Abstract. Microbial mats are self-sustaining benthic ecosystems composed of highly diverse microbial communities. It has been proposed that microbial mats were widespread in Proterozoic marine environments, prior to the emergence of bioturbating organisms at the Precambrian-Cambrian transition. One characteristic feature of Precambrian biomarker records is that steranes are typically absent or occur in very low concentrations. This has been explained by low eukaryotic source inputs, or degradation of primary produced sterols in benthic microbial mats (“mat-seal effect”). To better understand the preservational pathways of sterols in microbial mats we analysed freely extractable and carbonate-bound sterols as well as decalcified extraction residues in different layers of a recent calcifying mat (~1500 years) from the hypersaline Lake 2 on the island of Kiritimati, Central Pacific. A variety of C₂₇-C₂₉ sterols and distinctive C₃₁ 4 α -methylsterols (4 α -methylgorgosterol and 4 α -methylgorgostanol, biomarkers for dinoflagellates) were detected in both lipid pools. These sterols most likely originated from organisms living in the water column and the upper mat layers. This autochthonous biomass experienced progressive microbial transformation and degradation in the microbial mat, as reflected by a significant drop in total sterols concentrations, up to 98 %, in the deeper layers, and a concomitant decrease in total organic carbon. Carbonate-bound sterols were generally low in abundance, suggesting that incorporation into the mineral matrix does not play a major role for the preservation of eukaryotic sterols in this mat. Likewise, pyrolysis revealed that steroids (i.e., including sterenes, steranes and sterols), in contrast to hopanoids, were not sequestered into insoluble organic matter which may give rise to a further bias in the preservation of steroids vs. hopanoids, particularly in the later stages of burial. While these findings argue for a strong ‘mat-seal effect’ in the mat studied, they markedly differ from recent findings made for another microbial mat growing in the near-by hypersaline Lake 22 on the same island, where sterols showed no systematic decrease with depth. The observed discrepancies in the taphonomic pathways of sterols in microbial mats from Kiritimati may be linked to multiple biotic and abiotic factors including salinity and periods of subaerial exposure, implying that caution has to be exercised in the interpretation of sterols distributions in modern and ancient microbial mat settings.

1 Introduction

Sterols, biological precursors of steroids, are commonly used as biological markers for specific classes of organisms (Atwood et al., 2014; Brocks and Summons, 2004; Rampen et al., 2009; Volkman, 1986; Volkman, 2005). Sterols have been found in many different types of depositional environments such as soils (van Bergen et al., 1997; Birk et al., 2012; Otto and Simpson, 2005), recent lacustrine and marine sediments (Brassell and Eglinton, 1983; Gaskell and Eglinton, 1976; Robinson et al., 1984; Volkman, 1986), as well as microbial mats from meso- to hypersaline conditions (Grimalt et al., 1992; Scherf and Rullkötter, 2009). Further, the hydrocarbon skeleton of sterols is relatively stable, and thus significant amounts can be preserved in the geological record (Brocks et al., 2017; Mattern et al., 1970).

Microbial mats are vertically laminated organo-sedimentary structures, which are primarily self-sustaining ecosystems (Des Marais, 2003), ranging in thickness from millimeters to decimeters. The mineralized fossil product of microbial mats are microbialites, which have a long geological history of over 3 billion years, indicating that microbial mats probably represented the earliest complex ecosystems on Earth (Reitner and Thiel, 2011). Microbial mats typically consist of many different functional groups of microorganisms which control the organic matter (OM) turnover in the microbial mat. Major groups include cyanobacteria, colorless sulfur bacteria, purple sulfur bacteria and sulfate-reducing bacteria, but also eukaryotic organisms (Schneider et al., 2013; van Gemerden, 1993). A large proportion of the OM consists of extracellular polymeric substances (EPS), secreted by the microorganisms, which are crucial for the support and the development of the microbial mat (Wingender et al., 1999; Decho, 2011; Reitner and Thiel, 2011). EPS are rich in acidic groups that bind cations such as Ca^{2+} , thereby inducing a strong inhibitory effect on the precipitation of common minerals formed within microbial mats, such as CaCO_3 (Arp et al., 1999; Dupraz et al., 2009; Ionescu et al., 2015). Consequently, carbonate precipitation often occurs in deeper and older mat layers in which decomposing EPS gradually releases previously-bound Ca^{2+} , thus facilitating carbonate supersaturation (Arp et al., 1999; Dupraz et al., 2009; Ionescu et al., 2015). Previous studies indicate that early sequestration into a mineral matrix may promote the preservation of organic compounds (Summons et al., 2013; Smrzka et al., 2017; Thiel et al., 1999). Hence, microbial mats possibly provide an enhanced chance for OM to survive in the geosphere if carbonate or other mineral precipitation occurs therein.

In the Proterozoic, microbial mats have been proposed to be a predominant life form in marine environments, in contrast to the Phanerozoic that is characterized by prosperity of biota (including fauna and flora) and a low abundance of benthic microbial mats (Grotzinger and Knoll, 1999; Riding, 2011; Walter, 1976). One of the characteristic features of the Precambrian biomarker records is that eukaryotic steranes are typically absent or occur in very low concentrations. This may be explained by a limited ecological distribution of eukaryotic algae and thus minor contributions of sterols to sedimentary OM (Anbar and Knoll, 2002; Blumenberg et al., 2012; Brocks et al., 2017; Knoll et al., 2007), and/or by a thermal degradation of sterols during catagenesis (e.g. in the 1640 Ma Barney Creek Formation and 1430 Ma Velkerri Formation, Northern Australia, Dutkiewicz et al., 2003; Summons et al., 1988). An alternative explanation would be that eukaryotic lipids have been subject to a preservation bias due to the ubiquity of benthic microbial mats. It has been hypothesized that

these mats would have formed a significant mechanical and chemical barrier against the preservation of eukaryotic lipids sourced from water column and upper mat layers, a phenomenon termed as “mat-seal effect” (Pawlowska et al., 2013). Selective preservation induced by the mat-seal effect would also impart a bias in favour of lipids derived from heterotrophic microorganisms living in the deeper mat layers, and cause a suppression of the primary ecological signal. This is different
5 from the situation in the Phanerozoic, where OM from planktonic primary producers (including algae and bacteria) is more rapidly transferred to the sediment through sinking aggregates (such as crustacean faecal pellets), and without being reworked in benthic microbial mats (Close et al., 2011; Fowler and Knauer, 1986; Logan et al., 1995).

The Kiritimati atoll (Kiribati Republic, Central Pacific, Fig. 1) is an ideal study site for investigating the taphonomy of sterols in microbial mats. The island is covered by c. 500 brackish to hypersaline lakes, most of which are populated by thick
10 and highly developed benthic mats that are clearly laminated and show ongoing mineral precipitation, i.e. microbialite formation (Arp et al., 2012; Trichet et al., 2001; Valencia, 1977). Therefore, Kiritimati enables studies on the behaviour of sterols within various types of microbial mats thriving under different environmental conditions and showing different degrees of mineralization.

A recent study conducted on a microbial mat from Lake 22 on Kiritimati demonstrated that a range of sterols were
15 abundantly present in all parts of that mat. The lack of any systematic decrease with depth suggested that the sterols in that particular mat had not been impacted by a major mat-seal effect (Shen et al., 2018a). On the other hand, an earlier study on insoluble OM obtained from a microbial mat from a different lake of the same island (Lake 2, located about 10 km south of Lake 22) reported an increasing trend of hopane/sterane ratios with depth (Blumenberg et al., 2015). In conjunction with other findings, this was considered indicative of a “*suppression of biosignatures derived from the upper mat layers*” and
20 thus, a mat-seal effect (Blumenberg et al., 2015). Since that work had a different focus and did not report detailed sterol data, it is not directly comparable with the results on the Lake 22 mat reported by Shen et al. (2018a). Therefore we revisited the microbial mat from Lake 2 and performed a detailed analysis of sterol compounds, investigating both freely extractable as well as carbonate-bound lipid fractions, and also decalcified extraction residues. Our study was aimed at further examining general trends in the preservation of sterols in hypersaline microbial mat systems by comparing the results from different
25 settings within the same geological and geographical context (i.e. Lakes 2 and 22).

2 Materials and methods

2.1 Location and samples

The atoll of Kiritimati (Republic of Kiribati) is located in the central part of the Pacific Ocean, close to the Equator (Fig. 1). Its surface displays a complex reticular pattern encompassing c. 500 lakes with salinities that range from brackish to
30 hypersaline. Most of the lakes harbour thick microbial mats that show ongoing mineralization processes (Figs. 1, 2) and generally occur on top of older, more developed microbialites (i.e. already fossilized microbial mats; Arp et al., 2012; Ionescu et al., 2015; Trichet et al., 2001; Valencia, 1977). Vegetation around the lake areas comprises the mangrove

Rhizophoramucronata, the parasitic climber *Cassytha filiformis*, the grass *Lepturus repens*, and the ironwood *Pemphis acidula* (Fig. 2e; Saenger et al., 2006). The climate of Kiritimati is broadly controlled by the El Niño-Southern Oscillation (ENSO) atmospheric phenomenon. During El Niño wet events, heavy rains occur, decreasing lake salinities; whereas reduced precipitation during La Niña dry events triggers higher evaporation and increasing lake salinities (Arp et al., 2012; Saenger et al., 2006; Trichet et al., 2001). Materials studied in this work were sampled from Lake 2 (Fig. 1), whose salinity was 97 ‰ in 2002 and 125 ‰ in 2011 (own data, unpublished). This high and variable salinity causes low metazoan diversity within Lake 2. Faunal elements include abundant *Tilapia* fish (Fig. 2d) and *Artemia* brine shrimp as well as few land crabs, and unicellular miliolid foraminifera (Saenger et al., 2006; Shen et al., 2018a). Events of mass mortality of fish have been observed in some of the lakes (Fig. 2d), which may be linked to extreme hypersaline conditions probably due to heavy evaporation during La Niña dry periods. More detailed information about the environmental setting of Kiritimati can be found elsewhere (Arp et al., 2012; Saenger et al., 2006; Shen et al., 2018a; Trichet et al., 2001).

In this work, a microbial mat from the hypersaline Lake 2, previously studied by Blumenberg et al. (2015), was analysed for sterols (Fig. 1). This mat is 10 cm thick and was sampled from the centre of the lake (water depth c. 4 m) during a field campaign in March 2011 (Figs. 1, 2). Samples were stored at -20°C until laboratory preparation. Based on the macroscopic appearance, Blumenberg et al. (2015) divided the mat in five layers, the topmost layer corresponding to the photosynthetically active mat, and layers 2-5 representing ancient mat generations being degraded by recent anaerobic microorganisms (Figs. 1, 2). For this study, we used the same layer division as Blumenberg et al. (2015). However, a thin but distinctive mineral crust occurring just below layer 2 (Fig. 2c) has not been analysed in the previous study and is additionally included here (corresponding to our layer 3, Figs. 1, 2). Therefore, six layers in total were analysed in this work, each one c. 1-2 cm thick (except layer 3 ~0.15 cm).

2.2 Bulk analysis

Homogenized (mortar) aliquots of the freeze-dried samples (both original mat layers and extraction residues) were subjected to C/N/S analysis, using a Hekatech EA 3000 CNS analyzer and LECO RC 612 multiphase carbon analyser as described elsewhere (Shen et al., 2018a).

2.3 Extraction and derivatization

Aliquots of the freeze-dried samples (5-20 g) were homogenized and extracted using 4×50 ml portions of dichloromethane/methanol (3:1; V/V) (10 min ultrasonication) to obtain the freely extractable lipids. The remaining extraction residues were decalcified using 37 % HCl (dropwise until CO₂ development ceased), and again extracted as described above to yield the carbonate-bound lipids. The remaining extraction residues (after decalcification) were freeze dried for the analysis of bulk C_{org} and pyrolysis.

To make alcohols (including sterols) GC-amenable, aliquots of the lipid extracts (both freely extractable and carbonate-bound lipid fractions) were silylated using BSTFA (N,O-bis(trimethylsilyl)trifluoroacetamide) containing 5 % (V/V)

trimethylchlorosilane (TMCS) as a catalyser (70°C, 60 min). The resulting trimethylsilyl (TMS-) derivatives were dried under gentle N₂ flow, re-dissolved in *n*-hexane, and analysed by gas chromatography-mass spectrometry (GC-MS).

To make fatty acids GC-amenable, a mixture of TMCS/MeOH (1:9, V:V) was added to all aliquots of lipid extracts and samples were heated at 80°C for 60 min. The resulting fatty acid methyl esters were extracted from the reaction mixture by vigorous shaking with 3×1 ml *n*-hexane. The extracts were combined and evaporated to near-dryness under a gentle stream of N₂, re-dissolved in *n*-hexane, and analysed by gas chromatography-mass spectrometry (GC-MS).

2.4 GC-MS

GC-MS analyses were carried out using a Thermo Fisher Trace 1310 GC coupled to a Thermo Fisher Quantum XLS Ultra MS as described elsewhere (Shen et al., 2018a). Due to low sterol concentrations and co-elutions, particularly in the deeper mat layers, sterols were not quantified via peak integration in the total ion currents (TIC). Instead, the summed ion traces of [m/z 129 + (M⁺-90) + M⁺] for the TMS-derivatives of Δ⁵- and Δ^{5,22}-stenols, and [m/z 215 + (M⁺-90) + M⁺] for the TMS-derivatives of stanols were used. Appropriate correction factors were applied according to the response of these ions vs. concentration in the mass spectra of standard compounds. Average standard deviations of sterol concentrations were determined from repeated analyses of sample material.

2.5 Pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS)

Aliquots of the decalcified extraction residues were pyrolysed on a fast-heating Pt-filament using a Pyrola 2000 pyrolysis device (Pyrolab SB) coupled to a Varian CP3800 GC and a Varian 1200L MS as described elsewhere (Shen et al., 2018a).

2.6 Compound-specific stable carbon isotopes analysis

Compound-specific stable carbon isotope ratios were measured for sterols and fatty acids in the freely extractable lipid fractions of the microbial mat. Analyses were conducted using a Thermo Scientific Trace gas chromatograph (GC) coupled to a Delta Plus isotope ratio mass spectrometer (IRMS). The conventional CuO/NiO/Pt reactor was used and combusted at 940°C. The GC-column used was an Agilent DB-5 coupled to an Agilent DB-1 (each 30 m length, 250 μm internal diameter, and 0.25 μm film thickness). Lipid fractions were injected into a splitless injector and transferred to the GC column at 290°C. The carrier gas was helium at a flow rate of 1.2 ml/min. The temperature program for analyzing lipid fractions was ramped from 80°C, followed by heating to 325°C (at 5°C/min, held for 60 min). Analysis of laboratory standards were carried out to control the reproducibility of measuring conditions and measurements were calibrated by using CO₂ gas of known isotopic composition.

3 Results

3.1 General characterization of the microbial mat

The microbial mat has a thickness of c.10 cm. Based on its macroscopic appearance it shows two major phases of development. The upper, younger growth phase is represented by layer 1 (photosynthetically active mat) and layer 2 (each c. 1 cm thick, Figs. 1, 2). These layers have a cohesive texture, sticking together when handled, due to abundant and relatively fresh organic material (i.e. EPS) of bright orange, green and brown colours. Layer 1 includes small and scarce mineral precipitates, whereas layer 2 shows more abundant whitish minerals within its organic matrix (Fig. 2c). Layer 2 is underlain by a thin but distinctive, laterally continuous mineral crust (layer 3). Below the crust, layers 4, 5 and 6 (c. 7 cm thick in total, Figs. 1, 2) are more friable, having a crumbly appearance, due to a higher abundance of mineral particles as compared to EPS. In this older growth phase, brown and beige colours predominate (Fig. 2c). The minerals observed within the mat layers are mainly aragonite (CaCO_3), with minor amounts of gypsum (CaSO_4) found only in the uppermost layer 1 (Shen et al., 2018b). Previously reported ^{14}C ages of the mat (Blumenberg et al., 2015) show that its upper growth phase formed in approximately 1000 years (62 ± 40 years BP for layer 1, 551 ± 40 years BP for layer 2 and 1111 ± 40 years BP for layer 3; Fig. 1b) whereas the older (and thicker) growth phase formed approximately in the preceding 300 years (1331 ± 40 years BP for layer 5 and 1440 ± 40 years BP for layer 6; Fig. 1b).

3.2 Bulk geochemical data

Bulk geochemical data for individual mat layers are shown in Table 1a. In the original mat (i.e. bulk sample before decalcification) relatively high C_{org} contents were observed in layers 1 and 2 (4.7 and 6.2 %, respectively; Table 1a and Fig. 3a), consistent with a more fresh, cohesive appearance of the organic matrix in these layers. Below layer 2, the earlier growth phase consistently showed low and constant C_{org} contents < 2 %, with the lowest value found for layer 6 (1.2 %) (see 3.1). The CaCO_3 content of the mat increased significantly with depth (Fig. 3a; Table 1a). The lowest value was observed in the top layer 1 (27.1 %), a strong enrichment occurred in layer 2 (73.1 %), and constantly high contents > 90 % were found for all deeper mat layers. This is consistent with the observation of more abundant mineral precipitates downwards in the mat. The highest S content was detected for layer 1 (9.8 %), due to gypsum precipitates. Below, S decreased sharply (1.2 % in layer 2) and retained low values (< 1 %) in the earlier growth phase of the mat (~ 0.3 -0.5 %). N showed generally low contents (0.14-0.75 %) throughout the mat.

In the decalcified extraction residues (i.e., extraction residues after decalcification; Table 1b), C_{org} showed a broad range but increased significantly with depth, with the highest value observed in layer 6 (42.3 %; also see Fig. 3b). N was likewise enhanced in the deeper parts, with the highest amount found in layer 5 (6.7 %). By contrast, a decrease in S content was observed with depth, with highest values occurring in the topmost mat layer 1 (10.4 %).

3.3 Sterol distributions and concentrations

Various sterols were detected within the mat, including saturated sterols (stanols; $C_{27}\Delta^0$, $C_{28}\Delta^0$, $C_{29}\Delta^0$, $C_{31}\Delta^0$) and unsaturated sterols (stenols; $C_{27}\Delta^5$, $C_{28}\Delta^{5,22}$, $C_{28}\Delta^5$, $C_{29}\Delta^{5,22}$, $C_{29}\Delta^5$, $C_{31}\Delta^5$, see Fig. 4; Table 2). Based on the retention characteristics and comparison with published mass spectra (Atwood et al., 2014; Houle et al., In Press), the C_{31} sterols were identified as
5 22,23-methylene-4 α ,23,24-trimethylcholest-5-en-3 β -ol (4 α -methylgorgosterol) and 22,23-methylene-4 α ,23,24-trimethylcholestan-3 β -ol (4 α -methylgorgostanol), respectively (see Fig. S1).

In the freely extractable lipids, stenols were by about an order more abundant than stanols. Both groups showed highest concentrations in layer 1, and a major decrease with depth (see Table 2a). Figure 5a shows the variations of C_{27} - C_{29} sterols (e.g. stenols vs. stanols) in the freely extractable lipids through the mat profile. The highest abundance of sterols occurred in
10 the topmost layer 1 (26.05 $\mu\text{g/g}$ dry mat, see Fig. 5a). Concentrations decreased drastically in the upper layers, and remained low from layer 3 onwards. C_{28} and C_{29} sterols were the most dominant sterols in layer 1 while the C_{31} sterols dominated in the deeper layers (Fig. S3). The C_{31} -sterol distributions differed from the other sterol distributions identified in this mat, with concentrations in layer 5 being three to ten times higher than in layers 3, 4 and 6 (Fig. 3c; Table 2a). Further, in the freely extractable lipids, the ratios of 5 α -stanols to their corresponding Δ^5 -stenols (stanol/stenol ratios) showed no consistent trend
15 within the profile (Fig. 6a; Table 3). As expected, the C_{27} -, C_{28} - and C_{29} - ratios increased in the upper, younger growth phase of the mat, with the highest value observed for layer 3, but decreased again in the deeper, older growth phase (Fig. 6; Table 3). In contrast, stanol/stenol ratios for the C_{31} sterol declined from layer 1 to layer 5, and showed a remarkable increase in layer 6.

Sterol concentrations in the carbonate-bound lipid fractions are given in Table 2b. In the topmost layer 1, no carbonate-
20 bound sterols were observed. In mat layers 2 and 3, carbonate-bound sterols occurred, but were still much less abundant as freely extractable sterols (below detection limit to $\sim 10^{-2}$ $\mu\text{g/g}$ dry mat). In the deeper mat layers (4-6), however, sterols showed similar absolute concentrations ($\sim 10^{-2}$ - 10^{-3} $\mu\text{g/g}$ dry mat) in both, the carbonate-bound and the freely extractable fractions. Sterenes were also detected in both lipid pools, but only at trace abundances (not discussed further).

In the carbonate-bound lipids, stenols comprised the predominant portion (c. from 65 % up to 90 % of all sterols) (Fig.
25 5b). Overall low abundances of carbonate-bound sterols were observed throughout the mat (10^{-1} $\mu\text{g/g}$ dry mat range). C_{31} -groups were the primary contributors in both lipid fractions (ranging up to ca. 85 % in the deeper part of the mat), and C_{29} -groups were the second major inputs (Fig. S3). Carbonate-bound C_{31} -sterols increased in the bottom layer 6, which is distinguished from the other sterols (Fig. 3d). The stanol/stenol ratios in the carbonate-bound lipids, increased for the C_{27} -, C_{28} - and C_{29} - pairs between layers 1 and 3, and again decreased downwards as they did in the freely extractable lipids (see
30 Fig. 6b; Table 3). No stanol/stenol ratios could be obtained for the carbonate-bound C_{31} sterols, as C_{31} stenols were virtually absent throughout the mat.

3.4 Pyrolysis

Ion chromatograms representing steroids (i.e., including sterenes, steranes and sterols) and hopanoids released by pyrolysis of the decalcified extraction residues are shown in Fig. S2. Steroids were not observed in the pyrolysates throughout the mat, while hopanoids were found in the insoluble matter of each mat layer. Notably, only small amounts of hopanoid moieties were observed in the pyrolysates of layer 1, but their abundance gradually increased with depth.

3.5 Compound-specific $\delta^{13}\text{C}$ values

A reliable compound-specific $\delta^{13}\text{C}$ value could be obtained for the coeluting C_{31} -sterols from the freely extractable lipids in layer 1. This compound showed a strong enrichment in ^{13}C ($\delta^{13}\text{C} = -7.2$ ‰). Fatty acids (including C_{14} - C_{19} homologues) showed similarly high $\delta^{13}\text{C}$ values ranging from -4.4 to -11.7 ‰.

10 4 Discussion

4.1 Biological sources of sterols

The studied mat contained a broad variety of C_{27} - C_{29} sterols as well as two C_{31} sterols, indicating potential sources like animals (C_{27}), fungi (C_{28}), algae including dinoflagellates (C_{27} - $\text{C}_{29} + \text{C}_{31}$) and terrestrial plants (C_{29}) (Atwood et al., 2014; Houle et al., In Press; Volkman, 1986; Volkman, 2003). The concentrations of freely extractable sterols in the topmost layer 1 in the studied Lake 2 mat are similar to Lake 2A and Lake 22 ($\sim 10^2$ - 10^3 $\mu\text{g/g C}_{\text{org}}$; Bühring et al., 2009; Shen et al., 2018a; see Fig. 5a). However, sterols in the deeper layers are much less abundant in the Lake 2 mat as compared to other mats in Kiritimati lakes.

Figure S3 shows the relative distribution of summed C_{27} - vs. C_{28} - vs. C_{29} - vs. C_{31} - sterols in the microbial mat layers. In both lipid fractions, the C_{31} -sterols are predominant, suggesting inputs from dinoflagellates (Atwood et al., 2014; Houle et al., In Press). C_{29} -sterols make up the next most abundant group, potentially indicating contributions from either algae or terrestrial plants (Volkman, 1986); also these compounds are known to be produced by diatoms and other algal groups (Rampen et al., 2010; Volkman, 2003).

The high $\delta^{13}\text{C}$ value of -7.2 ‰ for the C_{31} -sterols, and similarly high values for the fatty acids measured from layer 1, imply that the carbon source of these compounds was autochthonous and derived from the hypersaline, CO_2 -limited ecosystem of Lake 2 (cf. Schouten et al., 2001). Previous work on carbon isotope compositions of sterols in a mat from the adjacent Kiritimati Lake 2A showed $\delta^{13}\text{C}$ values from -19 to -23 ‰ (Bühring et al., 2009). In addition, Trichet et al. (2001) reported $\delta^{13}\text{C}$ values for sedimentary bulk OM from -14 to -17 ‰ in Kiritimati Lake 30. Both studies showed more depleted values than those observed for Lake 2. An explanation could be a better CO_2 exchange in those lakes, due to their shallow water layer (a maximum depth of 0.2 m in Lake 2A, Bühring et al., 2009; depth of 0.9 m in Lake 30, Trichet et al., 2001), leading to the relatively light $\delta^{13}\text{C}$ signatures. Another explanation could be that shrinking lake water bodies caused by La

Niña dry events are often associated with massive increases in lake salinities (Trichet et al., 2001). For instance, Lake 2A (Bühning et al., 2009) was observed to be nearly dried out during our sampling campaign in 2011. The increasing salinities may result in a CO₂-limited ecosystem, leading to enrichment in ¹³C. The resulting reinforced CO₂-limitation in Lake 2 is not only reflected by the high δ¹³C values of sterols and fatty acids in this work, but also δ¹³C values of carbonates that were
5 observed to be as high as +6 ‰ (Arp et al., 2012).

4.2 Taphonomy of sterols

The sterols in the studied mat are probably sourced from plankton or organisms thriving at the mat surface, because eukaryotes are generally depending on an oxygenated environment and would hardly thrive in anoxic, deeper parts of the mat. It can also be expected that sterols were initially introduced as stenols. Subsequent alteration by early diagenetic
10 processes within the mat would have resulted in a variety of sterol transformation products. Reduction of Δ⁵-stenols to 5α-stanols (hydrogenation) is a known result of anaerobic microbial degradation (Rosenfeld and Hellman, 1971; Wakeham, 1989). Consequently, stanol/stenol ratios may reflect the extent of microbial stenol alteration under anoxic conditions (i.e. under low redox potential; Gaskell and Eglinton, 1975; Nishimura, 1977; Wakeham, 1989). Several investigations have reported such conversion in microbial mats (Grimalt et al., 1992; Scherf and Rullkötter, 2009; Słowakiewicz et al., 2016),
15 including some mats from other lakes on Kiritimati (Bühning et al., 2009; Shen et al., 2018a).

In the mat studied, stanol/stenol ratios for C₂₇-C₂₉ pairs initially increased with depth and showed highest values in layer 3, suggesting low redox potentials and a pronounced anaerobic microbial transformation of stenols therein. In the deeper layers (4-6), ratios decreased again. We interpret this to result from a more efficient microbial OM degradation, which occurred under higher redox potentials during the more rapid accretion of the earlier growth phase of the mat (1440-1111
20 years BP, see Fig. 1b). This idea is supported by constantly lower C_{org} contents in the earlier growth phase of the mat (1.20-1.47 %, see Table 1a). Exclusively for the C₃₁-stanol/stenol ratios, they showed a steady decrease with depth but sharply increased again in the bottom layer 6. It could be possible that input variations of the C₃₁ stanol and stenol played a more important role than microbial alteration for the distributions of C₃₁ sterols. 4α-methylgorgostanol has been reported in a few dinoflagellate species belonging to the genera *Peridinium*, *Alexandrium* and *Pyrodinium*, (Atwood et al., 2014; Houle et al.,
25 In Press, and refs therein), and the mass spectra of the sterol we tentatively identified as 4α-methylgorgosterol is similar to that reported for a sterol occurring in resting cysts but not in the motile cells of the dinoflagellate *Peridinium umbonatum* var. *inaequale* (Amo et al., 2010). As a result, C₃₁ sterols could partly have been derived from sedimentary resting cysts that may have been less affected by degradation during transport or microbial recycling than conventional C₂₇-C₂₉ sterols. It may also be speculated that the unusual side-chain structure and methylation pattern of 4α-methylgorgosterols hamper enzymatic
30 microbial degradation (e.g. Giner et al., 2003, and refs therein). The steadily increasing relative abundances of C₃₁- vs. C₂₇-C₂₉ sterols in the mat profile (Fig. S3) suggest that C₃₁ sterols experienced different degradation patterns as compared to conventional sterols.

For the total sterols, concentrations of freely extractable sterols were high in the top layer but dropped sharply immediately below and kept at very low concentrations throughout the deeper mat ($< 1 \mu\text{g/g}$ dry mat). Carbonate-bound sterols, on the other hand, were hardly detectable at the top of the mat, and likewise showed constantly low abundances below. These observations suggest that (i) freely extractable sterols are rapidly degraded in the upper layers of the mat and

5 (ii) the carbonate matrix played no important role in encasing (i.e., preserving) sterols in this mat. This is in agreement with previous reports about minor amounts of such sterols in methane seep microbialites and ooids (Birgel et al., 2006; Thiel et al., 1999; Thiel et al., 2001; Summons et al., 2013). However, in those settings, high concentrations of microbial lipids preserved in the carbonate matrix possibly reflect a constructive role of their source organisms in carbonate formation and/or their continuous incorporation into carbonate during the precipitation processes (Summons et al., 2013; O'Reilly et al., 2017). For

10 instance, abundant ^{13}C -depleted acyclic isoprenoids encased in ancient methane-derived carbonates have been shown to originate from methane-oxidizing archaea whose metabolism immediately enhanced calcification (Peckmann and Thiel, 2004).

Blumenberg et al. (2015) pointed out that organic compounds in the deeper parts of the Lake 2 mat, unlike those at the top, are better preserved in the insoluble OM fraction, which is concordant with the results in this work (Fig. 2S). Specifically, our pyrolysis of the decalcified extraction residues revealed that steroids were not sequestered into insoluble

15 OM, while hopanoids were present in all mat layers (Fig. S2). This phenomenon was also observed for pyrolysates in Lake 22 mat (Shen et al., 2018a). An explanation could be that the low number of reactive sites in common sterols (i.e. one hydroxyl-group) would lead to a low tendency to incorporate into macromolecular OM as compared to hopanoids (e.g. highly functionalized bacteriohopanepolyols with several hydroxyl-groups). This behaviour may eventually give rise to a

20 further preservational bias of steroids vs hopanoids over geological time.

In the Lake 2 mat studied here, the strong decline in freely extractable sterols below the uppermost mat layer, along with the lack of any significant carbonate incorporation, suggests major degradation of steroids vs. hopanoids during early diagenesis (i.e. on a timescale of 10^2 - 10^3 years).

4.3 Comparison with sterol taphonomy in other microbial mats

25 The results from the Lake 2 mat differ significantly from the results of a previous study on a microbial mat profile in another lake in Kiritimati (Lake 22; Shen et al., 2018a). Sterol concentrations from the topmost layers are similar in both mats ($10^2 \mu\text{g/g } C_{\text{org}}$ range), but the Lake 22 mat showed no systematic decrease in sterols with depth. Such entirely different behaviour of sterols in these two lakes raises questions about potential mechanisms causing the observed variation.

One explanation for the differences between the Lake 2 and 22 mats could be variations in salinity. In 2011, the salinity

30 of Lake 22 (Shen et al., 2018a) was 250 ‰, whereas Lake 2 showed 125 ‰. High salinity may reduce microbial cell growth and reproduction, and limit the metabolism of microorganisms. The resulting decrease in bacterial activity would affect the biodegradation rates of organic compounds (Abed et al., 2006). Several studies reported that the degradation rates of hydrocarbons significantly decrease as salinity increases (microbial mat from Saudi Arabia, Abed et al., 2006; water and tar

samples from Great Salt Lake, Ward and Brock, 1978). On the other hand, lower salinity supports the proliferation of a more diverse microbial community (Bolhuis et al., 2014), thus possibly enhancing OM biodegradation. As a consequence, conditions for mat-forming microorganisms would be more favourable in Lake 2 as compared to the extremely hypersaline Lake 22, thus accelerating the biodegradation rates of organic molecules, including sterols. Another possible reason might be

5 decreased precipitation resulting in the decline of water depth. A major drought period prevailed in Kiritimati from 2002 to 2011, as a result of a very strong La Niña dry event. Due to reduced rainfall, the water level of the lakes in Kiritimati generally dropped, so that, in some areas, parts of the lake bottoms became subaerially exposed. The Lake 22 microbial mat was collected at the margin of the lake (Fig. 2f; water depth c. 0.2 m; Shen et al., 2018a). Therefore, mats from this shallow

10 sampling site may have suffered from heavy evaporation due to such major drought events. As pointed out by Shen et al. (2018a), the Lake 22 mat shows an irregular top layer of V-shaped fractures, which are general characteristic features of evaporitic settings, thus further demonstrating the repeated occurrence of dry periods in the region. On the other hand, the Lake 2 mat was collected in the lake centre (water depth c. 4 m) which is clearly less prone to subaerial exposure. These interpretations are further supported by other studies that highlighted how environmental conditions such as water depth and salinity may have a significant influence on the microbial composition of microbial mats (Pagès et al., 2014). In addition to

15 these environmental conditions, the differences of stanol/stenol ratios between the two lakes are noteworthy. Much higher ratios were observed in Lake 22 mat (Shen et al., 2018a), indicating a much more intense anaerobic microbial transformation (yet no degradation) as compared to the Lake 2 mat (Fig. 6). Whereas sterols in Lake 22 mat experienced major microbial transformation (sterols => stanols => sterenes), sterols in Lake 2 apparently suffered from major degradation that suppressed the primary ecological signal. The contrasting distributions observed for the Kiritimati mats studied also suggest

20 that sterols have a higher preservation potential in microbial mats under stronger salinities and/or more desiccated conditions, such as those of Lake 22. Our finding of such significant differences in two adjacent mat settings on the same island calls for great caution when studying sterols in microbialites or in modern microbial mats and making generalizations for the fossil record. Sterol preservation within microbial mats is a complex process that may be strongly influenced by environmental parameters. Therefore, palaeoenvironments must be thoroughly constrained if the presence, or absence, of

25 these compounds is interpreted in the study of ancient deposits.

5 Conclusion

The preservation of primary eukaryotic sterols and their progressive alteration was studied in a c. 1500 years old microbial mat from the hypersaline Lake 2 on Kiritimati. High $\delta^{13}\text{C}$ values of C_{31} -sterols and fatty acids suggest an autochthonous origin for these lipids. Total sterols decreased immediately below the uppermost layer, suggesting a major degradation of

30 these compounds within the mat. A different pattern was observed for unusual, isotopically heavy C_{31} -sterols (4α -methylgorgosterol and 4α -methylgorgostanol; $\delta^{13}\text{C} = -7.2\text{‰}$), which showed increasing abundances in the deeper mat layers as compared to the conventional C_{27} - C_{29} sterols. These C_{31} sterols may have partly derived from resting cells of

dinoflagellates, or their unusual side-chain might hamper degradation, which may have enhanced the resistance of these sterols against degradation. No significant ‘trapping’ of sterols into the mineral lattice occurred in this mat. Likewise, steroids were not sequestered into insoluble organic matter (as opposed to hopanoids). It is therefore suggested that the studied mat might have formed an effective filter against the preservation of sterols in the sedimentary record. The results
5 from this microbial mat, therefore, support the hypothesis of a ‘mat-seal effect’ describing the degradation of eukaryote-derived lipids in benthic microbial mats. Our results are markedly different from those recently obtained from another mat from Kiritimati Lake 22, where sterols showed no systematic decrease with depth, suggesting that the preservation of sterol carbon skeletons in that microbial mat did not suffer from a mat-seal effect. In that lake, an even higher salinity or temporal subaerial exposure may have hampered microbial metabolism and instead promoted sterol transformation rather than
10 degradation. The combined data show that sterol taphonomy may strongly vary between different mat systems, and even contrasting sterol degradation patterns may be expected in response to environmental conditions.

Code and data availability. Data can be found in the Supplement or can be requested from Yan Shen (yshen@gwdg.de).

Author contributions. YS had the main responsibility for analysing the data and writing the manuscript. JR and VT designed the project. JR conducted the field works, collected all the sample materials and participated in the writing process. VT contributed the conceptualisation of this work, participated in constructing the measurement setup and the writing process.

5 PSG had the main responsibility for the bulk data measurements, participated in the writing process. SWP participated in the interpretation of the data and the writing process. All the co-authors contributed to this work.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We thank Prof. Dr. Gernot Arp and Dr. Martin Blumenberg for helpful information and constructive comments. Dr. Andreas Reimer is acknowledged for hydrochemical measurements. We are grateful that Dr. Jens Dyckmans
10 analyse the compound-specific carbon isotopes. Dr. Pablo Suarez-Gonzalez acknowledges funding by a postdoctoral research fellowship of the Alexander von Humboldt Foundation. Wolfgang Dröse, Birgit Röring and Dorothea Hause-Reitner are kindly acknowledged for laboratory assistance. This research has received funding from the German Research Foundation (DFG, Project Re 665/18-2 and Research Unit 571 “Geobiology of Organo- and Biofilms”).

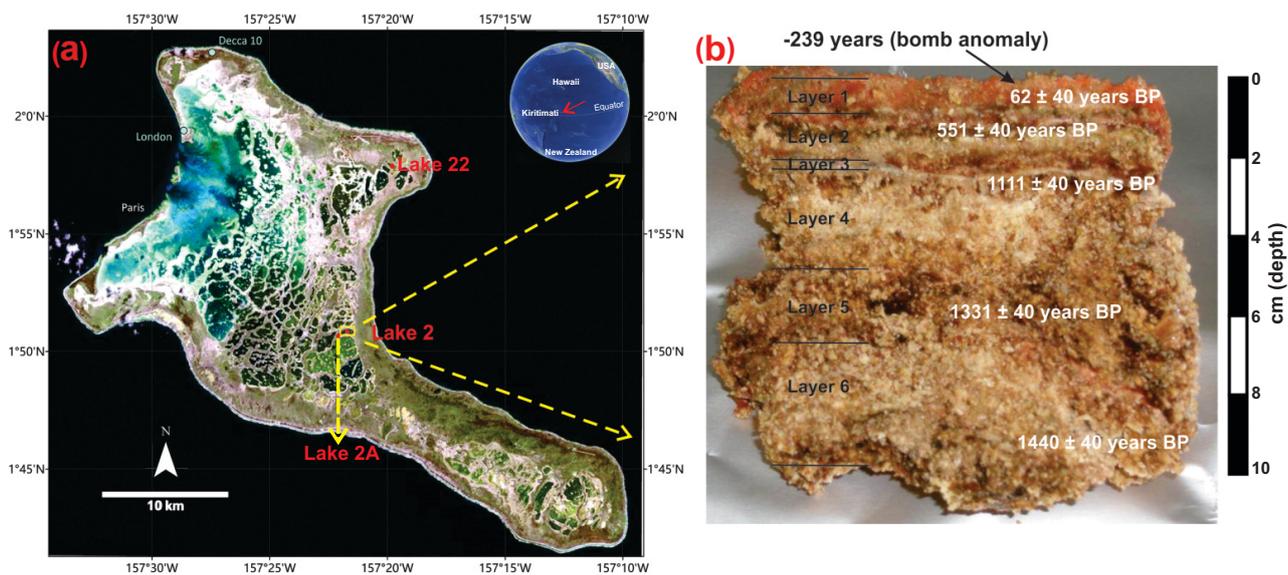

Figure 1. (a) Location of Kiritimati atoll in the Pacific Ocean and its satellite image showing reticulate distribution pattern of the lakes (red dots: Lake 2 studied in this work; Lake 2A and 22 previously studied by Bühring et al., 2009 and Shen et al., 2018a); (b) the microbial mat sample from Lake 2 studied in this work (^{14}C data from Blumenberg et al., 2015).

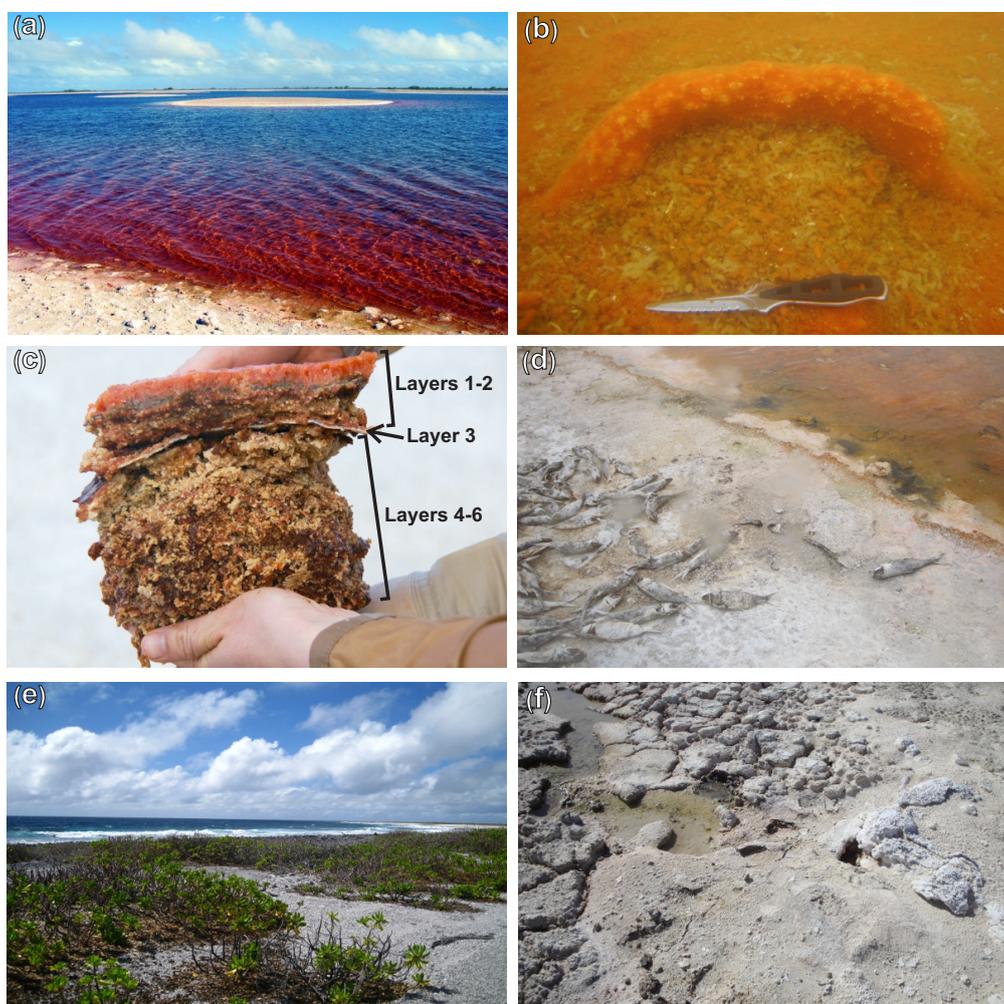

Figure 2. Field images: (a) general view of hypersaline Lake 2 in Kiriritimati; (b) underwater photograph showing an example of a currently-active, orange-coloured microbial mat at the bottom of the lake; (c) the microbial mat sampled for this study, with clear colour-zonation; note the whitish mineral crust (Layer 3) separating the upper younger growth phase from the older, more mineralized layers; (d) lake shore showing dead fish; (e) vegetation around the lake area; (f) sampling site for hypersaline Lake 22 mat (Shen et al., 2018a)

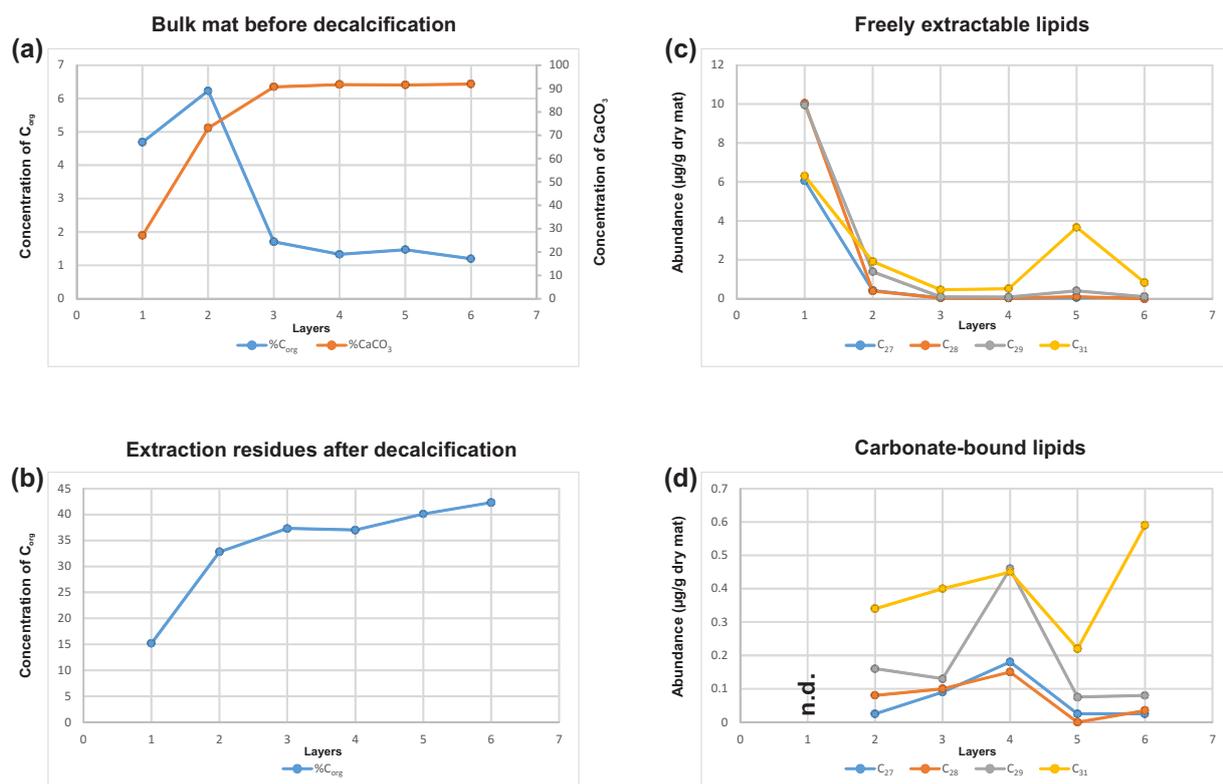

Figure 3. (a) C_{org} and CaCO₃ contents of the bulk mat (%_{wt}); (b) C_{org} content of the extraction residues after decalcification (%_{wt}); (c) Distribution of C₂₇- vs. C₂₈- vs. C₂₉- vs. C₃₁- sterols in the freely extractable lipids (µg/g dry mat); (d) Distribution of C₂₇- vs. C₂₈- vs. C₂₉- vs. C₃₁- sterols in the carbonate-bound lipids of the microbial mat (µg/g dry mat).

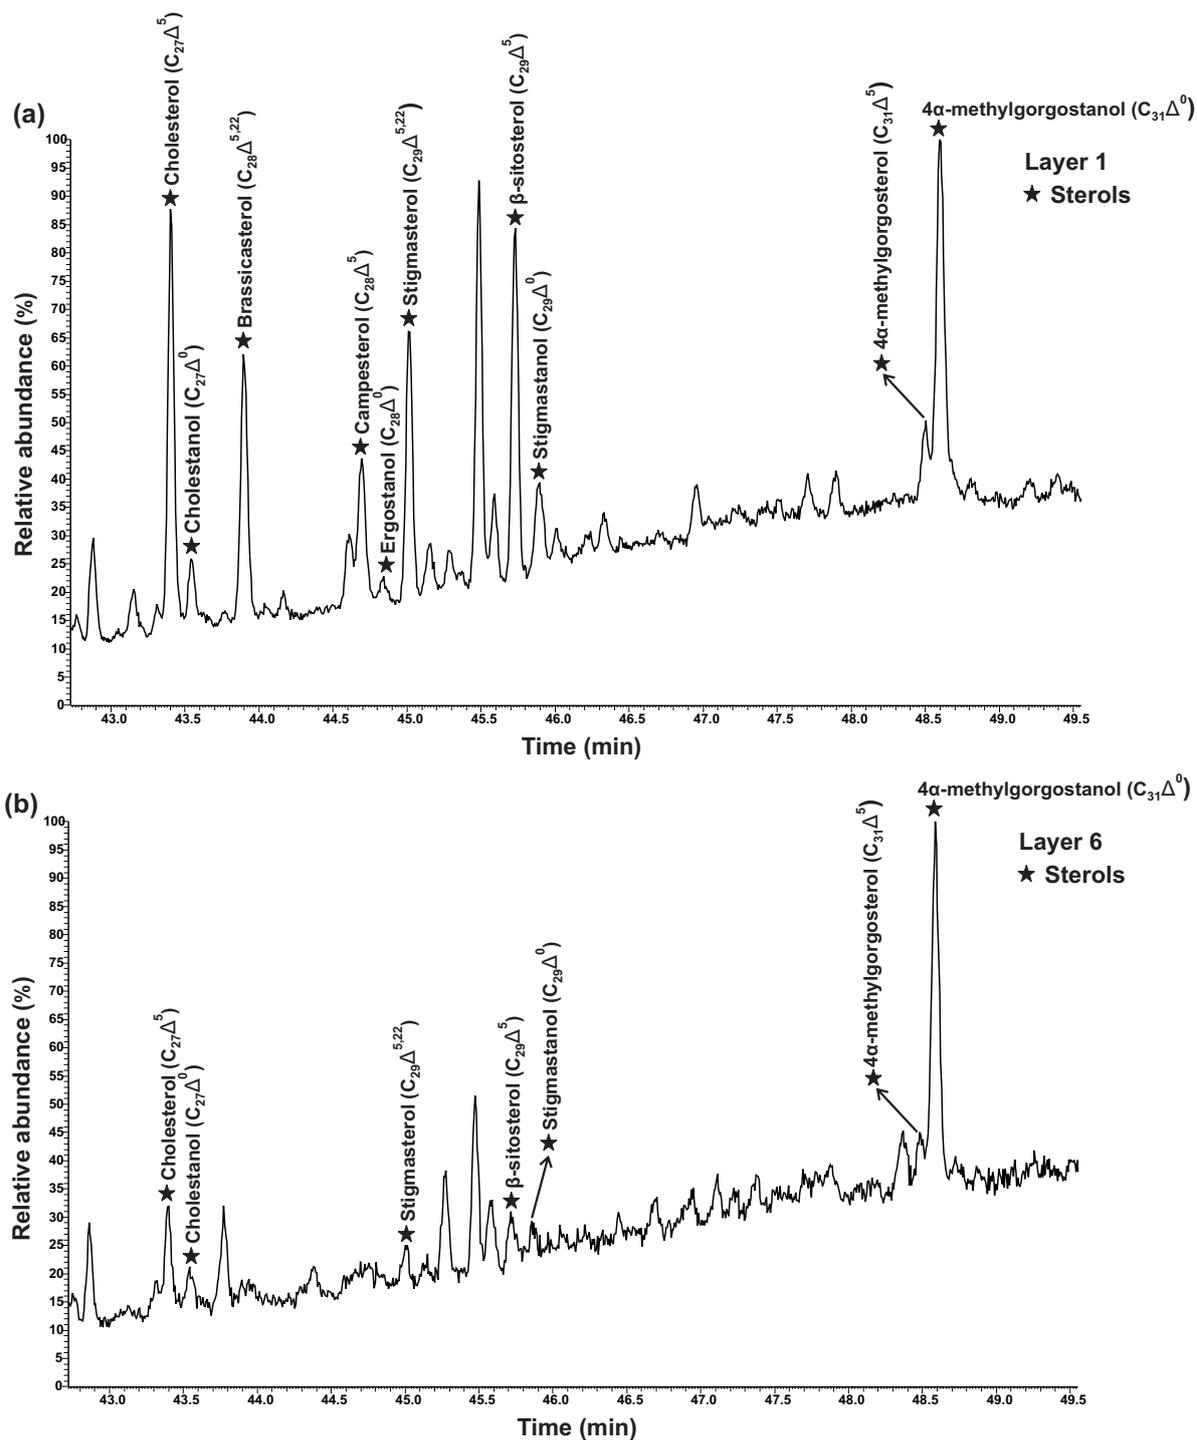

Figure 4. Partial GC-MS chromatograms (total ion current) showing the distributions of freely extractable sterols (TMS-derivatives) in (a) layer 1, and (b) layer 6 of the microbial mat.

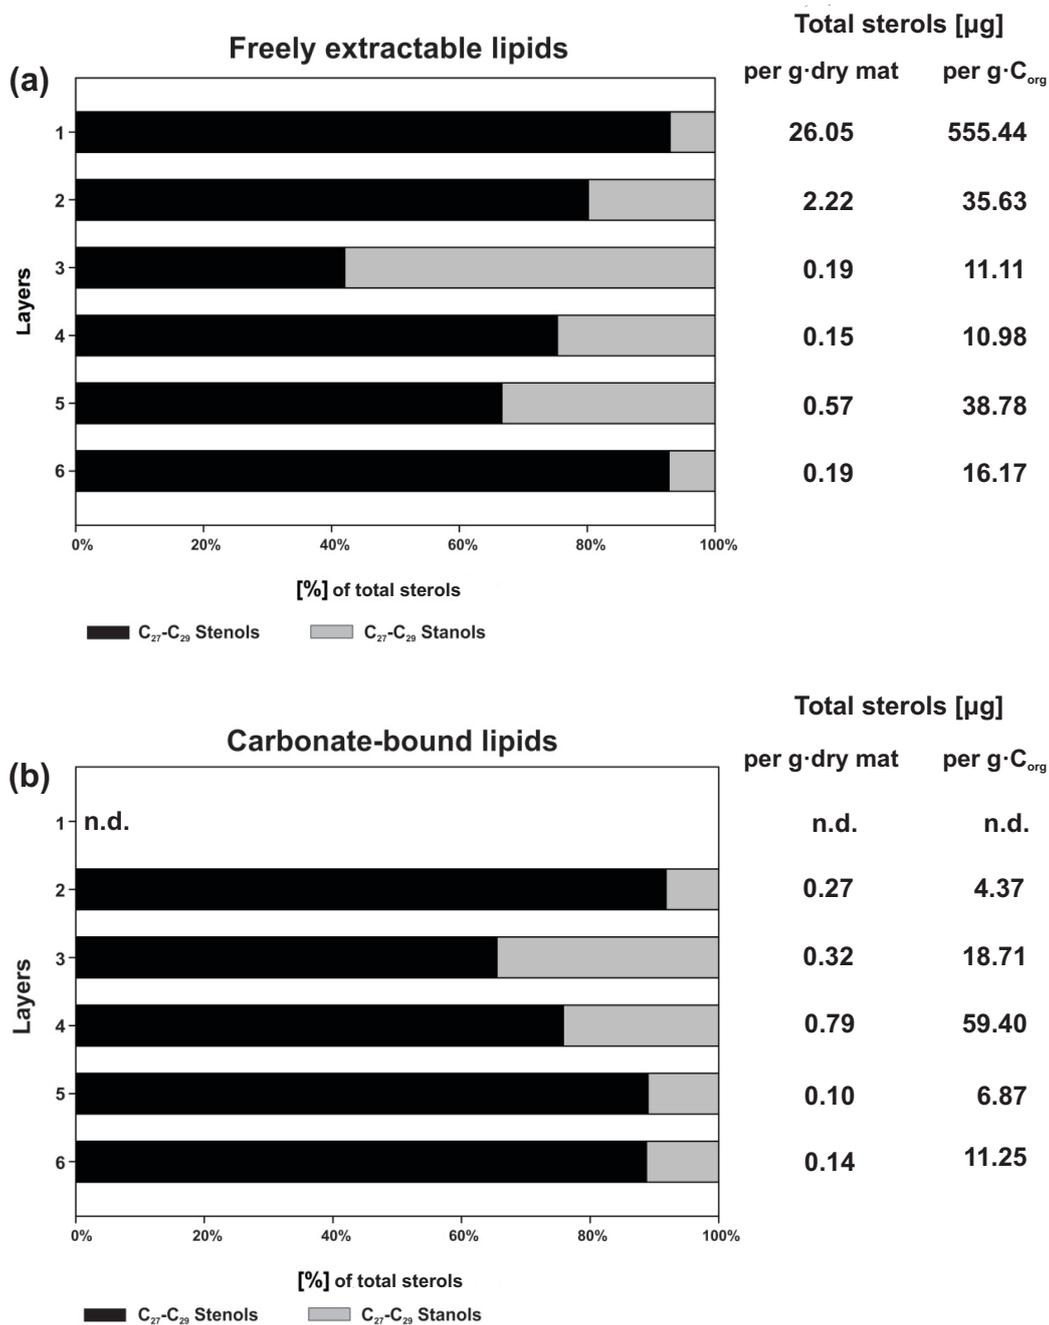

Figure 5. Distributions and concentrations of C₂₇-C₂₉ sterols in the microbial mat layers, (a) freely extractable lipids, and (b) carbonate-bound lipids.

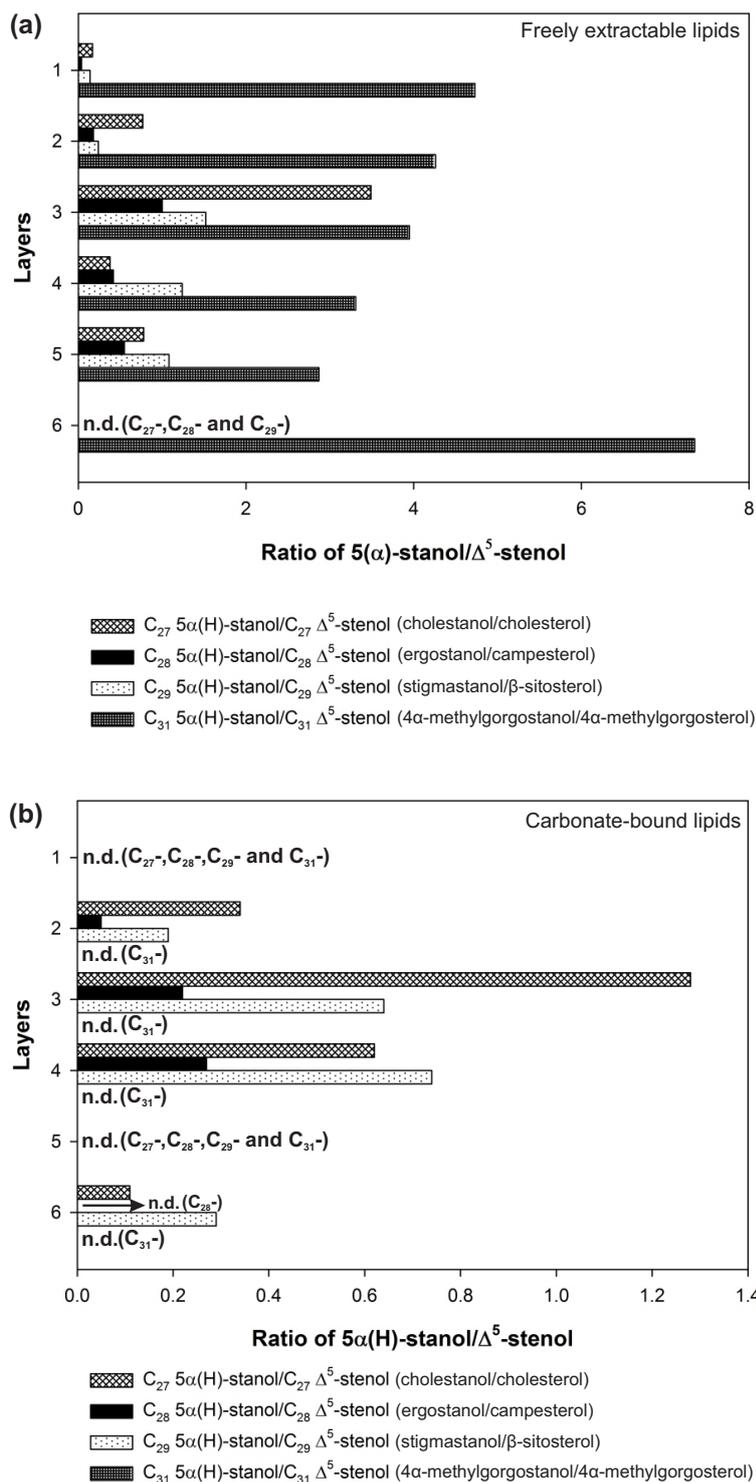

Figure 6. Stanol/stenol ratios for the microbial mat layers, (a) freely extractable lipids, and (b) carbonate-bound lipids.

**Table 1a.** Bulk geochemical data for the microbial mat (original mat layers before decalcification)

Layers	C _{tot} (%)	C _{org} (%)	C _{carb} (%)	CaCO ₃ (%)	N _{tot} (%)	S _{tot} (%)	C _{org} /N	C _{org} /S
1	7.94	4.69	3.25	27.10	0.41	9.78	11.40	0.50
2	15.00	6.23	8.77	73.10	0.74	1.21	8.40	5.20
3	12.59	1.71	10.88	90.70	0.16	0.33	10.50	5.10
4	12.33	1.33	11.00	91.70	0.19	0.49	7.00	2.70
5	12.45	1.47	10.98	91.50	0.20	0.52	7.30	2.80
6	12.23	1.20	11.03	91.90	0.14	0.48	8.50	2.50

Table 1b. Bulk geochemical data for the microbial mat (extraction residues after decalcification; modified after Blumenberg et al., 2015)

Layers	C _{org} (%)	N _{tot} (%)	S _{tot} (%)	C _{org} /N	C _{org} /S
1	15.2	1.9	10.4	7.9	1.5
