impose fundamental physiological restrictions on microbial activities. Soil pH ranges from acidic to circumneutral (pH 4-7.5) in northern Alaska and varies substantially through the soil profile and along the microtopographic gradient. Accumulation of organic acids in anoxic soils leads to pH decline (Jones et al., 2003), while consumption of organic acids by methanogenesis and iron reduction increases the alkalinity of the system via the production of HCO<sub>3</sub><sup>-</sup> and OH<sup>-</sup> (Drake et al., 2015; Roy Chowdhury et al., 2015; Howell et al.). The interplay of these processes leads to strong nonlinear pH feedbacks in the system, and previous studies have observed up to 1-2 pH unit changes during short-term anoxic incubations (Xu et al., 2015; Drake et al., 2015; Roy Chowdhury et al., 2015). These relationships between pH and organic carbon decomposition can vary in sign and magnitude. Our model simulations with mechanistic pH evolution indicate that constant pH assumed in previous models may cause significant errors in simulating long-term anaerobic CO<sub>2</sub> and CH<sub>4</sub> production. The intrinsic soil pH buffering capacity plays a large role in stabilizing soil pH and may be heterogeneous depending upon solution acidity or alkalinity, cation exchange capacity and residual acidity or mineral dissolution. These properties derive from SOM characteristics, moisture, mineral content, and additional geochemical properties, leading to complex correlations between soil pH and SOC decomposition rate that require future investigation.

#### 4.3 Fast-decomposing carbon pool

Substrate availability is a primary determinant of potential CO<sub>2</sub> and CH<sub>4</sub> production (Lee et al., 2012; Schuur et al., 2015; Tarnocai et al., 2009). Total SOC is composed of heterogeneous C pools characterized by different turnover times. Carbon release during short term incubation originates from the C pool with relatively rapid turnover. The size and turnover time of this quickly-metabolized carbon pool is usually estimated by two-pool or three-pool conceptual models with a maximum likelihood solution using time series of CO<sub>2</sub> data (Schädel et al., 2013). A previous study on Siberian permafrost soils using a two-pool model estimated

a turnover time of 0.26 years for the fastest-responding pool (Knoblauch et al., 2013). A three-pool model was applied using more extensive incubation datasets collected from 23 high-latitude ecosystems, yielding an estimate of 0.35 years mean turnover time for the fastest-responding carbon pool (Schädel et al., 2014).

5 In our synthesis study, we directly quantified WEOC and assumed it represented the fast-decomposing labile carbon pool. The size of the labile carbon pool is constant during anaerobic decomposition, while total CO<sub>2</sub> and CH<sub>4</sub> release represent up to 194% of the labile carbon pool, indicating continuous replenishment of labile carbon pool from non-labile carbon pools within the hierarchy. The replenishment of labile carbon pool can be attributed mostly to decomposition of SOM1 and SOM2 pools with faster turnover (Koven et al., 2013). Overall, we estimated the fast-decomposed carbon pool is approximately 2-4% of total SOC, similar to  
10 previous estimates. The turnover time calculated from the fermentation rate was comparable to estimates of the turnover time of the fastest-responding carbon pool in previous studies (Figure 9), suggesting these quantifications and parameterization in the anaerobic carbon decomposition framework apply broadly.

#### 4.4 Key features of the anaerobic model framework and future considerations

Here we present an anaerobic carbon decomposition framework by combining three well-known modeling approaches developed  
15 in different disciplines. A pool-based model to represent upstream carbon transformations and replenishment of a DOC pool, a thermodynamically-based model to calculate rate kinetics and biomass growth for methanogenesis and Fe(III) reduction, and a humic ion-binding model for aqueous phase speciation and pH calculation are implemented into the open source geochemical model PHREEQC (Charlton and Parkhurst, 2011). The model framework presented here has several unique features. First, this model is built upon a thermodynamically-based approach, which allows consistent parameterization of individual reactions along  
20 the redox ladder. Such a model structure is particularly useful in circumstances when function-specific microbial growth is difficult to quantify and parameterize. Second, calculations of free energy changes of redox couples are used to modulate redox reaction hierarchy. Considering the difficulty in obtaining growth-associated parameters for every functional group, a thermodynamically-based approach significantly decreases the number of parameters that are difficult to measure. In addition, proton production and consumption during redox reactions are incorporated into a dynamic pH calculation, allowing various simulations on aqueous  
25 solubility and reactivity of different elements. The anaerobic carbon decomposition framework presented here holds a significant advantage over traditional models in simulating carbon decomposition process within a wide range of environmental settings.

In permafrost affected regions, studies consistently identify iron reduction, denitrification and sulfate reduction (Lipson et al., 2010; Lipson et al., 2013; Ernakovich et al., 2017; Hansen et al., 2007) as alternative anaerobic pathways, which are recognized  
30 as energetically more favorable processes than methanogenesis. Fe reduction makes a significant contribution to total respiration (Roy Chowdhury et al., 2015; Herndon et al., 2015), and adding Fe reduction simulations to a baseline model (without Fe reduction or dynamic pH calculations) caused faster decreases in TOAC and WEOC pools and increased CO<sub>2</sub> production as expected (Figure S10). More indirect feedbacks were revealed when dynamic pH calculation was enabled. With dynamic pH simulation during anaerobic decomposition, the model revealed strong pH dynamics that are counterbalanced by Fe reduction. By including both Fe  
35 reduction and dynamic pH calculations, the model accurately reproduced the initial pH drop and subsequent pH rise during incubations, which were commonly observed in permafrost affected soils (Roy Chowdhury et al., 2015; Herndon et al., 2015). The new model framework presented here provides a basis for a deeper understanding of carbon decomposition under oxygen-limited conditions where the importance of accounting for alternative electron acceptors and pH feedbacks becomes more pronounced. Future fine-scale experiments on carbon decomposition using alternative electron acceptors would be beneficial for more  
40 comprehensive parameterization of this model framework. Additional observations on temperature and pH sensitivity of specific redox reactions would also be quite useful in reducing large uncertainties generated by the current representation of temperature

and pH responses. Application of such a modeling framework at the field scale requires close coupling with hydrology models to facilitate estimations of aqueous phase concentrations. Additional assumptions on vertical mixing and gas diffusion in the soil column should also be considered.

## 5 5. Conclusion

Microbial processes are the driving forces for biogeochemical cycling of soil carbon and are subjected to environmental constraints beyond temperature and organic substrate availability. The present study incorporated microbial redox reactions and mechanistic pH evolution to simulate anaerobic carbon decomposition in Arctic soils with depth and across soil moisture gradients. Our data synthesis and modeling results quantify direct effects of temperature on anaerobic carbon decomposition, as well as indirect effects of soil geochemistry that cause strong redox reaction-pH feedback. We identified substantial pH feedbacks on the predictions on CO<sub>2</sub> and CH<sub>4</sub> production. The anaerobic carbon decomposition framework presented in this study provided the essential model structure to incorporate redox reactions of alternative electron acceptors for accurate simulation of CO<sub>2</sub> and CH<sub>4</sub> production. Soil geochemistry imposes critical constraints on SOM decomposition, and further regulates permafrost carbon feedback in response to changing climate.

## 15 Code and data availability

PHREEQC (Version 3) is publicly available at [http://wwwbrr.cr.usgs.gov/projects/GWC\\_coupled/phreeqc/](http://wwwbrr.cr.usgs.gov/projects/GWC_coupled/phreeqc/)

The model is archived at (Zheng et al., 2018c), with a detailed description of model implementation, input files and various sensitivity analyses described in this paper.

20

Data sets used in this work can be found at (Herndon et al., 2017; Zheng and Graham, 2018; Zheng et al., 2017), and a synthesis of the incubation data is available at (Zheng et al., 2018a).

## Author contributions

DG, SW, and BG conceived and organized the research study; PT, SP, DG and JZ built the conceptual model framework; JZ preformed all model simulations; JZ and DG drafted the manuscript. All authors contributed revisions to the manuscript and have given approval to the final version of the manuscript.

## Competing interests

The authors declare no competing interests.

## 30 Acknowledgements

We appreciate comments and suggestions on earlier versions of this paper offered by Ethan Coon and manuscript reviewers. ## Appendix A: Anaerobic carbon decomposition model

5 This section lists reactions used in the anaerobic carbon decomposition model. Under anaerobic conditions, dissolved organic carbon is converted to low molecular weight organic acids via fermentation. One simplified fermentation reaction is used to represent this lumped fermentation process, where 1/3 of the fermented organic carbon is converted to CO<sub>2</sub> (Tang et al., 2016; Xu et al., 2015):

10 This fermentation reaction generates protons and decreases pH in the system. Fermentation products acetate and H<sub>2</sub> are further consumed via methanogenesis and iron reduction. The growth equations of methanogenesis and iron reduction were derived for each group using a thermodynamically-based approach, in which biomass synthesis is included in paired electron donor and electron acceptor half-reactions. A general molecular formula C<sub>5</sub>H<sub>7</sub>O<sub>2</sub>N is used for microbial biomass and the growth equations are written as (Istok et al., 2010)

25 In addition, Fe(III) concentration was calculated based on the dissolution of representative amorphous ferric hydroxides (A6), with a solubility constant  $K_{s0} = 10^{3.96}$ . This process consumes many protons and contributes to pH increases.

30 A complete set of rate constants used in this model can be found in Table S1.

## Appendix B: Temperature and pH response functions

35 We used the CLM\_CN temperature response function (B1) in our simulations (Thornton and Rosenbloom, 2005). Additional tested temperature response functions included B2 used by the CENTURY model (Parton et al., 2001), Arrhenius equation B3 used in *ecosys* (Grant, 1998), and the quadratic equation B4 (Ratkowsky et al., 1982).  $T_{ref}$  is set at 25 °C,  $E_a$  is the activation energy (J mol<sup>-1</sup>), and R is the universal gas constant (J K<sup>-1</sup> mol<sup>-1</sup>).  $T_m$  used in Ratkowsky's model represents a conceptual temperature of no metabolic significance and is set at -8 °C in this study.

$$\ln f(T) = 308.56 \times \left( \frac{1}{71.02} - \frac{1}{T-227.13} \right) \quad (B1)$$

$$f(T) = 0.56 + 0.465 \arctan [0.097(T - 15.7)] \quad (B2)$$

$$f(T) = e^{\frac{-E_a}{R} \left( \frac{1}{T} - \frac{1}{T_{ref}} \right)} \quad (B3)$$

$$f(T) = \left( \frac{T - T_m}{T_{ref} - T_m} \right)^2 \quad (B4)$$

55 The discontinuous bell-shaped pH response function from the DLEM model was used here (equation B5, Tian et al., 2010)

$$f(pH) = \frac{1.02}{1.02 + 10^6 \exp(-2.5pH)} \quad (0 < pH < 7) \quad (B5)$$

$$f(pH) = \frac{1.02}{1.02 + 10^6 \exp(-2.5(14 - pH))} \quad (7 < pH < 14)$$

5

**Figure 1. Conceptual diagram showing key processes in the anaerobic carbon decomposition framework. The numbers indicate different processes: 1. SOM degradation from soil organic carbon pools with increasing turnover time produces dissolved organic carbon (DOC) and CO<sub>2</sub>; 2. Fermentation of DOC into organic acids, H<sub>2</sub> and CO<sub>2</sub>; 3. Methanogenesis from organic acids or H<sub>2</sub>; 4. Fe(III) reduction from organic acids or H<sub>2</sub>; 5. Fe(OH)<sub>3</sub> dissolution.**

10

15

10 **Figure 2. Comparison between modeled and observed production of CO<sub>2</sub> (a) and CH<sub>4</sub> (b). Averaged measurements of triplicate microcosms at each time point from each incubation temperature were calculated as observed values.**

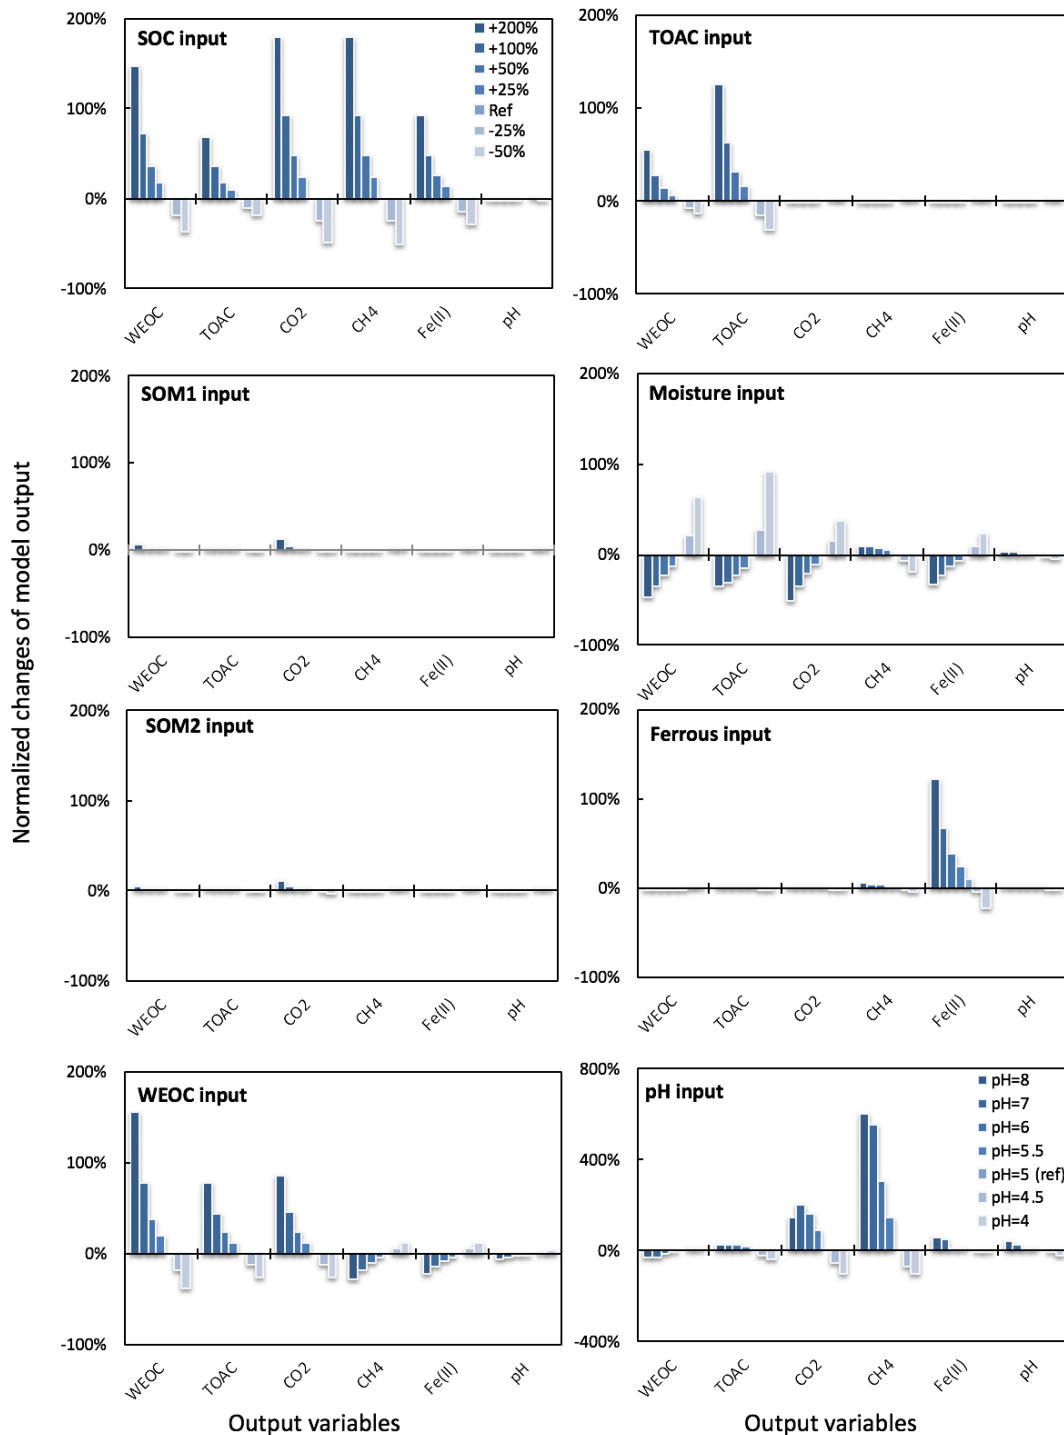

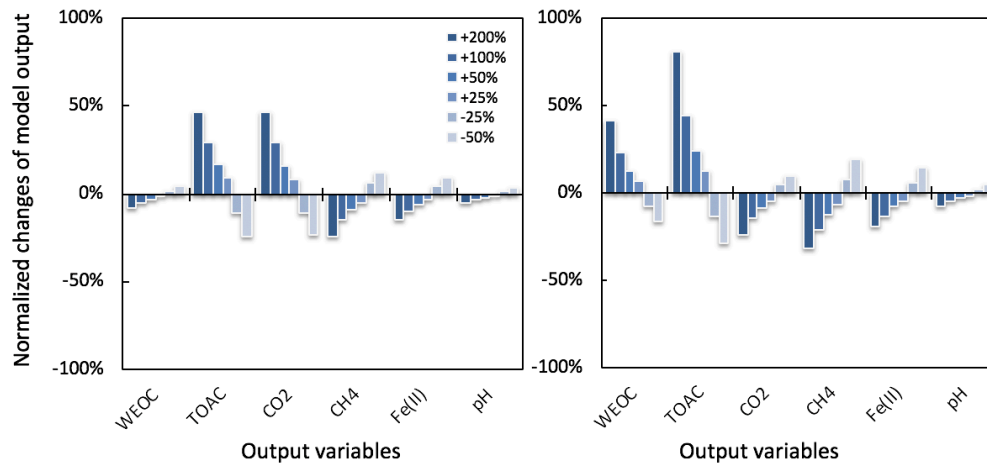

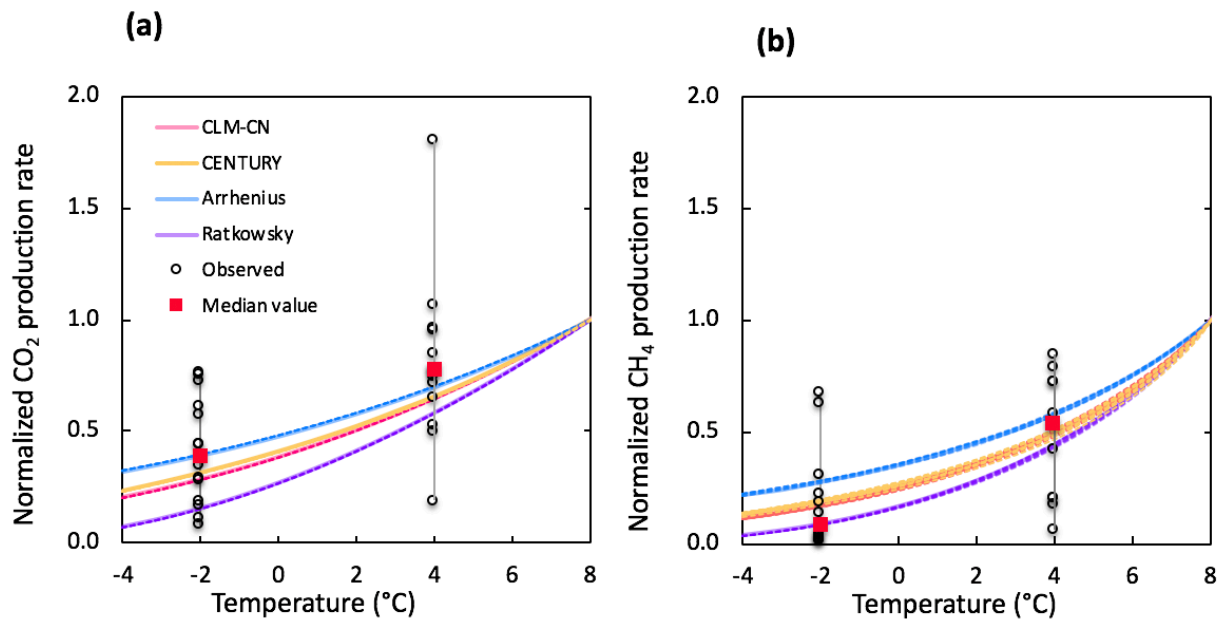

Figure 3. Perturbations of initial soil geochemical conditions differentially affected model predictions (including CH<sub>4</sub>, CO<sub>2</sub>, Fe(II), TOAC, WEOC, and pH) during anaerobic carbon decomposition. For example, when the initial pH decreased by 8% and 17%, CH<sub>4</sub> production decreased by 40% and 80%, respectively. Normalized changes in model output were calculated as the ratio of changes caused by perturbation simulations (differences between perturbation and reference runs) to reference simulation output after 60 days of anaerobic decomposition at 8 °C. To test model sensitivity in response to initial pH, the reference run started with pH 6, and up to 1 pH unit changes was applied in perturbation simulations to represent a realistic pH range for soils. Reference simulations were based on soils with 30% SOC (water content=2 g g<sup>-1</sup> dwt, and pH=5).

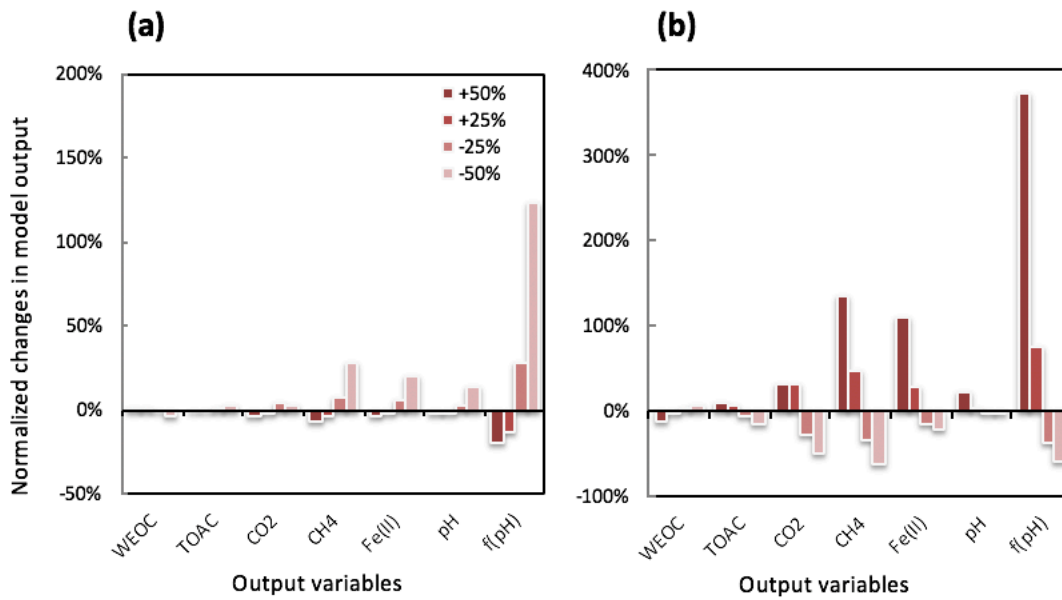

5

Figure 4. Simulated changes in model predictions (including CH<sub>4</sub>, CO<sub>2</sub>, Fe(II), TOAC, WEOC, and pH) during anaerobic carbon decomposition in response to perturbations of (a) fermentation rate and (b) fermentation stoichiometry (Acetate:CO<sub>2</sub>=1:1 for reference simulation). Normalized changes in model output were calculated as the ratio of perturbation simulation output to reference simulation output after 60 days of anaerobic decomposition at 8 °C. Reference simulations were based on soils with 30% SOC (water content=2 g g<sup>-1</sup> dwt, and pH=5).

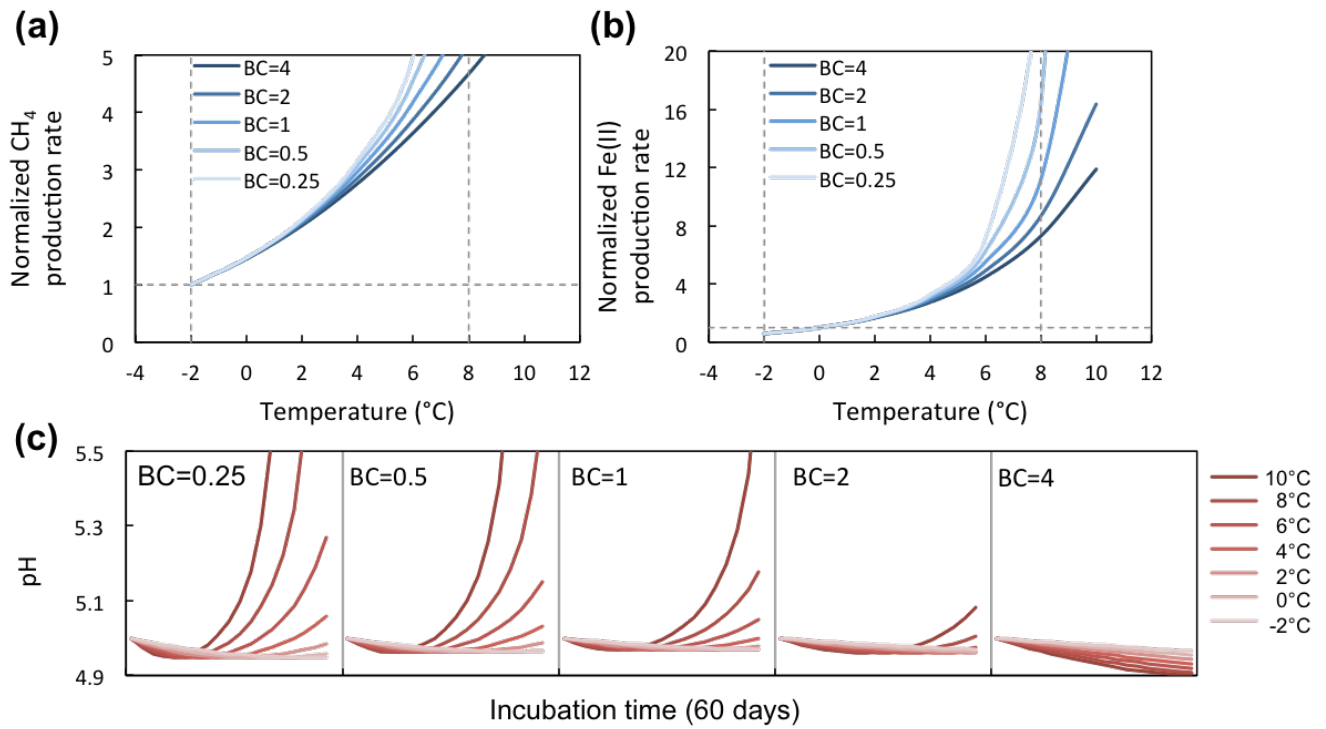

10

5 Figure 5. Comparison of simulated and observed temperature response for the production of CO<sub>2</sub> (a) and CH<sub>4</sub> (b). Results were all normalized to CO<sub>2</sub> or CH<sub>4</sub> production rates at 8 °C for direct comparison. Observations at -2 °C and 4 °C were plotted in black dots and the median value were marked in red. The shaded area represents output uncertainties generated from rate estimations within 60 ± 5 days. Reference simulations were based on soils with 30% SOC (water content=2 g g<sup>-1</sup> dwt, and pH=5).

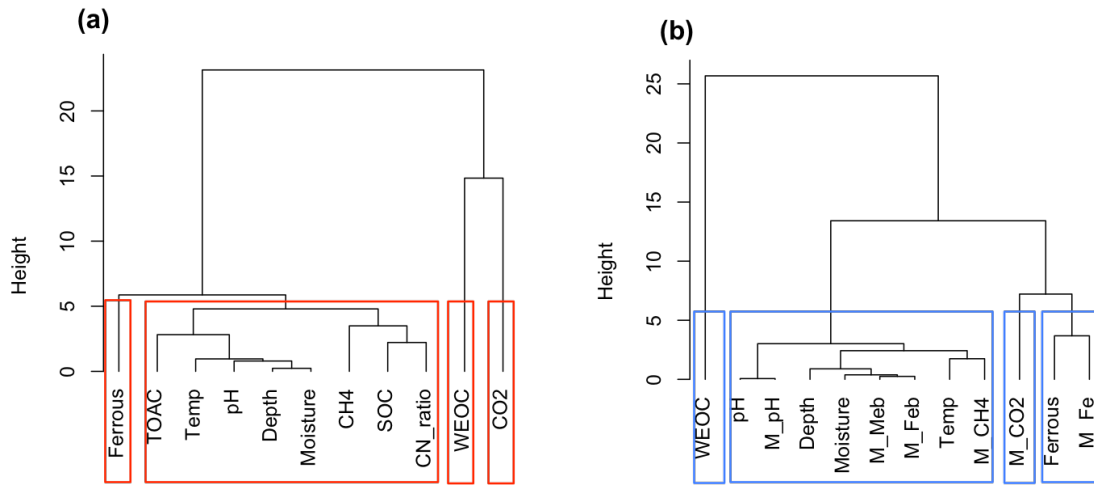

5 **Figure 6. Simulated changes in model predictions (including CH<sub>4</sub>, CO<sub>2</sub>, Fe(II), TOAC, WEOC, pH and  $f_{pH}$ ) during anaerobic carbon decomposition in response to perturbations of (a) pH buffering capacity, and (b) pH response function. Normalized changes in model output were calculated as the ratio of perturbation simulation output to reference simulation output after 60 days of anaerobic decomposition at 8 °C. Reference simulations were based on soils with 30% SOC (water content=2 g g<sup>-1</sup> dwt, and pH=5).**

**Figure 7. Temperature response of CH<sub>4</sub> and Fe(II) production rates at varying soil pH buffering capacities (BC). Varying BCs with respect to the reference simulation (BC=1) creates strong feedback to rates of methanogenesis and iron reduction. Reference simulations were based on soils with 30% SOC (water content=2 g g<sup>-1</sup> dwt, and pH=5).**

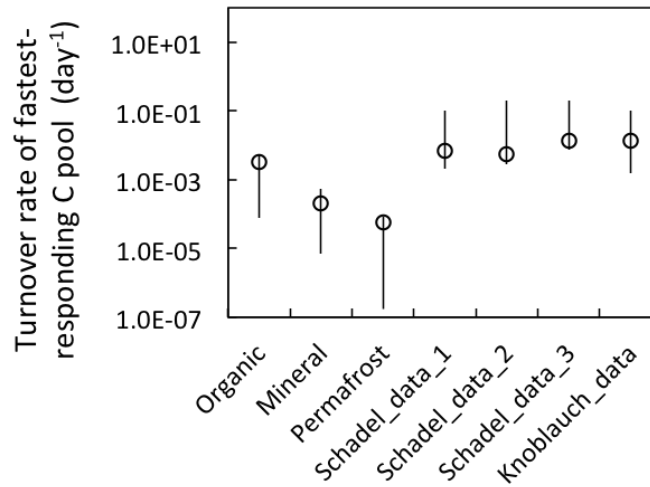

5

**Figure 8. Cluster analysis of soil geochemical properties related to CO<sub>2</sub> and CH<sub>4</sub> production using Ward's linkage method. (a) cluster analysis of measured soil geochemical characteristics and observed CO<sub>2</sub> and CH<sub>4</sub> production ( $n=42$ ); (b) cluster analysis of modeled results ( $n=42$ ). Model simulated CO<sub>2</sub>, CH<sub>4</sub>, and Fe(II) production and final pH are labeled as M\_CO<sub>2</sub>, M\_CH<sub>4</sub>, M\_Fe, and M\_pH, respectively. Biomasses of methanogens and iron reducers were tracked in the model and labeled M\_Meb and M\_Feb, respectively.**

10

5 **Figure 9. Model estimated turnover rates of the fastest-decomposing carbon pool. Organic, Mineral, and Permafrost labels represent estimations from our model simulations (rates estimated at 4 °C). Schadel\_data represent turnover rates estimated via a three-pool model from pooled anaerobic incubations with normalized incubation temperature of 5 °C (tag 1, 2, and 3 represent pool estimation from different soil types: 1. Organic, 2. Mineral <1m, 3. Mineral >1m) . Knoblauch\_data are rate estimates (at 4 °C) made via a two-pool model (Schädel et al., 2014; Knoblauch et al., 2013). Open**  
 10 **symbols represent the average values, and the vertical lines represent the estimated range.**
