21 **Abstract.** Carbon and nitrogen uptake rates by small phytoplankton (0.7-5 μm) in the Kara,
22 Laptev, and East Siberian seas in the Arctic Ocean were quantified using *in situ* isotope labeling
23 experiments; this research was novel and part of the NABOS (Nansen and Amundsen Basins
24 Observational System) program, took place from August 21 to September 22, 2013. The depth-
25 integrated carbon (C), nitrate (NO_3^-), and ammonium (NH_4^+) uptake rates by small
26 phytoplankton ranged from 0.54 to 15.96 $\text{mg C m}^{-2}\text{h}^{-1}$, 0.05 to 1.02 $\text{mg C m}^{-2}\text{h}^{-1}$, and 0.11 to 3.73
27 $\text{mg N m}^{-2}\text{h}^{-1}$, respectively. The contributions of small phytoplankton towards the total C, NO_3^- ,
28 and NH_4^+ varied from 25 to 89%, 31 to 89%, and 28 to 91%, respectively. The turnover times for
29 NO_3^- and NH_4^+ by small phytoplankton found in the present study indicate the longer residence
30 times (years) of the nutrients in the deeper waters, particularly for NO_3^- . Additionally, the
31 relatively higher C and N uptake rates by small phytoplankton obtained in the present study from
32 locations with less sea ice concentration indicate the possibility that small phytoplankton thrive
33 under the retreat of sea ice as a result of warming conditions. The high contributions of small
34 phytoplankton to the total C and N uptake rates suggest the capability of small autotrophs to
35 withstand the adverse hydrographic conditions introduced by climate change.

41

42 **1. Introduction**

43 The Arctic Ocean has always been a key attraction for oceanic expeditions due to its rapid
44 response to changing environmental conditions caused by both natural and anthropogenic factors.
45 It has been reported that the rate of decrease in the sea ice extent in the Arctic Ocean is
46 significantly high and has gradually caused a decline in sea ice thickness over recent decades
47 (Stroeve et al., 2008; Comiso et al., 2008; Kwok et al., 2009; Overland and Wang, 2013). As an
48 immediate effect, sea ice retreat could benefit the primary production by autotrophs due to
49 increased exposure to sunlight (Hill and Cota, 2005; Bélanger et al., 2008; Gradinger, 2009;
50 Arrigo et al., 2012; Arrigo and van Dijken, 2015; Kahru et al., 2016). It was also reported that
51 primary production in the Barents Sea increased by 30% during the warm period (i.e., 1989-1995)
52 compared to the cold period during the 1960s (Arrigo et al., 2008; Wassmann et al., 2011).
53 However, as a result of sea ice melting, the ice-algal communities may be replaced by pelagic
54 communities. Although ice-algal communities are not a large contributor to primary production,
55 their absence could potentially alter the vertical flux of organic carbon and coupling between the
56 euphotic and benthic zones (Walsh, 1989).

57 Sea surface warming can also result in strong water column stratification, which can
58 reduce the nutrient supply to the surface water and consequently cause a decrease in primary
59 production (Bopp et al., 2001; Li et al., 2009; Tremblay and Gagnon, 2009; Martin et al., 2010;
60 Steinacher et al., 2010; McLaughlin et al., 2010; Slagstad et al., 2011; Lee et al., 2007, 2012;
61 Thomas et al., 2012); these conditions would cause alterations in the C dynamics in the Arctic
62 Ocean (Arrigo et al., 2008; Bates and Mathis, 2009; Cai et al., 2010). How phytoplankton
63 communities in the Arctic Ocean would respond to the physical, chemical, and biological stress
64 introduced by global warming has been a heavily debated topic. One group of researchers has

65 reported that there has been an enhancement in annual primary production due to increased light
66 availability and warmer temperature in the Arctic Ocean (Arrigo et al., 2008; Arrigo and Dijken,
67 2011; Thomas et al., 2012). However, another group has suggested that excess moisture fluxes
68 under warmer sea conditions can introduce wider cloud cover conditions during summer and
69 early fall, and thus, the possibility of reducing autotrophic primary production is inevitable
70 (Eastman and Warren, 2010; Vavrus et al., 2012; Bélanger et al., 2013). Water column
71 stratification is also a contrary effect introduced by global warming, and stratification can
72 significantly reduce the amount of vertical mixing of nutrient-rich deep waters, lowering primary
73 productivity (Tremblay and Gagnon, 2009; Lee et al., 2007, 2012; Yun et al., 2015). On the other
74 hand, a decline in the nutrient concentrations in surface waters and sustained nutrient levels in
75 the deeper waters could be an immediate effect of global warming (Vancoppenolle et al., 2013).
76 Such an environment would be adverse for large phytoplankton communities who require more
77 nutrients to achieve a given potential primary production level (Li et al., 2009). However, small
78 phytoplankton (size range: 0.7-5 μm), which have lower nutrient requirements, proliferate under
79 such conditions (Daufresne et al., 2009; Li et al., 2009). Hence, understanding the mechanism
80 and processes of small phytoplankton metabolic activities under various environmental
81 conditions would be a crucial aspect of Arctic Ocean ecosystem research.

82 A few studies have been conducted to understand the fate of small phytoplankton under
83 changing environmental scenarios (Li et al., 2009; Yun et al., 2015). These studies have
84 identified that the smallest phytoplankton cells can flourish under such nutrient-replete
85 conditions; however, the larger cells decline in number (Li et al., 2009). Hence, the reduction in
86 the community average body size of the autotrophs is expected to be an obvious response to
87 global warming (Daufresne et al., 2009). Consequently, the primary production contribution by

88 small phytoplankton would be a substantial part of the Arctic Ocean biogeochemistry. However,
89 the contribution of small phytoplankton to autotrophic C and dissolved inorganic nitrogen [here;
90 $\text{DIN}=\text{NO}_3^-+\text{NH}_4^+$] fixation has been one of the least investigated topics in global oceanic
91 research, particularly in the Arctic Ocean (Semiletov et al., 2005; Arrigo and Dijken, 2011; Lee
92 et al., 2007, 2012; Yun et al., 2012, 2015; Hill et al., 2017).

93 Apart from global warming, localized influences are also an important factor in
94 controlling primary production in the Arctic Ocean. It has been reported that Arctic Ocean
95 biogeochemistry is mainly governed by the high riverine inputs and intrusions of Atlantic and
96 Pacific waters (Shiklomanov et al., 2000; Carmack and Macdonald, 2002; Peterson, et. al., 2002;
97 Anderson et al., 2004). The major rivers those flow into the Arctic Ocean are the Ob', Lena,
98 Yenisey, and Mackenzie rivers, and numerous smaller rivers flow in both the Amerasian and
99 Eurasian sectors. It has been reported that the Ob' and Yenisey rivers increased in their
100 freshwater discharge since the 1980s (Semiletov et al., 2005; Anderson et al., 2009). These seas
101 are situated along the continental shelf of the Arctic Ocean, which is known to be the widest and
102 shallowest shelf in the world's oceans (Semiletov et al., 2005). These seas are characterized by
103 highly dynamic organic matter production and export to the deeper ocean as well as profound
104 atmospheric exchanges of volatile gases (Semiletov et al., 2005; Anderson et al., 2009).

105 A few studies have estimated the influence of river effluences on the C and DIN uptake
106 rates (Lee et al., 2007, 2012; Yun et al., 2015). However, the potential impact of riverine influx
107 on small phytoplankton uptake rates, which is relevant for the accountability of natural and
108 anthropogenic influences on Arctic primary production, has not been investigated thus far. The
109 present study reports the first investigation results on small phytoplankton (size: 0.7-5 μm)
110 contributions to the C, NO_3^- , and NH_4^+ uptake rates in the Kara, Laptev, and East Siberian seas.

111 Considering the global relevance of Arctic Ocean biogeochemistry, the present study aimed to (1)
112 estimate the contribution of small phytoplankton to total primary production as well as the NO_3^-
113 and NH_4^+ uptake rates and (2) investigate various factors influencing small phytoplankton
114 community efficiency in the Kara, Laptev, and East Siberian seas.

115 **2. Materials and Methods**

116 **2.1. Study Area**

117 The investigations on biochemical parameters and C and DIN transformation rates in the Kara,
118 Laptev, and East Siberian seas were conducted at 19 monitoring stations selected from a total of
119 116 NABOS stations (Fig. 1; Table 1). The geographical boundaries of each sea were defined as
120 per the classification performed by Pabi et al. (2008) (Fig. 1). Based on this classification, there
121 were 4, 13, and 2 stations located in the Kara, Laptev, and East Siberian seas, respectively. The
122 Kara and East Siberian seas have surface areas almost two times ($926 \times 10^3 \text{ km}^2$ and 987×10^3
123 km^2 , respectively) larger than that of the Laptev Sea ($498 \times 10^3 \text{ km}^2$) (Jakobsson, 2001).
124 Additionally, the Laptev and East Siberian seas hold the shallowest zones of the Arctic Ocean
125 basin, with a mean depth of 48 m, while the Kara Sea has a mean depth of 131 m (Jakobsson,
126 2001).

127 **2. 2. Sampling**

128 The sampling was conducted from 21st August to 22nd September 2013 onboard the Russian
129 vessel “*Akademik Fedorov*”. The temperature and salinity were measured using a Seabird SBE9
130 plus CTD (conductivity-temperature-depth tool) equipped with dual temperature (SBE3) and
131 conductivity (SBE4) sensors. Samples for major inorganic nutrients [i.e., NO_3^- , nitrite (NO_2^-),
132 NH_4^+ , phosphate (P), and silicate (Si)] were collected using Niskin bottles attached to the CTD

133 device, and analysis was performed onboard using an Alpkem Model 300 Rapid Flow Nutrient
134 Analyzer (5 channels) based on Whitley et al. (1981). The chlorophyll *a* (Chl *a*) samples for
135 the small phytoplankton fraction were obtained from 3 light depths (100, 30, and 1%). The
136 preparation of Chl *a* samples was based on the standard procedure reported in previous studies
137 on the Arctic Ocean (Lee and Whitley, 2005; Lee et al., 2012). Water samples for small Chl *a*
138 fractions were sequentially filtered through a 5 μ m Nucleopore and then 0.7 μ m pore-sized
139 Whatman GF/F filters (47 mm). Furthermore, the GF/F filters were wrapped in aluminum foil
140 and kept frozen at -80°C until analysis. During the analysis, the Chl *a* fractions from the filters
141 were extracted using 90% acetone treatment at 5°C for 24 hours. The extracted Chl *a* samples
142 were subjected to spectrophotometric analysis onboard using a pre-calibrated Turner Designs
143 model 10-AU fluorometer. Samples for the C and DIN uptake rates were collected from six *in*
144 *situ* light level depths (100, 50, 30, 12, 5, and 1%) determined at each station based on the
145 euphotic depth, which is based on Lambert-Beer's law. Underwater PAR sensors (and/or optical
146 instruments) could not be used due to logistical problems, and the euphotic depth was calculated
147 using the Secchi depth, which is a widely used method (Son et al., 2005; Tremblay et al., 2000;
148 Lee et al. 2012; Bhavya et al., 2016; 2017; Lee et al., 2017a, 2017b).

149 **2.3 ¹³C and ¹⁵N labeling experiments**

150 The estimation of the C and DIN uptake rates was performed using ¹³C and ¹⁵N dual isotope
151 labeling experiments (Dugdale and Goering, 1967; Slawyk et al 1977; Dugdale and Wilkerson,
152 1986). Seawater samples at each light depth were collected using Niskin bottles attached to the
153 CTD Rosette and transferred to acid-cleaned polycarbonate incubation bottles (approximately 1
154 L) wrapped with neutral density light filters (LEE filters) to match the desired light levels.
155 Immediately, samples were spiked with 98-99% enriched tracer solutions of NaH¹³CO₃, K¹⁵NO₃,

156 or $^{15}\text{NH}_4\text{Cl}$ at concentrations of ~ 0.3 mM, $\sim 0.8\mu\text{M}$, and $\sim 0.1\mu\text{M}$ for the estimations of the C,
157 NO_3^- , and NH_4^+ uptake rates, respectively. Furthermore, the samples were subjected to 4-6 hrs of
158 incubation in large transparent Plexiglas incubators on deck under natural light conditions, and
159 these incubators were provided with running surface seawater. Immediately after the incubation,
160 0.3 L of incubated samples were filtered through pre-combusted GF/F filters (25 mm diameter)
161 for the total uptake rate estimation. The samples for the small fraction, sub-samples (0.5 L) of the
162 incubated waters were passed through $5\mu\text{m}$ Nuclepore filters (47 mm) to remove large
163 phytoplankton cells ($>5\mu\text{m}$), and then the filtrate was passed through pre-combusted GF/F (25
164 mm) for the small phytoplankton (Lee et al., 2013). The values for large phytoplankton in this
165 study were obtained from the difference between the small and total fractions (Lee et al., 2013).
166 Samples were kept frozen (-20°C) until the mass spectrometric analysis (Finnigan Delta+XL) at
167 the stable isotope laboratory of University of Alaska Fairbanks, USA. The uncertainties for the
168 $\delta^{13}\text{C}$ and $\delta^{15}\text{N}$ measurements were $\pm 0.1\text{‰}$ and $\pm 0.3\text{‰}$, respectively. The DIN uptake rates of
169 small phytoplankton were estimated using the mathematical formula given by Dugdale and
170 Goering (1967).

$$171 \text{ DIN uptake rate} = P * \Delta I_p / (T * (I_0 S_a + I_r S_t) / (S_a + S_t) - I_0)$$

172 where P is the amount of particulate N in the post-incubation sample; ΔI_p is the increase in ^{15}N
173 atom% in particulate N during incubation; S_a and S_t are the ambient and added NO_3^- (or NH_4^+)
174 concentrations, respectively; I_r and I_0 are ^{15}N atom% of added tracer and natural ^{15}N atom%; and
175 T is the incubation time period. This equation assumes no formation of nutrients during
176 incubation; therefore, the rates presented here are the potential rates. Similarly, the C uptake
177 rates were also calculated using the same equation, where P denotes the particulate organic C,
178 and S_a and S_t are the ambient dissolved inorganic carbon and added ^{13}C tracer concentrations,

179 respectively. I_r and I_0 are the ^{13}C atoms% of the added tracer and natural ^{13}C atom%,
180 respectively (Slawyk et al., 1977).

181 **3. Results and discussion**

182 **3.1 Environmental parameters in the Arctic Ocean**

183 The biological, chemical, and physical properties of the Arctic Ocean are mainly controlled by
184 the circulation patterns governed by the waters of the Pacific and Atlantic Oceans (Anderson et
185 al., 2004; Quadfasel, 2005) along with the river inputs (Peterson et al., 2002). The nutrient-rich,
186 low saline (<33) Pacific Ocean waters and nutrients replete relatively more saline (≈ 34.8)
187 Atlantic Ocean waters collectively regulate the biogeochemical activities of the Arctic Ocean
188 (Maslowski et al., 2004). The present study was conducted during the late summer season, when
189 the sea surface temperature (SST) ranged from -1.76°C to 1.62°C . The sea surface salinity (SSS)
190 during the study period varied from 28.29 to 33.44 (Table 1), which could be due to the influence
191 of both the circulation patterns and the freshwater inputs. The present study retrieved the sea ice
192 concentration (SIC) data from the National Snow & Ice Data Center, who obtained the data from
193 a 2013 cruise. The results show that the SIC ranged from 0% to 100% (Table 1).

194 **3.2 Carbon and nitrogen uptake rates by small phytoplankton**

195 Fig. 2 shows the depth profiles of the C, NO_3^- , and NH_4^+ uptake rates per hour in the
196 Laptev, Kara, and East Siberian seas. Only a few stations showed significant subsurface maxima
197 for the C, NO_3^- , and NH_4^+ uptake rates during the present study, while the rest of the stations
198 exhibited no significant variation throughout the euphotic zone. The AF019 station showed
199 exceptionally higher C, NO_3^- , and NH_4^+ uptake rates, in general, with sharp subsurface maxima.

200 The depth-integrated C, NO_3^- , and NH_4^+ uptake rates by small phytoplankton in the East Siberian
201 Sea were observed to be very low compared to those of the other seas (Table 2, Figs. 3 & 4). The
202 depth-integrated C uptake rates by small phytoplankton ranged from 0.54 to 15.96 $\text{mg C m}^{-2}\text{h}^{-1}$.
203 The depth-integrated NO_3^- uptake rates ranged from 0.05 to 1.02 $\text{mg N m}^{-2}\text{h}^{-1}$, while the NH_4^+
204 uptake rates varied from 0.11 to 3.73 $\text{mg N m}^{-2}\text{h}^{-1}$. The station AF019 showed the maximum
205 small phytoplankton uptake rates for C (15.96 $\text{mg C m}^{-2}\text{h}^{-1}$), NO_3^- (1.02 $\text{mg N m}^{-2}\text{h}^{-1}$), and NH_4^+
206 (3.73 $\text{mg N m}^{-2}\text{h}^{-1}$). The contribution of small phytoplankton to the total uptake was also very
207 high at station AF019 (Table 2). The lowest C, NO_3^- , and NH_4^+ uptake rates were observed at
208 stations AF044 and AF041. The highest SIC (100% and 60% at AF044 and AF041, respectively)
209 in this region might be one explanation for the lower primary productivity due to light limitation.

210 **3.3 Sea ice and small phytoplankton primary production**

211 Previous investigations on SIC over the Arctic Ocean proved that, during winter, high ice
212 formation leads to the expelling of salt content to the surrounding water. This condition
213 introduces a relatively higher salinity and density water layer at the surface or just below the sea
214 ice layer relative to the surrounding area. Such conditions lead to the sinking of the very cold and
215 saline surface waters and the replacement by nutrient-rich deeper water, which is less dense and
216 slightly warmer. This process leads to deep vertical mixing and the replenishment of the surface
217 nutrient inventories (Niebauer et al., 1990; Falk-Petersen et al., 2000). However, during spring,
218 the melting of sea ice results in strong surface ocean stratification, where the nutrient-rich waters
219 are exposed to light, creating favorable conditions for phytoplankton growth (Kirk, 1983;
220 Niebauer et al., 1990; Falk-Petersen et al., 2000). It has also been reported that the increasing
221 atmospheric temperature due to global warming has caused a considerable reduction in SIC in

222 the Arctic Ocean over the past three decades, with a rapid decrease in recent years (Parkinson,
223 1999; Levi, 2000).

224 Because ice cover has a significant role in controlling primary production, the dynamics
225 of SIC is an integral part of Arctic Ocean research (Arrigo et al., 2008; Ardyna et al., 2014;
226 Kahru et al., 2016). It has been reported that a reduction in SIC would facilitate photosynthetic
227 activity and increase CO₂ intake by the seas (Anderson and Kaltin, 2001; Bates et al., 2006;
228 Kahru et al., 2016). Apparently, it can cause a relative decline in the contribution by algae
229 growing within the sea ice (Subba Rao and Platt, 1984; Legendre et al., 1992; Gosselin et al.,
230 1997), although the sea ice community contributes less than 10% to the total amount of Arctic
231 Ocean C sequestration (Clasby et al., 1973; Horner and Schrader, 1982). A detailed study
232 conducted on the inter-annual variations in SIC and primary production by Kahru et al. (2016)
233 suggested that primary production is enhanced with a decline in SIC. Kahru et al. (2016)
234 reported that a decrease in the SIC initially starts from June onwards in the northeastern Barents
235 Sea and between Greenland and the North American continent, with an increase in primary
236 productivity. This extends to the Kara and Laptev seas during July and August, and these areas
237 exhibit a gradual enhancement in primary productivity. Furthermore, this process migrates
238 towards the region off Siberia and eventually into the Beaufort and Chukchi seas. However, the
239 major enhancement of primary production generally occurs in the Laptev and Barents seas
240 (Kahru et al., 2016). In agreement with this, our results also show relatively lower SIC and
241 higher small phytoplankton C and DIN uptake rates in the Laptev Sea region (Table 2, Figs. 3 &
242 4). The maximum SIC in the Laptev Sea was observed at station AF071, with a value of 65%.
243 The Kara Sea was mostly void of ice cover, and only one station (AF095) was observed with an
244 SIC of 40%. Relatively lower small phytoplankton C and DIN uptake rates were observed at

245 both stations in the East Siberian Sea (AF041: 60% and AF044: 100%), where the SIC was
246 observed to be the maximum among all stations. However, there was no significant inverse
247 correlation between small phytoplankton C and DIN uptake rates and SIC found during the
248 present study (Figure not shown). This result could be due to the influence of other
249 environmental constraints, such as low nutrients and temperature, on the metabolic activities of
250 small phytoplankton.

251 The investigations conducted in the Amundsen Sea, Antarctic Ocean, reported that there
252 is no significant difference in the small phytoplankton C uptake rates between polynya and non-
253 polynya regions. The depth-integrated small phytoplankton C uptake rates obtained from
254 polynya and non-polynya regions in the Amundsen Sea ranged from 58.6–193 mg C m⁻²d⁻¹ (126
255 ± 55.2 mg C m⁻²d⁻¹) and 62.2– 266 mg C m⁻²d⁻¹ (124 ± 69.3 mg C m⁻²d⁻¹), respectively (Lee et
256 al., 2017a). These values showed that the depth-integrated small phytoplankton C uptake rates
257 reported from the Amundsen Sea from both polynya and non-polynya regions were relatively
258 higher than those obtained from the Arctic Ocean during the present study (5.86-191 mg C
259 m⁻²d⁻¹; average=37.7± 41.6). The daily NO₃⁻ uptake rates of the small phytoplankton obtained
260 from the Amundsen Sea were 7.5–26.6 mg N m⁻²d⁻¹ (16.7 ± 7.8 mg N m⁻²d⁻¹) and 6.1–40.9 mg
261 N m⁻²d⁻¹ (20.1 ± 13.1 mg N m⁻²d⁻¹), and the values of the NH₄⁺ uptake rates varied from 9.1–
262 22.4 mg N m⁻²d⁻¹ (15.8 ± 6.4 mg N m⁻²d⁻¹) and 9.9–81.1 mg N m⁻²d⁻¹ (30.7 ± 24.5 mg N
263 m⁻²d⁻¹), respectively, for the non-polynya and polynya regions. Similar to the C uptake rates, the
264 small phytoplankton uptake rates for NO₃⁻ (0.75-12.2 mg N m⁻²d⁻¹; 3.21±2.61 mg N m⁻²d⁻¹) and
265 NH₄⁺ (2.68-69.3 mg N m⁻²d⁻¹; average: 16.12±14.54 mg N m⁻²d⁻¹) were also significantly lower
266 than those of the Amundsen Sea. The lower small phytoplankton uptake rates in the Arctic
267 waters compared to the Antarctic waters may be due to the lower nutrient concentrations and co-

268 limitation of N in the Arctic waters (Harrison and Cota, 1991). Sakshaug & Holm-Hansen (1984)
269 reported that the maximum Arctic nutrient concentrations are typically lower than the minimum
270 Antarctic concentrations.

271 **3.4 Nutrient sources and influences on small phytoplankton primary production**

272 The shallow water column depths and the existence of long coastlines along with river
273 runoff provide a wide opportunity for autotrophs in the Arctic Ocean to obtain sufficient light
274 and nutrients (Kirk, 1983). Additionally, the Arctic Ocean is known to be a large receptor of
275 freshwater discharge that exceeds 4000 km³ per year (Shiklomanov, 2000; Carmack and
276 Macdonald, 2002). The riverine discharges may have a great role in keeping those stations near
277 river inlets distinctive in terms of their physico-chemical conditions. Similarly, the freshwater
278 discharge from the six largest Eurasian rivers has increased by 7% during the period of 1936-
279 1999 (Peterson et al., 2002). Among the various seas in the Arctic Ocean, the Kara and Laptev
280 seas are known to be the first and second largest receptors, respectively, of total organic carbon
281 fluxes, while the East Siberian Sea receives the least (Rachold et al., 2000).

282 In most stations, the NO₂⁻ + NO₃⁻ concentrations were observed to be homogeneous in
283 the water column up to a depth of 20 m (approximately 30% light depth); however, they
284 increased exponentially towards the bottom waters (Figure not shown). The depth profiles of
285 NH₄⁺ and P did not show any significant variation throughout the euphotic zone (Figure used in
286 Lee et al., unpublished). However, the nutrient concentrations were considerably distinct among
287 the stations. The depth-integrated NO₂⁻ + NO₃⁻ concentrations varied between 22.3 and 189
288 mmol m⁻². The depth-integrated concentrations of P and Si ranged from 7.62 to 35.4 mmol m⁻²
289 and 19.5 to 308 mmol m⁻², respectively (Table 1). Generally, high concentrations of NO₂⁻ + NO₃⁻

290 and phosphate were found at the AF005, AF068, and AF071 stations in the Laptev Sea and at
291 one station in the Kara Sea (AF100), and they were relatively higher than those of the East
292 Siberian Sea (Table 1, Figs. 3 & 4). However, the Si concentrations were higher in the East
293 Siberian Sea than in the other two seas. These results are comparable with the earlier studies
294 conducted by Codispoti and Richards (1968). They suggested that the concentrations of P and
295 NO_3^- were so low as to indicate nutrient limitation for phytoplankton production in the upper
296 layers.

297 The details of the euphotic depths and the depth-integrated nutrient concentrations are
298 shown in Table 1. The euphotic depths observed are different in almost all of the stations and
299 range from 33 to 76 m. However, the data from our present study did not show any dependency
300 of the depth-integrated nutrient budget with euphotic depth. For example, the AF019, AF080,
301 and AF095 stations have deeper euphotic zones; however, they do not have depth-integrated
302 $\text{NO}_2^- + \text{NO}_3^-$ concentrations close to the highest values obtained at the AF068, AF071, and AF005
303 stations, which have relatively shallower euphotic depths. The depth-integrated P values also
304 showed higher values at stations (AF019, AF068, AF100, AF080, AF095, and AF091) with both
305 deeper and shallower euphotic depths. Hence, the variation in the euphotic depth seems to be
306 insignificant in determining the nutrient budgets in the present study area.

307 The stations AF005, AF068, and AF071 in the Laptev Sea and AF100 in the Kara Sea,
308 which were nearby the river inlets, were observed to have relatively higher nutrient
309 concentrations (Table 1). The sampling locations away from the river inputs were mostly
310 invaded by the nutrient-poor Atlantic waters instead of the nutrient-rich Pacific waters. Moreover,
311 the Pacific Ocean nutrient inputs are generally restricted to the Chukchi Sea and the Amerasian
312 Basin (Carmack et al., 1997; Dmitrenko et al., 2006). It is worth noting that all the sampling

313 locations in the Arctic Ocean showed significantly lower small phytoplankton C and DIN uptake
314 rates, possibly due to the lack of light and nutrients. The nutrient stoichiometry analyses
315 suggested that the Arctic Ocean waters are N starved and the N:P (here N = DIN: $\text{NO}_2^- + \text{NO}_3^- +$
316 NH_4^+ and P: PO_4^{3-}) ratios are always below Redfield's ratio, which is 16:1 (mol: mol) (Redfield,
317 1963; Sakshaug, 2004). The relative abundances of micronutrients are also important factors in
318 controlling primary production (Glibert et al., 2013; Bhavya et al., 2016, 2017). The DIN: P
319 observed during the current study ranged from 2.60 to 16.4, with an average of 6.6 ± 3.0 , which
320 is also in agreement with the previous studies that have been reported. These ratios point towards
321 the N-starvation of phytoplankton, which can potentially prevent them from growing to a bloom.
322 It has been reported that such cases with lower nutrient concentrations are generally less starving
323 for small phytoplankton sizes ranging from 0.7-5 μm , and they appeared to be dominant in
324 euphotic water columns (Lee and Whitley, 2005; Li et al., 2009; Yun et al., 2015).

325 In general, experimental and theoretical evidence suggest that smaller cells have higher
326 rates of nutrient uptake per unit biomass and lower half-saturation constants due to their higher
327 surface area to volume ratios (Eppley and Thomas, 1969; Aksnes and Egge, 1991; Hein et al.,
328 1995). Hence, the lower minimum cellular metabolic requirement for small phytoplankton
329 selectively allows them to survive under lower resource concentrations than those of larger cells
330 (Shuter, 1978; Grover, 1991). Hence, small phytoplankton cells appear to have substantial
331 advantages over larger phytoplankton cells under nutrient-limited steady-state environmental
332 conditions (Grover, 1989; Grover, 1991). However, under very poor nutrient conditions, small
333 phytoplankton may also undergo nutrient starvation.

334

335 3.5 Nutrient co-limitation

336 Nutrient co-limitation is a major problem facing marine phytoplankton in oligotrophic
337 and pelagic ecosystems. Recent studies have suggested that the maximum uptake of
338 phytoplankton generally occurs when the nutrient stoichiometry is close to Redfield's ratio,
339 which is 16:1 (Li et al., 2011; Glibert et al., 2013; Bhavya et al., 2016, 2017), irrespective of the
340 individual nutrient concentration. Because the present study addresses completely different
341 ecosystems with high SIC, low nutrients and low SSTs, understanding the influence of DIN:P
342 would be challenging. In agreement with this, there were no significant correlations observed
343 between the C, NO_3^- , and NH_4^+ uptake rates and the DIN: P during the present study. However,
344 Fig. 5 shows a weak, although positive, correlation of small phytoplankton contribution towards
345 DIN:P. This result indicates the possibility of small phytoplankton efficiency to peak at a
346 nutrient stoichiometry close to Redfield's ratio. However, the lack of sufficient stations with
347 higher DIN:P values limits the present study from claiming the influence of nutrient
348 stoichiometry on the small phytoplankton contribution. It is also important to note that the
349 stations are located at geographical locations with diverse hydrographical parameters. However,
350 on the basis of few studies conducted from various parts of oceanic and estuarine regions, it has
351 been shown that DIN:P has a strong control on the total C and DIN uptake rates (Li et al., 2011;
352 Glibert et al., 2013; Bhavya et al., 2016, 2017). Although there was no significant correlation
353 obtained between the small phytoplankton uptakes and the DIN:P, the N co-limitation in the
354 Arctic Ocean is clearly seen (Table 1). Thus, the relative abundances of DIN and P are highly
355 important for the proper functioning of the C and DIN uptake mechanisms by autotrophs.

356

357 3.6 Turnover times of nutrients

358 The present study shows that N co-limitation persists in the Arctic Ocean and can potentially
359 limit the small phytoplankton contribution. In that case, any inorganic N substrate introduced to
360 the surface waters might be immediately used by the phytoplankton to facilitate organic matter
361 production under favorable environmental conditions. The turnover time for any substrate is an
362 important measurement to estimate how rapid an N substrate can be consumed. The estimation
363 of turnover time is performed by dividing the substrate concentrations with the corresponding
364 uptake rates. Figs. 6 & 7 show the turnover times for the NO_3^- and NH_4^+ substrates when small
365 phytoplankton communities are the only consumers. Fig. 7 shows that the turnover times for the
366 NH_4^+ substrate (within 500 hours) in the surface waters are longer; however, they are relatively
367 faster than those of the NO_3^- in the upper layers of the euphotic zone at almost all the stations in
368 the Arctic Ocean. However, the bottom waters of the euphotic zone showed relatively longer
369 (1000-1700 hours) turnover times for NH_4^+ substrate compared to the surface waters. The
370 sampling location in the East Siberian Sea (AF044) was observed to have relatively longer
371 turnover times for both NO_3^- and NH_4^+ substrates at the surface layers (Figs. 6 & 7), which was
372 possibly due to the lower uptake rates in that region. A continuous supply of nutrients through
373 rivers and less efficient DIN uptake rates might be major reasons for longer turnover times.
374 Compared to NH_4^+ , NO_3^- is consumed in distinctively longer periods as 14-fold at the surface
375 waters and 25-fold at the bottom of the euphotic zone. Primarily, such a difference is due to the
376 relative preference for NH_4^+ by the small phytoplankton and second, due to the high
377 concentrations of NO_3^- in the deep waters relative to the NH_4^+ concentrations. The research
378 outputs from a tropical eutrophic estuary in India have shown rapid turnover time (3.4-232 hrs
379 for NH_4^+ and 7.13-2419 hrs for NO_3^-) by total phytoplankton communities for DIN substrates

380 despite higher nutrient concentrations (Bhavya et al., 2016). In general, inhibition of NO_3^- uptake
381 is a very common phenomenon when higher NH_4^+ concentrations occur (e.g., Glibert, 1982;
382 Harrison et al., 1987; McCarthy et al., 1999; Bhavya et al. 2016). It is also very likely there will
383 be different turnover times with similar DIN concentrations under different hydrographic
384 properties that can govern the C and DIN metabolism in a given region.

385 **3.7 Quantum yield**

386 During the present study, the size-fractionated Chl *a* concentrations at the three light levels (100,
387 30, and 1%) were measured. The comparative analysis with the total Chl *a* fraction suggests that
388 the small phytoplankton communities are major contributors in the Laptev, Kara, and East
389 Siberian seas (Figure not shown; data used from Lee et al., unpublished). The results showed
390 significantly high contributions of small phytoplankton to total Chl *a* at all three light levels
391 (63.3 (S.D. = $\pm 17.5\%$), 61.4 (S.D. = $\pm 19.9\%$), and 59.0% (S.D. = $\pm 18.4\%$) at 100, 30, and 1%,
392 respectively).

393 The ability of Chl *a* to fix C and DIN in small phytoplankton communities is a matter of
394 concern in the Arctic Ocean. The quantum yield for the present study is defined as the efficiency
395 of unit Chl *a* in the small phytoplankton communities to fix DIN and C, which is calculated by
396 dividing the uptake rates by the Chl *a* concentration. The lower temperatures and salinities, ice
397 cover, and poor light availability can potentially lower the quantum yields. The quantum yields
398 for the C and DIN are shown in Figs. 8 and 9, respectively. The maximum yields for both C and
399 DIN were observed at AF091 for the 100 and 30% light depths. However, the quantum yield for
400 C at the 1% light level in all stations was observed to be very low, more likely due to light
401 limitation (Talling, 1957). Although the quantum yield for DIN was lower at 1% than at the other

402 two light levels, a drastic drop in the quantum yield for DIN at the 1% light level, such as
403 quantum yield for C, was not observed. This result can be due to the existence of significant
404 NH_4^+ uptake rates in the light-scarce conditions.

405 **3.8 Small and large phytoplankton contributions**

406 It is known that the impact of global warming on the Arctic Ocean has introduced rapid changes
407 in its physicochemical properties. Hence, the necessity to trace the changes in primary
408 production patterns in the Arctic Ocean has gained attention in the recent era. It has been
409 reported that the contribution of small phytoplankton to the total C and DIN fixations would
410 increase under warming conditions (Li et al., 2009, Thomas et al., 2012). A significant number
411 of total primary production estimates are available from the Arctic Ocean (Platt et al., 1982;
412 Vedernikov et al., 1994; Gosselin et al., 1997; Boetius and Damm, 1998; Tremblay et al., 2002;
413 Arrigo et al., 2008; Wassmann et al., 2011; Arrigo and Dijken, 2011; Yun et al., 2012, 2015;
414 Kahru et al., 2016; Lee et al., 2007; 2012, 2017a; Lee et al., unpublished). However, a deep
415 understanding regarding the boosting of small phytoplankton under warming conditions and their
416 contributions towards the total primary production is still rudimentary. The present study
417 provides the first report on small phytoplankton contributions to the total primary production in
418 the Kara, Laptev, and East Siberian seas in the Arctic Ocean. The results from the study suggest
419 that the small phytoplankton potentially contributed 24 to 89%, 32 to 89%, and 28 to 91%, to the
420 total C, NO_3^- , and NH_4^+ uptake rates, respectively, in the whole study region. Studies from
421 various oceanic bodies suggest that the small phytoplankton contribution to the total annual C
422 and DIN fixation varies between 20 and 65% (Agawin et al., 2000; Hodal and Kristiansen, 2008;
423 Joo et al. 2017; Lee et al. 2017a). The contributions of small phytoplankton to total C uptake
424 rates were significantly higher in the Amundsen Sea, with an average of 50.8% ($\pm 42.8\%$) and

425 14.9% ($\pm 8.4\%$), respectively, for the non-polynya and polynya regions (Lee et al. 2017a). The
426 contributions of small phytoplankton to the total NO_3^- uptake rates were 28.2% ($\pm 15.9\%$) in the
427 non-polynya region and 18.1% ($\pm 6.8\%$) in the polynya region. Similar to the C assimilation rates,
428 the small phytoplankton contributions to the total NH_4^+ uptake rates were higher in both non-
429 polynya (52.8%; $\pm 40.5\%$) and polynya (31.6%; $\pm 10.1\%$) regions (Lee et al., 2017a). Similarly,
430 the small phytoplankton contribution in the western Canada basin in the Arctic Ocean was
431 reported to be 64% (Yun et al., 2015). A recent study from the Chukchi Sea reported that the
432 average contributions of small phytoplankton to the C and total DIN uptake rates were
433 approximately 32% (S.D. = $\pm 24\%$) and 37% (S. D. = $\pm 26\%$), respectively (Lee et al., 2013).
434 Similar investigations conducted in the northern Barents Sea found that small phytoplankton
435 contributed almost half (46%) of the total primary production (Hodal and Kristiansen, 2008).
436 The MODIS-derived data in the Ulleung Basin from 2003 to 2012 suggested that the annual
437 contribution by small phytoplankton communities, in general, ranged from 19.6% to 28.4%, with
438 an average of 23.6% (S.D. = $\pm 8.1\%$) (Joo et al., 2017). This study suggested that large
439 phytoplankton communities are the major contributors to primary production in the Ulleung
440 Basin. Similarly, Legendre et al. (1992) reported that primary production in the high-latitude
441 Arctic region waters, in general, was dominated by large phytoplankton cells ($>5 \mu\text{m}$), while the
442 standing stock was dominated by small cell-sized phytoplankton ($0.7\text{--}5 \mu\text{m}$) due to strong
443 grazing stress on large cells. The present study also estimated large phytoplankton contributions
444 (total-small phytoplankton contributions) to the total uptake rates (Table 2). The assessments by
445 Tremblay et al. (2000) suggested that large phytoplankton can fix relatively more C per unit
446 NO_3^- and thus export more C than can small phytoplankton. However, the results from the
447 present study showed that the large phytoplankton communities in the Arctic Ocean could

448 contribute only an average of 40%, 34%, and 35% to the total C, NO_3^- , and NH_4^+ uptake rates,
449 respectively. Hence, small phytoplankton appear to be the major contributors of C, NO_3^- , and
450 NH_4^+ uptake, with percentage contributions of 60%, 66% and 65%, respectively, in the Laptev,
451 Kara, and East Siberian seas. These values are much higher than the global average contribution
452 (39%) of small phytoplankton production, as assessed by Agawin et al. (2000).

453 **4. Conclusions**

454 The present study attempted to estimate small phytoplankton contributions towards the
455 total C, NO_3^- , and NH_4^+ uptake rates in the Kara, Laptev, and East Siberian seas. The
456 contributions of small phytoplankton to the total C, NO_3^- , and NH_4^+ uptake rates ranged from 25-
457 89%, 31-89%, and 28-91%, respectively, in the Arctic Ocean. There was no significant influence
458 of ice cover on uptake rates; however, the stations with high SIC generally showed low surface
459 small phytoplankton uptake of C, NO_3^- , and NH_4^+ . It was also observed that the DIN: P can
460 potentially play a major role in controlling the small phytoplankton contributions towards the
461 DIN uptake rates by small phytoplankton. The significant contributions of small phytoplankton
462 indicate their efficiency to withstand hostile conditions, such as low nutrients, changing SST, and
463 high ice cover. However, to understand the influence of global warming on small phytoplankton
464 activity, growth, and community shifts, long-term *in situ* analyses as well as laboratory
465 manipulations and experiments are highly recommended.

767 Table 1. The physical and chemical properties of the sampling locations in the East Siberian Sea
768 and the Laptev Sea, where station depth, euphotic depth, sea surface temperature (SST), and sea
769 ice cover (SIC) are represented in m, m, °C, and %, respectively. The sea surface salinity (SSS)
770 is represented in practical salinity unit (PSU). The nutrient concentrations ($\text{NO}_2^- + \text{NO}_3^-$,
771 phosphate (P), silicate (Si), and NH_4^+) are given as the depth-integrated values in the euphotic
772 zones, with a unit of mmol m^{-2} . The DIN: P is the nutrient stoichiometry calculated from the
773 available nutrient data.

793

794 Figure 1. Sampling locations in the Kara, Laptev, and East Siberian seas in the Arctic Ocean. The red straight lines indicate the geographic
795 boundaries used to define the seas as per Pabi et al. (2008).

796

797

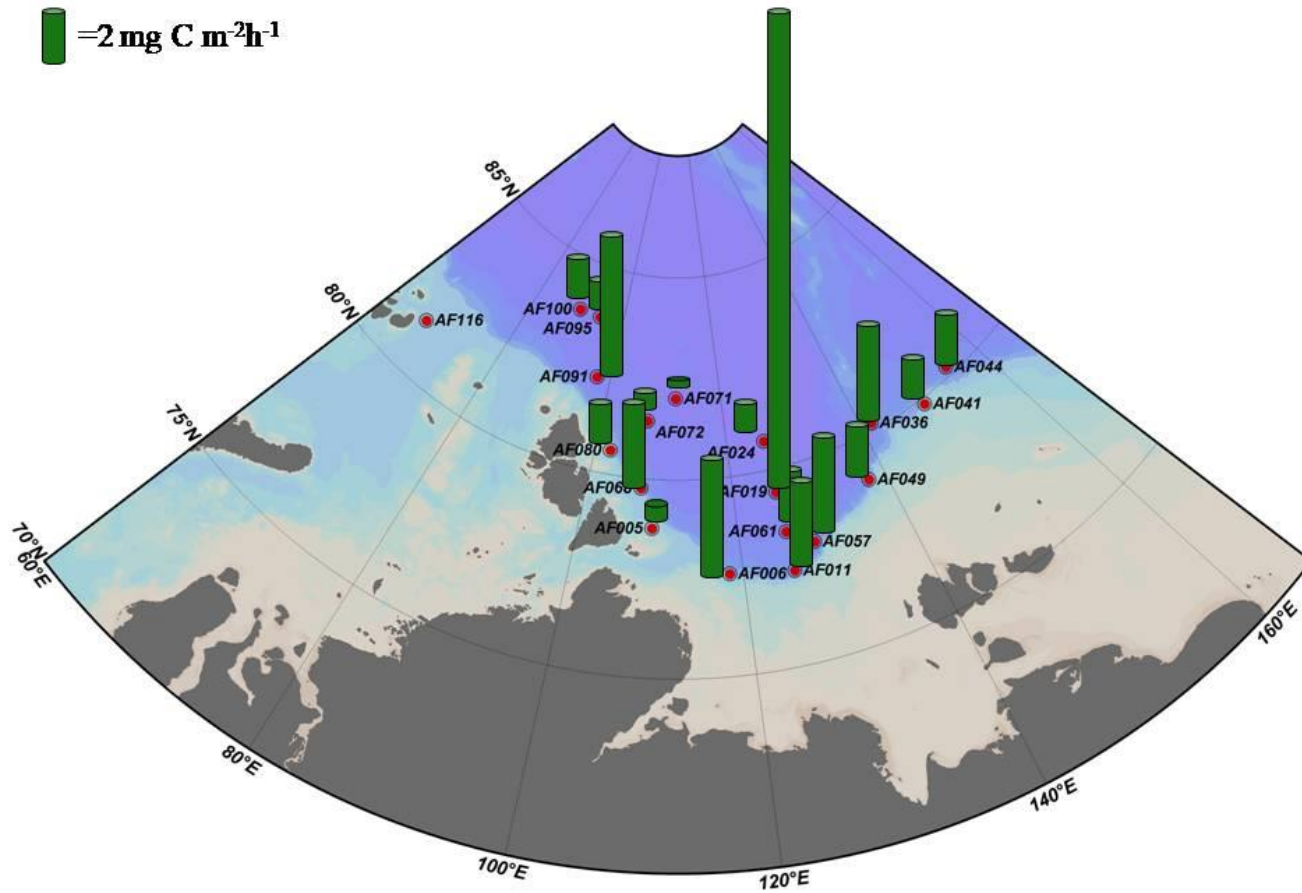

798

799 Figure 2. Depth-wise small phytoplankton uptake rates of C, NO_3^- , and NH_4^+ in the Kara, Laptev, and East Siberian seas.

800

801

802

803

804 Figure 3. The depth-integrated small phytoplankton C uptake rates in the sampling locations.

805

806

807 Figure 4. The depth-integrated small phytoplankton NO_3^- and NH_4^+ uptake rates in the sampling locations. The maroon and yellow
 808 cylinders indicate the small phytoplankton NO_3^- and NH_4^+ depth-integrated uptake rates, respectively.

809

810

811 Figure 5. The relationship of the contribution of small phytoplankton towards the total NO₃⁻ and NH₄⁺uptake rates with DIN: P.

812

813

814

815 Figure 6. Turnover time for the NO₃⁻ substrate, when small phytoplankton are the only consumers, in the sampling locations in the
 816 Arctic Ocean.

817

818

819 Figure 7. Turnover times for the NH_4^+ substrate, when small phytoplankton are the only consumers, in the sampling locations.

820

821

822 Figure 8. Quantum carbon yield of small phytoplankton in the sampling locations.

823

824

825

826 Figure 9. Quantum nitrogen yield of small phytoplankton in the sampling locations.
