10 **Abstract.** The daily vertical movement of zooplankton, known as diel vertical migration (DVM), can enhance the vertical  
11 flux of carbon (C) and so contribute to the functioning of the biological pump in the ocean. The magnitude and efficiency of  
12 this active transport of C may depend on the size and taxonomic structure of the migrant zooplankton. However, the impact  
13 that a variable community structure can have on zooplankton-mediated downward C flux has not been properly addressed.  
14 This taxonomic effect may become critically important in highly productive eastern boundary upwelling systems (EBUS),  
15 where high levels of zooplankton biomass are found in the coastal zone and composed by a diverse community with variable  
16 DVM behavior. In these systems, presence of a subsurface oxygen minimum zone (OMZ) can impose an additional  
17 constraint to vertical migration and so influence the downward C export. Here, we address these issues based on a high-  
18 resolution zooplankton sampling at three stations off northern Chile (20°S-30°S) during November-December 2015.  
19 Automated analysis of zooplankton composition and taxa-structured biomass allowed us to estimate daily migrant biomass  
20 by taxa and their amplitude of migration. We found that a higher biomass aggregates above the oxycline, associated with  
21 more oxygenated surface waters and this was more evident upon a more intense OMZ. Some taxonomic groups, however,  
22 were found closely associated with the OMZ. Most taxa were able to perform DVM in the upwelling zone withstanding  
23 severe hypoxia. Also, strong migrants, such as Copepods Eucalanidae and Euphausiids, can exhibit a large migration  
24 amplitude (~500 m), remaining either temporarily or permanently during the day or night condition within the core of the  
25 OMZ and so contributing to the release of C below the thermocline. Our estimates of DVM-mediated C flux suggested that a  
26 mean migrant biomass of ca. 958 mg C m<sup>-2</sup> d<sup>-1</sup> may contribute with about 71.3mg C m<sup>-2</sup> d<sup>-1</sup> to the OMZ system through  
27 respiration, mortality and C excretion at depth, accounting for ca. 4% of the net primary production, and so implying the  
28 existence of an efficient mechanism to incorporate freshly produced C into the OMZ. This downward C flux mediated by  
29 zooplankton is however strongly variable in the space and mostly dependent on the taxonomic structure due to variable  
30 migration amplitude and DVM behavior.

## 31 1 Introduction

32 The Oxygen Minimum Zone (OMZ) in the Southeast Pacific, the fourth largest of the six permanent hypoxic regions in the  
33 world oceans (Paulmier *et al.*, 2006), is a key component of the water column and a permanent feature intruding the coastal  
34 zone of Ecuador, Peru and Chile (Fuenzalida *et al.*, 2009; Paulmier *et al.*, 2006). In the highly productive upwelling region  
35 of Northern Chile, the OMZ is closely linked to wind-driven upwelling in the coastal area and associated to the Equatorial  
36 Subsurface Water (ESSW), which is transported southward along the continental shelf by the Peru-Chile Undercurrent  
37 (PUC), as far south as 48°S (Fuenzalida *et al.*, 2009; Morales *et al.*, 1996a; Silva and Neshyba, 1979). Off Iquique (20°S) the  
38 OMZ is characterized by being thick (500 m), very intense ( $< 20 \mu\text{mol kg}^{-1}$ ) and with O<sub>2</sub> concentrations in the core of OMZ  
39 among the lowest found in the global ocean reaching the current detection limit ( $< 1 \mu\text{M}$ ) (Ulloa and Pantoja, 2009), although  
40 it becomes thinner at about 30°S (Paulmier *et al.*, 2006).

41 During the last decades, the OMZ systems have attracted much scientific interest because of evidence showing that hypoxic  
42 and anoxic conditions in coastal areas are expanding and becoming more intense (Ekau *et al.*, 2010; Stramma *et al.*, 2008).  
43 At present, ongoing ocean deoxygenation is widely recognized as linked to global warming and it is rising much concern in  
44 modern oceanography (Breitburg *et al.*, 2018).

45 The presence of oxygen-depleted water becomes a critical physiological constraint for pelagic and benthic organisms  
46 inhabiting the upwelling zone, impacting their biomass and productivity, the species diversity, distribution, behaviour and  
47 metabolic activity (Wishner *et al.*, 2018; Ekau *et al.*, 2010; Grantham *et al.*, 2004). For instance, diel vertical migration  
48 (DVM), a common feature of the various size groups of zooplankton and also one of the most important movements of  
49 biomass in the ocean, can also be affected by changes in intensity and distribution of the OMZ (Wishner *et al.*, 2018, 2013;  
50 Escribano *et al.*, 2009; Fernández-Álamo and Färber-Lorda, 2006; Hidalgo *et al.*, 2005; Morales *et al.*, 1996; Judkins, 1980).  
51 The OMZ can act as an ecological barrier for vertical distribution of many organisms, constraining most zooplankton to a  
52 narrow (50 m) upper layer, as shown in the coastal upwelling zone off Chile according to the works of Escribano (2006) and  
53 Donoso and Escribano (2014). Zooplankton also become limited to the upper 150 or 300 m in the eastern tropical north  
54 Pacific (Wishner *et al.*, 2013). However, the OMZ can also offer refuge for species adapted to live there, creating  
55 microhabitats of differing oxygen concentration that are characterized by layers of high zooplankton biomass and abundance,  
56 with distinct species zonation (Antezana, 2009; Wishner *et al.*, 2008; Fernández-Álamo and Färber-Lorda, 2006), which, in  
57 turn, may have important consequences for carbon (C) cycling and its vertical flux. For example, it is known that  
58 zooplankton in the coastal upwelling region off northern Chile may play a significant biogeochemical role by promoting  
59 carbon flux into the subsurface OMZ (Escribano *et al.*, 2009). Therefore a significant proportion of the vertical material flux  
60 from the euphotic zone to the deep sea ( $> 200 \text{ m}$ ) and within the food chain could be determined by DVM of zooplankton  
61 (Longhurst and Williams, 1992; Steinberg and Landry, 2017).

62 As important contributors to the functioning of the biological pump, diel zooplankton migrants can actively increase the  
63 magnitude of C export by transporting surface-ingested material in their guts to deep waters where it can be metabolized

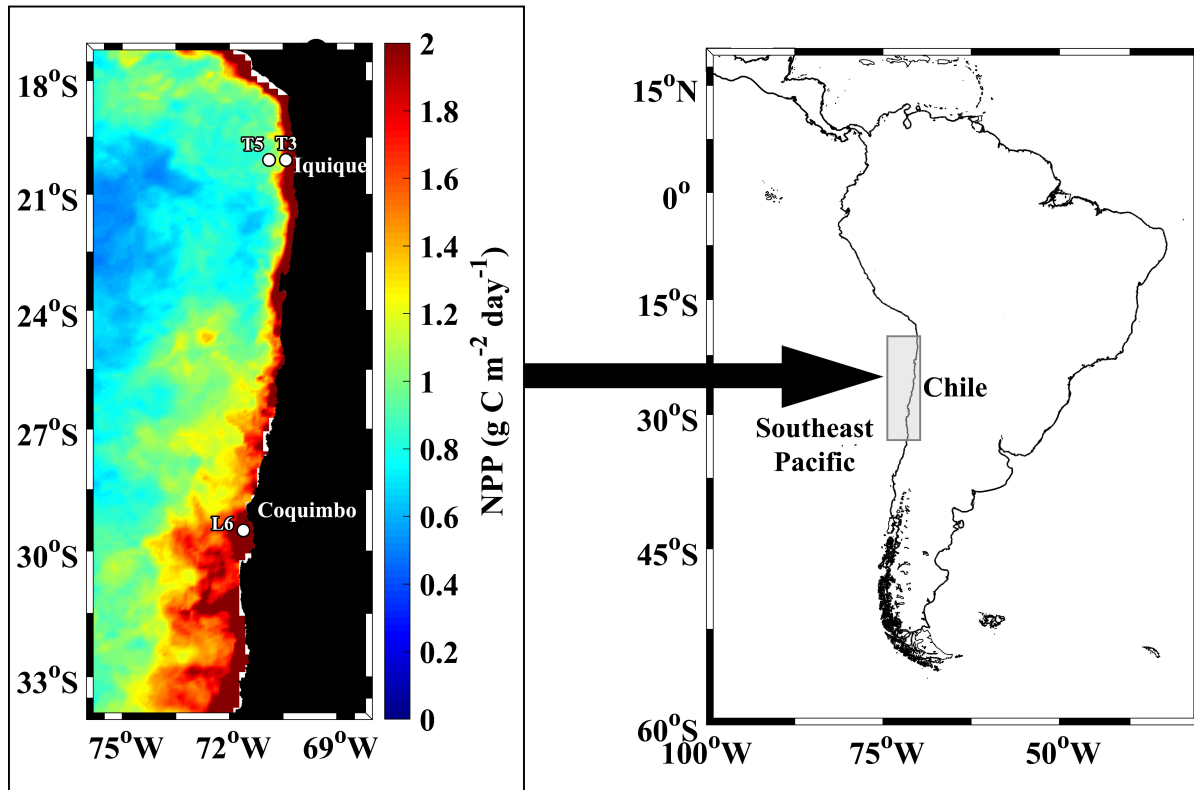

64 (Steinberg and Landry, 2017). Zooplankton moults or mortality at depth can also contribute to the transportation of  
65 assimilated organic biomass into the deep waters (Ducklow *et al.*, 2001). The biological pump process is also thought to be  
66 related to the size structure of dominant zooplankton. This because some groups with large body sizes may exhibit a greater  
67 range of vertical migration and sometimes higher levels of biomass, and so influencing the biogeochemical fluxes (Dai *et al.*,  
68 2016; Ducklow *et al.*, 2001). However, the effect of variable size structure on DVM performance and its consequence for  
69 active C transport has not indeed been assessed. Size-structure is certainly related to zooplankton composition which has  
70 hardly been properly addressed when examining the role of DVM on C flux. For instance, in areas with hypoxic subsurface  
71 layers some species are more active migrants and thus more efficient C-transporters, because they have developed  
72 adaptations to low oxygen conditions and can even use the OMZ as their habitat, either temporarily or permanently  
73 (Escribano *et al.*, 2009; Gonzalez and Quiñones, 2002; Seibel, 2011). Adaptation may include in some cases reduction of  
74 aerobic metabolism by more than 50% during exposure to hypoxia conditions, as a mechanism to facilitate low oxygen  
75 tolerance, and so reducing dramatically energy expenditure during daytime within low oxygen waters, and therefore affecting  
76 the carbon C flux in areas subjected to low concentrations of oxygen (Seibel *et al.*, 2016).  
77 C-export to depth may also depend on the amount of biomass being produced in the photic zone. Primary production  
78 promotes zooplankton feeding and growth and therefore determining C availability for both passive and active transport to  
79 depth. In this context, highly productive upwelling zones can be assumed as systems where the C-flux mediated by  
80 zooplankton DVM can be enhanced, although certainly depending on the size and taxonomic structure of zooplankton. In  
81 these regions, a shallow OMZ might exert a further impact on the C-flux by affecting DVM or zooplankton metabolism at  
82 depth. In the present study, based on high resolution sampling and automated analysis of mesozooplankton, we assessed  
83 zooplankton vertical migration and downward C to the OMZ in the highly productive upwelling region of Northern Chile.  
84 We aimed at understanding the role that taxonomic and size-structure can play in the magnitude and variability of the DVM  
85 behaviour interacting with a shallow OMZ, and the implications this interaction can have on the magnitude of the downward  
86 C flux in a highly productive coastal upwelling zone

## 87 **2Methods**

### 88 **2.1Study Area**

89 The study area was located in the Southeast Pacific Ocean and covered the coastal zone of the northern upwelling region of  
90 Chile (21-29°S) (**Fig. 1**), which is a region known to be subjected to wind-driven upwelling throughout the year and  
91 containing an intense and shallow OMZ (Ulloa *et al.*, 2012). The sampling design comprised three stations: Two stations (St.  
92 T3 and St. T5) across a zonal section off Iquique (20°S) and a coastal station (St. L6) off Coquimbo (29°S). The study was  
93 carried out during the LowpHox cruise conducted in November-December 2015 onboard the R/V *Cabo de Hornos*. At each  
94 station, temperature, salinity and dissolved oxygen (DO) were recorded from 1000 m (St.T5 and St.T3) and only 356 m (St.

95 L6) using an oceanographic rosette with a CTD SeaBird 911 (SBE 911 plus) equipped with a SeaBird SBE-43 oxygen sensor  
96 and a Seatech Fluorometer. Discrete water samples were also obtained for chemical measurements of oxygen.

97  
98 **Fig.1.** Study area at the northern upwelling region of Chile, indicating sampling stations during the LowpHox cruise  
99 conducted in November-December 2015 onboard the R/V *Cabo de Hornos*. Satellite estimated Net Primary Production  
100 (NPP), averaged for November-December 2015 is shown. NPP was obtained from  
101 <http://science.oregonstate.edu.ocean.productivity>.

## 102 2.2 Zooplankton sampling

103 Zooplankton samples were collected during daytime and night-time conditions in two consecutive days at the three stations  
104 off northern Chile (T5-T3-L6) (**Fig. 1**), also as indicated in **Table S1 (Supplemental Material)**. Vertical hauls of  
105 zooplankton were performed from 600 to 0 m depth with a Multi Plankton Sampler Hydro-Bios Multinet system with a 0.25  
106 m<sup>2</sup> opening area and equipped with 200- $\mu$ m mesh-size nets. The Multinet towing speed was 1 m s<sup>-1</sup> and the flowmeter was  
107 in the mouth of the Multinet to estimate the volume of filtered water. Once onboard the collected zooplankton samples were  
108 preserved immediately in 5% buffered formalin-seawater solution. At each station, 40 discrete samples were obtained from  
109 600 to 0 m depth. Each sample corresponded to a different depth stratum (30-0, 90-30, 150-90, 400-150 and 600-400m  
110 depth). These strata were defined in according to distribution of oxygen concentration and localization of the OMZ (**Fig. 2**).

111 Then, from the vertical profiles of oxygen and coinciding with the sampled layers of the Multinet, strata were defined as: A  
112 well oxygenated stratum with oxygen approaching air saturation ( $>250 \mu\text{mol O}_2 \text{ kg}^{-1}$ ) was defined as the oxic mixed layer  
113 (OX-ML), an upper  $\text{O}_2$  gradient (oxycline), defined by the level where  $\text{O}_2$  reaches 4% of the surface  $\text{O}_2$  (Paulmier *et al.*,  
114 2006), at whose base is located the upper boundary of the OMZ ( $45 \mu\text{mol O}_2$  isoline, OMZ-UB) (Escribano *et al.*, 2009;  
115 Hidalgo *et al.*, 2005; Morales *et al.*, 1999); the OMZ core defined by an upper boundary (OMZ-UC) with the lowest  
116 concentration of  $\text{O}_2$  ( $<20 \mu\text{mol O}_2 \text{ kg}^{-1}$ ) and a lower boundary (OMZ-LC) ( $1 \text{ to } <20 \mu\text{mol O}_2 \text{ kg}^{-1}$ ), and finally a lower  $\text{O}_2$   
117 gradient (OMZ-LW). Depth ranges and oxygen levels for these strata are detailed in **Table S2 (Supplemental Material)**.

118

### 119 **2.3 Taxonomic and size measurements**

120 Taxonomic identification and enumeration of taxa were carried out by analysis of digitized images obtained with the  
121 Hydroptic ZooScan digital imaging system (Gorsky *et al.*, 2010). Each sample was wet-sieved through a  $1000 \mu\text{m}$  mesh into  
122 two size fractions. Then, each size-fraction was fractionated again separately with a Motoda splitter until the zooplankton  
123 concentration was sufficiently diluted to avoid contact between organisms in the ZooScan scanning frame. Fractioning into  
124 small and large organisms and consequent separate image acquisition of the two size classes prevented underestimates of  
125 large-rare objects which may need less fractioning (Gorsky *et al.*, 2010). 179 subsamples were scanned and digitized at a  
126 resolution of 2400 dpi after manual separation of objects on the scanning tray. After processing the samples with ZooProcess  
127 software, each of the objects was automatically sorted with the help of a learning set, and then the sorting was visually  
128 validated by an expert (for details, see Chang *et al.*, 2012; Gorsky *et al.*, 2010). Organisms making up the ZooScan datasets  
129 were enumerated, measured, biomass-estimated and classified into 27 taxonomic groups, such as Copepods, Chaetognaths,  
130 Euphausiid, Gelatinous and other zooplankton. The abundance ( $\text{ind. m}^{-3}$ ) of total zooplankton or of each taxonomic group  
131 was calculated following Eq. (1):

132

$$133 \text{ Abundance}/\text{m}^3 = \frac{N * \text{Subpart}}{\text{Vol} * \text{Townb}}, \quad (1)$$

134

134 were, N is the number of individuals with same prediction (e.g. in last column written “copepod”), Subpart is the splitting  
135 ratio, Vol is net volume and Townb is the number of net tows in a sample. Townb = 1 in our case because of a single tow per  
136 sample. Stratum-integrated abundance ( $\text{ind. m}^{-2}$ ) was obtained after multiplying by width (m) of a given stratum.

137

### 138 **2.4 Biomass estimates and Carbon fluxes**

139 The ZooScan Integrated System also provided zooplankton body size in terms of area ( $\text{mm}^2$ ) or volume ( $\text{mm}^3$ ) for each  
140 organism. We used these organisms’ area or volume to estimate dry weight of each individual of different taxonomic groups  
141 using published regression equations relating organism size, area or volume to individual weight as detailed in **Table S3**

142 **(Supplemental Material).** Mass unit conversions between dry weight (DW) and carbon content (C) were performed using  
143 averaged conversion factors obtained for different zooplankton groups (Kjørboe, 2013) and ichthyoplankton (Childress and  
144 Nygaard, 1973) (Table S3 Supplemental Material). Added biomasses ( $\mu\text{g C ind.}^{-1}$ ) of individuals within taxonomic  
145 categories identified by ZooScan allowed us to estimate total biomass per taxa ( $\text{mg C m}^{-3}$ ) for each sample by station,  
146 daytime vs night-time condition, and depth strata. Integrated values of biomass per depth strata ( $\text{mg C m}^{-2}$ ) and taxa were  
147 calculated multiplying by strata width (m).

148 To calculate the migrant biomass, we integrated biomass in the upper 90 m layer from our two sampled strata 0-30 m and  
149 30-60 m. This 0-90 m stratum was considered the approximate above-oxycline layer after examining the vertical profiles of  
150 oxygen. Biomass at night was thus subtracted from the corresponding day biomass in this layer to assess daily changes  
151 involving migrants as in Putzeys *et al.* (2011). Thus, the negative values of the day-minus-night biomass corresponded to  
152 migrant biomass that reached the epipelagic layer at night including organisms inhabiting above and below the oxycline.

153 The proportion of migrant biomass with respect to observed biomass in the upper 90 m of a given taxonomic group was  
154 defined at the rate of migration on a daily basis. This rate of migration could thus be used as an index of DMV behaviour for  
155 a taxonomic group.

156 To estimate the active C flux at each sampling station, we considered three processes contributing to C at depth mediated by  
157 migrant zooplankton: respiration (R), excretion (E) and mortality (M) at depth. Respiration at depth ( $>90$  m) was estimated  
158 using the equation provided by Ikeda (1985) which relates individual respiration rate with body mass and temperature,  
159 independently of taxonomic category which may have a minor effect on R in according to a more recent assessment (Ikeda,  
160 2014). Mean body mass ( $\mu\text{g C}$ ) for each taxonomic group from ZooScan estimates and mean in situ temperature were used  
161 to obtain integrated R at each depth strata. Estimates of R for each taxonomic group are shown in Table S6 (Supplemental  
162 Material). Integrated R per station for the 0-600 depth strata along with the corresponding integrated biomass was then used  
163 to estimate the fraction of C being respired at depth by zooplankton. The contribution of C by excretion (E) at depth was  
164 assumed to be 31% of R as suggested by (Steinberg *et al.*, 2000) and daily mortality at depth (M) was considered to be in the  
165 range of 0.3 and 0.5 as suggested by Edvardsen *et al.* (2002), so that a median value of 0.4 as a fraction of migrant biomass  
166 was assumed. Vertical C flux mediated by zooplankton was thus estimated as,

167

$$168 \text{ C Flux} = \text{MB} \times [(\text{R} + \text{M} + 0.31\text{R})/2] \quad (2)$$

169

170 where MB is the migrant biomass ( $\text{mg C m}^{-2}$ ), R and M are daily Respiration and Mortality, and C excretion expressed as  
171  $0.31\text{R}$ . The three processes are divided by 2 assuming a 12 h incursion at depth.

## 172 **2.5 Patterns of vertical distribution of migrating zooplankton**

173 For the analysis of vertical distribution of organisms, the density estimates of the organisms were standardized to number of  
174 individuals per  $\text{m}^3$  (for each stratum) or per  $\text{m}^2$  (for integrated values). In order to quantify the presence and extent of DVM

175 of various taxa at each station, we calculated weighted mean depth (WMD) for zooplankton abundance, as a measure of the  
176 center of gravity of a population's vertical distribution for each taxon and haul, according to Andersen *et al.*(2004) following  
177 Eq. (3):

178

$$WMD = \frac{\sum(n_i * z_i * d_i)}{\sum(n_i * z_i)}, \quad (3)$$

179

180 where  $d$  is the mean depth of the strata (m),  $z$  the width (m) of the strata and  $n_i$  the abundance (ind. m<sup>-3</sup>) of a given  $i$   
181 taxonomic group.

182 We calculated the amplitude of vertical migration ( $\Delta$ DVM) as the difference between the WMD of the organisms during the  
183 day and the night and therefore this  $\Delta$ DVM was considered as the criterion to assess the DVM behaviour for each taxonomic  
184 group. Positive values indicated normal DVM (pattern of nocturnal ascent by individuals that reside at depth by day) and  
185 negative values indicated reverse DVM (pattern of nocturnal descent by individuals that reside near the surface by day). The  
186 individuals that occupied the same depth stratum by day and by night, whether near the surface or at depth were considered  
187 as non migrant in according to Ohman (1990).

## 188 2.6 Statistical analysis

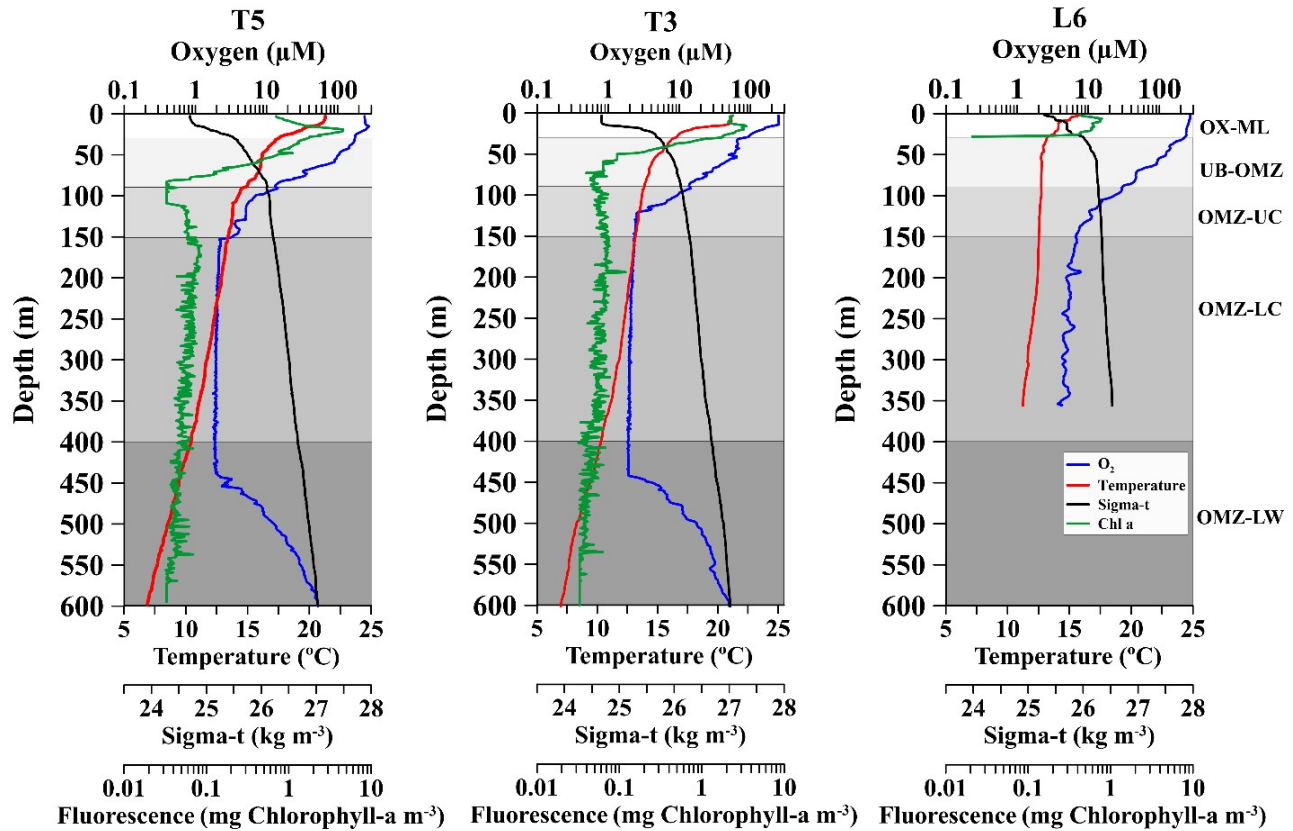

189 For statistical analysis, as a criterion for determining if the DVM was significant, we tested for differences in the WMD  
190 mean between day and night using a two-tailed  $t$  test. We considered the occurrence of DVM when the difference in the  
191 WMD mean between day and night was significant ( $p < 0.05$ ). In order to evaluate the similarity/dissimilarity in the  
192 abundance and biomass among stations, strata, and day–night conditions, the multivariate grouping techniques were applied  
193 ("cluster analysis"), ANOSIM (Two-Way Crossed Analysis) tests and multidimensional scaling (MDS) with the data  
194 transformed in PRIMER v 6.1.16 (2013), prior to the application of the Bray-Curtis similarity index (Bray and Curtis, 1957).  
195 In general, WMD for taxonomic groups did not exhibit a pronounced bimodal vertical distribution.

## 196 3 Results

### 197 3.1 Hydrographic conditions

198 Across the zonal section off Iquique the offshore station (St. T5) and onshore station (St. T3) showed two contrasting  
199 hydrographic regimes regarding the OMZ. Station T5 had a less pronounced and thicker OMZ than station T3. At both  
200 stations the 5 strata were well defined in the water column (**Fig. 2**). The OX-ML ( $>250 \mu\text{mol O}_2 \text{ kg}^{-1}$ ) was present at 18 m  
201 (St. T5) and 15 m (St. T3). The oxycline gradually decreased from oxic ( $\sim 250 \mu\text{mol O}_2 \text{ kg}^{-1}$ ) to suboxic ( $<20 \mu\text{mol O}_2 \mu\text{mol}$   
202  $\text{O}_2 \text{ kg}^{-1}$ ) conditions associated with a strong stratification in the upper 80 m depth. The  $45 \mu\text{mol O}_2$  isoline (OMZ -UB) was  
203 at the base of the oxycline at 70 m (St. T5) and 59 m (St. T3). The OMZ core ( $<20 \mu\text{mol O}_2 \text{ kg}^{-1}$ ) was below the  
204 thermocline and below the  $26.5 \text{ kg m}^{-3}$  isopycnal following description of Paulmier *et al.* (2006). In the oceanic station (St. T5)

205 the OMZ core was between 80 to 514 m, while in the coastal station (St. T3) it was between 80 to 507 m with 423 m  
 206 thickness. The O<sub>2</sub> concentration in the OMZ core was ca. 1 μmol O<sub>2</sub> kg<sup>-1</sup>. The OMZ-LW at both stations was delimited  
 207 above the core and below the depth where the O<sub>2</sub> slope changed significantly (slope break >20 μmol /m) (Fig. 2).  
 208

209  
 210  
 211 **Fig. 2.** Vertical profiles of dissolved oxygen (O<sub>2</sub>), temperature, Chlorophyll-a and water density (sigma-t), at 3 stations off  
 212 northern Chile (see Fig. 1) during the LowpHox Cruise in the austral spring 2015. Shaded areas represent different layers  
 213 defined according to oxygen concentration. OX-M= Oxidic mixed layer, OMZ-UB= Upper boundary of the oxygen minimum  
 214 zone, OMZ-UC= Upper core of the oxygen minimum zone, OMZ-LC= Lower core of the OMZ and OMZ-LW=lower  
 215 oxygen gradient.  
 216 The structure of the OMZ at the coastal station (St. L6) off Coquimbo (29°S) (Fig.1), was similar to St. T3 (21°S), but in this  
 217 area the OMZ was deeper and thinner. The OX-ML was shallower. The OMZ -UB (45 μmol O<sub>2</sub>) in the base of the oxycline  
 218 was down to 80 m. The low O<sub>2</sub> concentrations in the core were less intense than at 21°S (4 to 20 μmol O<sub>2</sub>kg<sup>-1</sup>) and it was  
 219 located below 100 m (Fig. 2). The OMZ-LW could not be assessed because of lack of CTD data below 350 m.

220 Additional oceanographic variables showed a surface warming (>20 °C) and strongly stratified conditions at the three  
221 stations with a sharp thermocline in the upper 100 m, coinciding with the oxycline, whereas Chlorophyll-a maximum (>5 mg  
222 Chlorophyll-a m<sup>-3</sup> was in the upper 20 m (Fig. 2).

### 223 3.2 Zooplankton composition and abundance

224 A total of 27 zooplankton taxa were identified by the ZooScan and ZooProcess (Table S4 Supplemental Material). The  
225 number of taxa varied among stations and strata. Across the zonal section off Iquique the number of taxonomic groups  
226 fluctuated between 23 (St. T3) and 26 (St. T5), whereas 25 taxa were off 29°S (St. L6). The most dominant taxa both  
227 daytime and night conditions, were: Copepods 87% (in St. T5), 79% (in St. T3) and 69% (in St. L6). This group was  
228 constituted by small Copepods, large Copepods, the Copepods Eucalanidae and the Copepods *Acartia* spp; fish eggs  
229 constituting 2% (in St. T5), 5% (in St. T3) and 6% (in St. L6); Nauplii being <1% (in St. T5), <1% (in St. T3) and 7% (in St.  
230 L6); Appendicularia 5% (in St. T5), 4% (in St. T3) and 3% (in St. L6) (Table S5 Supplemental Material). The remaining  
231 19 pooled groups only constituted <6% (in St. T5), 11% (in St. T3) and 15% (in St. L6). The total integrated abundances of  
232 zooplankton (0-600 m) by sampling station are in Table S4 (Supplemental Material). As based on a Two-Way Crossed  
233 Analysis ANOSIM test, this water-column integrated abundance did not show significant differences between day and night  
234 samples (p>0.05). However, the abundance of these zooplankton groups regarding stations was significantly different (Two-  
235 Way Crossed Analysis ANOSIM p<0.05), so that the stations were treated independently. Off Iquique the abundance was the  
236 lowest at the onshore station (St. T3 with 18% lower), which was characterized by the strongest and most extensive OMZ in  
237 the study area. These values increased at the offshore station (St. T5 with 31% greater), where the OMZ was less  
238 pronounced and thicker. Unlike stations T3 and T5, the onshore station off 29°S (St. L6) had a weaker and less extensive  
239 OMZ showing the highest zooplankton abundance (51% greater).

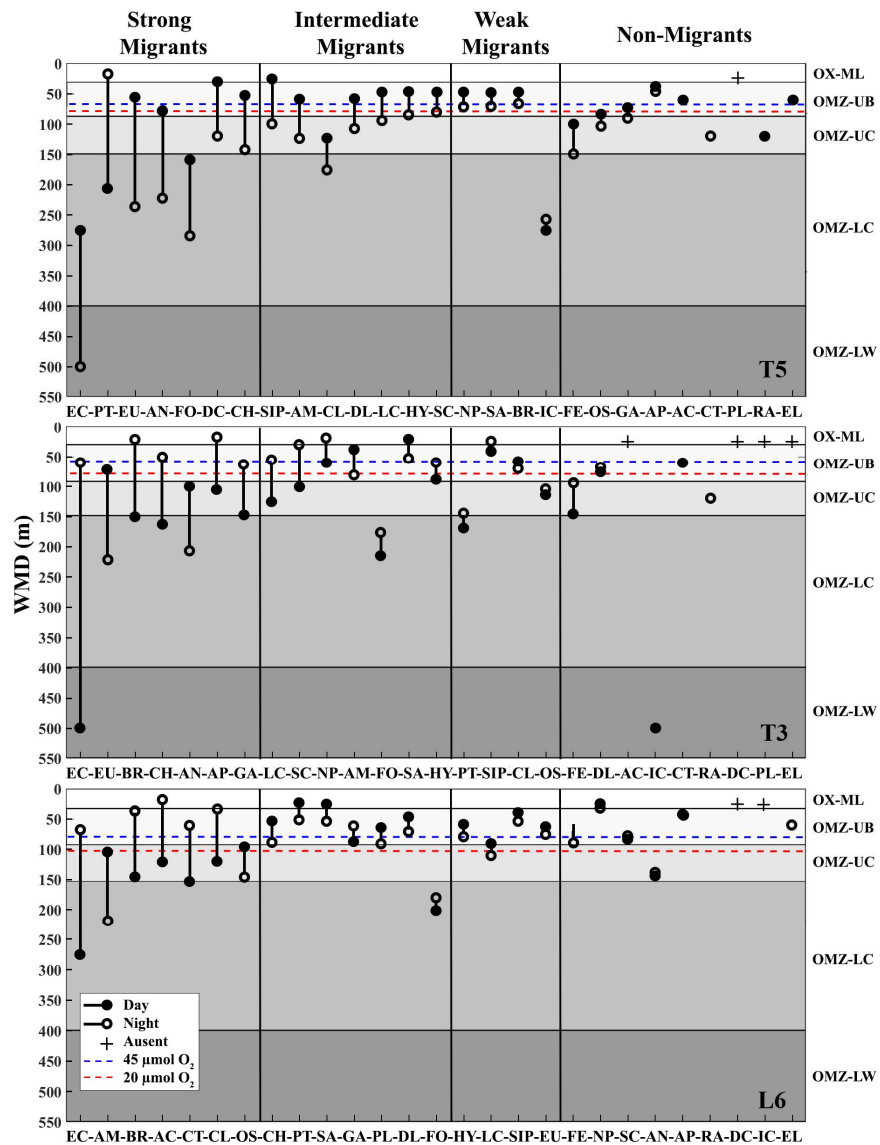

240

### 241 3.3 Diel vertical migration (DVM) and vertical distribution

#### 242 3.3.1 Main migrant groups of zooplankton

243 The diel vertical migration of 27 zooplankton taxa in the 0–600 m water column is in Fig. 3. These taxa were classified into  
244 four groups according to their amplitude of migration ( $\Delta$ DVM) (Table 1): **1) Strong migrants**, represented by taxa with a  
245 strong DVM and a broad range of  $\Delta$ DVM from 225 to 99 m (in St. T5), 440 to 84 m (in St. T3) and 208 to 87 m (in St. L6).  
246 This group constituted 70% of taxa with higher  $\Delta$ DVM. The composition of taxa in this group was variable at each station  
247 (Table 1), but in general was well represented by Eucalanidae Copepods (EC), Euphausiids (EU), *Acartia* Copepods (AC),  
248 Ctenophores (CT), Decapods (DC), Annelids (AN), Bryozoan L (BR), Pteropods (PT) and Chaetognaths (CH). These taxa  
249 were mostly concentrated in the oxic surface stratum (OX-ML), and the **OMZ core** showing a strong interaction with both  
250 the **OMZ-UC** and the **OMZ-LC**, and so changing from normoxia to hypoxia condition and vice versa between 0 to 550 m

251 **(Fig. 3), 2) Intermediate migrants**, represented by taxa with a moderate DVM and a range of  $\Delta$ DVM from 73 to 34 m (in  
252 St. T5), 70 to 27 m (in St. T3) and 49 to 22 m (in St. L6). This group constituted 23% of taxa with moderate  $\Delta$ DVM. The  
253 composition of taxa in this group was also variable at each station (**Table 1**), but it was mostly represented by small (SC)  
254 and large Copepods (LC), Amphipods (AM), Cirripedia Larvae (CL), Gastropods (GA), Siphonophores (SIP) and  
255 Appendicularia (AP). These taxa were mostly concentrated in the oxic surface strata (**OX-ML**) and in the **OMZ-UC**  
256 showing some interaction with the **OMZ core** and vertically changing from normoxia to hypoxia condition, and vice versa  
257 between 0 to 200 m, **3) Weak migrants**, represented by taxa that with a weak DVM and a range of  $\Delta$ DVM of 24 to 18 m (in  
258 St.T5), 23 to 12 m (in St.T3) and 21 to 11 m (in St. L6). This group constituted 5% of taxa of low range of  $\Delta$ DVM. The  
259 composition of taxa in this group was also variable at each station (**Table 1**), but in general it was represented by Hydrozoa  
260 (HY), Salps (SA), Platyhelminthes (PT), Decapoda Larvae (DL), Ostracods (OS), Nauplii (NL) and Ichthyoplankton (IC).  
261 These taxa were concentrated mainly in the oxic surface strata (**OX-ML**) and in the **OMZ-UP**, but also in the **OMZ-UC** at the  
262 onshore stations (Station T3 and Station L6), showing much less interaction with the **OMZ core**, while spatially moving  
263 from normoxia to hypoxia condition and vice versa between 0 to 100 m, and **4) Non-migrants**, represented by taxa which  
264 did not exhibit a significant DVM and had a range of  $\Delta$ DVM from 16 to 0 m (in St. T5), 7 to 0 m (in St. T3) and 6 to 0 m (in  
265 St. L6). This group constituted 1% of taxa with not significant  $\Delta$ DVM. The composition of taxa in this group was also  
266 variable at each station (**Table 1**), but in general it was represented by fish eggs (FE), Radiolarian (RA) and Echinoderm  
267 larvae (EL).  
268

269

270 **Fig.3.** Weighed mean depth distribution (WMD) of the zooplankton community interacting with the OMZ off Iquique  
 271 (Stations T5 and T3) and off Coquimbo (StationL6) at the northern upwelling area of Chile during the austral spring 2015.  
 272 Shaded gray areas represent different layers defined by their oxygen levels (defined in Methods). The taxonomic groups  
 273 were classified by automated analysis (ZooScan): EC= Eucalanidae Copepods, AM= amphipods, BR=Bryzoa larvae, AC=  
 274 *Acartia* Copepods, CT= Ctenophores, CL=Cirripedia larvae, OS=Ostracods, CH=Chaetognaths, PT= Pteropods, SA=salps,  
 275 GA= Gastropods, PL= Platyhelminthes, DL= Decapoda larvae, FO=Foraminifera HY=Hydrozoa, LC=Large Copepods,  
 276 SIP=Siphonophores, EU=Euphausiids, FE=fish eggs, NP=Nauplii, SC=Small copepods, AN= Annelids,  
 277 AP=Appendicularia, RA=Radiolarian, DC=Decapods, IC=ichthyoplankton, EL=Echinoderm larvae.

279 **Table 1-** Diel vertical migration indices for 27 taxonomic groups (TAXA) identified and sorted by ZooScan at 3 stations off  
 280 northern Chile (see **Fig. 1** for acronyms), during the austral spring 2015. Amplitude of migration ( $\Delta$ DVM) is in meters.  
 281 Positive values indicate normal DVM and negative values indicate reverse DVM (see Methods).. Four groups are defined in  
 282 according to DVM behaviour. Relative abundances are shown in %.

### 283 3.2 Vertical distribution and DVM of dominant groups.

284 Vertical distributions of zooplankton were assessed for 5 taxonomic groups, which represented 80% of total abundance in  
285 average: Copepods represented by small Copepods, Large Copepods, Eucalanidae Copepods and *Acartia* Copepods;  
286 Euphausiids; Decapods Larvae; Chaetognaths and Annelids, as well as their patterns of strata–station–abundance  
287 relationships are detailed in **Table S4 (Supplemental Material)**. The abundance of these zooplankton groups regarding  
288 depth strata was significantly different (ANOSIM,  $p < 0.05$ ) at each station, and therefore representing distinctive  
289 microhabitats characterized by specific depth and oxygen concentration. In general, the higher abundance (>80%) was  
290 found in the shallower strata and well oxygenated layers (**OX-ML and OMZ UB**) ( $>250 \mu\text{mol O}_2 \text{ kg}^{-1}$ ), and then it  
291 decreased rapidly in the strata associated with the OMZ core (**OMZ-UC and OMZ-LC**). Below this stratum a second slight  
292 peak in abundance was in the **OMZ-LW** in special at Sts. T5 and L6, occurring between 400-600 m, both daytime and night  
293 conditions.

294 As expected, Copepods dominated numerically the zooplankton community both within and outside the OMZ . Small  
295 Copepods (SC) were the most abundant (70%), followed by large Copepods (LC) (6%), whereas the Copepods *Acartia* (AC)  
296 and Eucalanidae (EC) showed the lowest abundances among Copepods. The largest aggregation of Copepods (pooled data)  
297 altogether during the entire study period was at the offshore station St. T5 (87%), where abundances reached  $192088 \text{ ind. m}^{-2}$ .  
298 At the onshore station (St. T3) the percentage of contribution of copepods was 79% and 69% at the St L6 (**Table S5**  
299 **Supplemental Material**). Off Iquique, the highest abundances were in the shallower strata (**OX-ML**) at St.T5 (46%) and at  
300 St. T3 (47%), and reduced in the core of the OMZ at St. T5 (4 to 1%) and at T3 (8 to 1%) between 90-400 m, where oxygen  
301 had the lowest concentrations ( $< 20 \mu\text{M}$  to  $1 \mu\text{M}$ ). At the St. T5 the second peak of abundances was in the **OMZ-LW** stratum  
302 during daytime condition, where oxygen levels increased after the extremely low levels within the OMZ, while at the  
303 onshore station St T3 it was much dimmer and during night condition. At the onshore station off  $29^\circ \text{ S}$  (St. L6), having a  
304 weaker and less extensive OMZ, the vertical distribution of abundance was similar. However, the abundance of copepods  
305 was lowest in this station (in about 69%) in comparison with stations off Iquique, in the core of the OMZ the percentage was  
306 between 5 to 3%.

307 DVM of Copepods was pronounced at onshore stations (Stations T3 and L6), but the strength of migration was higher overall  
308 at St. T3 off Iquique, as reflected by the migration indices (WMD and  $\Delta\text{DVM}$ ) (**Table 1**). The WMD of these taxa had a  
309 broad range (17–500 m), which varied significantly among copepods groups and stations, both in day and night samples ( $p$   
310  $< 0.05$ ) (**Fig. 3**). During the night, at the offshore station (St. T5) most Copepods exhibited normal DVM and they were  
311 concentrated mainly in the oxic surface strata (**OX-M**) and **OMZ-UB** (40-60 m) without interacting with the OMZ; except  
312 for Eucalanidae which concentrated deeper in the **OMZ-LC** stratum, associated with the lower core of the OMZ and  
313 showing a high  $\Delta\text{DVM}$  (225m). During the day these four groups of Copepods tended to remain deeper in the stratum  
314 associated with the lower core of the OMZ (**OMZ-UC**) and lower  $\text{O}_2$  gradient (**OMZ-LW**), except for small Copepods that  
315 remained at the **OMZ-UB** stratum with a smaller  $\Delta\text{WMD}$  (34 m). At the offshore stations (Stations T3 and L6) the DVM

316 was reverse in most Copepods, except for large Copepods (LC) which showed slightly normal DVM at St. L6 off 29°S. At  
317 night Copepods were concentrated deeper in the stratum associated with the lower core of OMZ (**OMZ-UC**) and lower O<sub>2</sub>  
318 gradient (**OMZ-LW**), particularly Eucalanidae with a strong DVM and high  $\Delta$ WMD of 440 m (St. T3) and 208 m (St. L6)  
319 and *Acartia* Copepods with 103 m (St. L6) (**Table 1**), whereas at St. L6 small Copepods (SC) were caught in abundance at  
320 the **OMZ-UB** stratum down to 82–90 m depth, respectively (**Fig. 3**). During the day, Copepods remained shallower than at  
321 night, although they concentrated at different depths. Small Copepods were in the oxic surface strata **OX-ML** (St. T3) and  
322 remained in the upper boundary of the OMZ (St. L6) without detectable DVM, as judging by the small difference between  
323 their day- and night-time distributions (ADV<sub>M</sub> ca. 4 m). Large Copepods (LC), as expected, showed a normal migration and  
324 stayed inside the OMZ, concentrated in the **OMZ-UC** stratum (St. L6) and **OMZ-UB** (St. T3). Finally, Eucalanidae, with a  
325 strong DVM tended to distribute in the **OMZ-UC** (St. T3) and the **OMZ UB** (St. L6) (**Fig. 3**).

326 Unlike copepods, the Euphausiids were more abundant at the onshore station L6 (<1%), where they reached up to  
327  $1683 \pm 473 \text{ ind. m}^{-2} \text{ d}^{-1}$ . The OMZ-UB stratum was the most abundant in this station, with a peak of abundance during the  
328 daytime, however no DVM was detectable, judging by the small difference between their day- and night-time distributions  
329 (**Fig. 3**). Off Iquique, also the highest abundance was in OMZ-UB stratum at night, but with a second peak in OMZ-LC  
330 stratum during daytime in both station (Sts. T3 and T5) (**Table S4 Supplemental Material**). The euphausiids appeared to  
331 perform a strong DVM in these stations (**Fig. 3**), with a vertical range between 236 and 56 m and a mean  $\Delta$ DVM of 181 m at  
332 T5 and at St. T3 between 222 and 73 m with a mean  $\Delta$ DVM of 149 m (**Table 1**).

333 Decapods larvae were more abundant at StT5 ( $428 \pm 132 \text{ ind. m}^{-2} \text{ d}^{-1}$ ) and were associated with the **OMZ-UB** stratum, where  
334 they performed a strong normal DVM with a vertical range between 120 and 30 m and a mean  $\Delta$ DVM of 90 m (**Table 1**). At  
335 the offshore station (St.T3), the surface peak of abundance was in the **OX-ML** stratum during the day and in the **OMZ-UB**  
336 layer at night, where they reached up to  $292 \pm 62 \text{ ind. m}^{-2} \text{ d}^{-1}$ , with a weak reverse DVM ( $\Delta$ DVM-7 m). Off Coquimbo (St.  
337 L6) they reached up to  $400 \pm 88 \text{ ind. m}^{-2} \text{ d}^{-1}$ , the **OMZ-UB** stratum was the most abundant, with a slight second peak in the  
338 OMZ-LW stratum during daytime, at this station the vertical range was between 70 and 48 m with a mean  $\Delta$ DVM of 22 m  
339 (**Fig. 3**).

340 The largest aggregation of Chaetognaths was at the onshore station St. L6 (~2%), where their abundances reached up to  
341  $4755 \pm 1038 \text{ ind. m}^{-2} \text{ d}^{-1}$ . The abundance and biomass of this group increased in the upper boundary of the OMZ (**OMZ-UB**)  
342 during day and night. No DVM was discernible for this group in this station, because of the slight difference between their  
343 day- and night-time distributions. By contrast, off Iquique they appeared to perform a strong DVM between the **OMZ-UB**  
344 and the **OMZ-UC** strata, as indicated by the migration indices (WMD- $\Delta$ DVM) (**Table 1**). However, at the onshore station  
345 (St. T3) they showed a reverse DVM.

346 The other main taxon, Annelida was more abundant at the onshore station St. L6, where their abundances reached up to  
347  $7395 \pm 847 \text{ ind. m}^{-2} \text{ d}^{-1}$  (**Table S4 Supplemental Material**). In the whole area, the highest of abundance was in the OMZ-UB,  
348 however a second peak of abundance was in the OMZ-LC during daytime at St T5 and T3 and during the night at St. L6. The

349 DVM of this group was high off Iquique with  $\Delta$ DVM of 145 m (St. T5) and 105 m (St. T3), while at St. L6 off Coquimbo no  
 350 DVM was discernible for this group.

### 351 3.3.3 Others groups with vertical distribution associated to OMZ UC

352 The remaining 19 groups constituted 11% (in St. T5) 17% (in St. T3) and 27% (in St. L6) in abundance. The DVM  
 353 behaviour was variable at each station, but in general it was Normal at St. T5 and reverse at Sts.T3-L6 (**Table 1**). These  
 354 groups clearly exhibited different daytime and night depths associated with the **OMZ core (OMZ UC-LC)**. Overall, they  
 355 tended to reside deeper by day and shallower by night in St. T5 than at the other sites (**Fig.3**).

### 356 3.4 Vertical distribution of zooplankton biomass

357 Estimates (mean  $\pm$  SD) of biomasses of the taxonomic groups integrated by depth strata are summarized in **Table 2**. These  
 358 data, averaged from day and night measurements, contrast with the numerical abundances, which were dominated by  
 359 copepods. In this case, the bulk of zooplankton biomass was dominated by different groups depending on Stations. In terms  
 360 of biomass, Copepods, Euphausiids, Decapods L. Chaetognaths, and Annelids accounted, more or less equally, for >84% in  
 361 the whole area (**Table 2**). At the stations less affected by the effect of OMZ the bulk of biomass was dominated by copepods  
 362 ~50% at St. T5 and ~40% at St. L6, while Decapods largely dominated the bulk of biomass at Station T3 (~40%), followed  
 363 by Copepods(19%) and Euphausiids (16 %). (**Table 2**).

364

365 **Table2.** Mean and Standard Deviation ( $\pm$ ) of integrated biomass (mg C m<sup>-2</sup>) by taxonomic groups identified and sorted by  
 366 ZooScan during daytime/ night-time conditions at three stations (T5, T3 and L6) sampled off northern Chile, during the  
 367 austral spring 2015. Mean  $\pm$  SD are from n=8for Stations T5 and T3, and n=4 for Station L6.

368

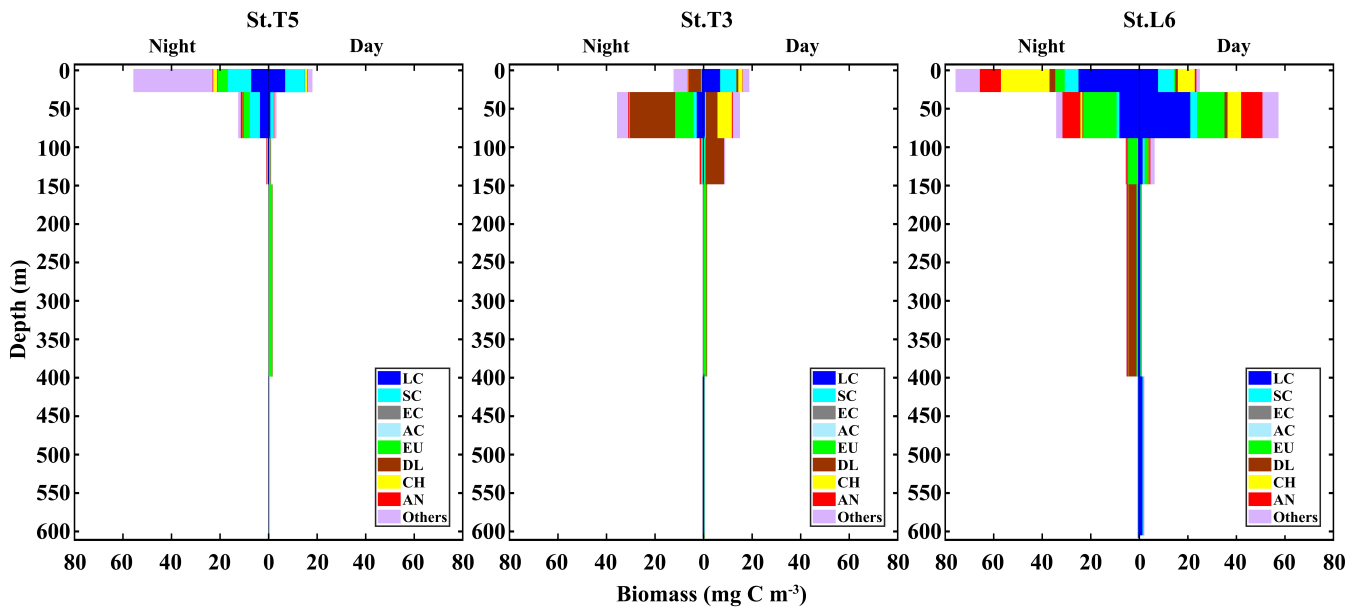

369 When assessing the day vs. night vertical distribution of taxonomic groups in terms of their contribution to biomass, different  
370 patterns arise compared to numerical abundance. In this case, we used 9 taxonomic categories to examine vertical  
371 distribution and DVM in terms of biomass: small Copepods (SC), large Copepods (LC), *Acartia* Copepods (AC),  
372 Eucalanidae Copepods (EC), , Euphausiids (EU), Decapod larve (DL), Chaetognaths (CH), Annelids and all the other taxa  
373 (**Fig. 4**). Contrasting with numerical abundance, the vertical distribution of biomass was more heterogeneously divided  
374 among taxonomic groups and DVM patterns vary strongly between stations. Small Copepods continue to dominate at the St.  
375 T5 (24%), with two peaks of biomass, a surface peak associated to the upper oxic layer (**OX-ML**) and OMZ-UB stratum  
376 during night condition, and a second peak associated to deeper stratum (OMZ-LW) during daytime. At the onshore Stations  
377 T3 and L6 the biomass had a similar vertical distribution but lower (~7%), at the Station T3 the peak of biomass was in the  
378 upper oxic layer (**OX-ML**) during daytime condition and then it decreases sharply within the **OMZ-UB** and within the OMZ  
379 core (**OMZ-UC** and **OMZ-LC**). This abrupt decrease in biomass coincides with the intense OMZ present at this station T3.  
380 The second peak of biomass during daytime was in deeper stratum (OMZ-LW), where oxygen conditions seem to be  
381 restored. Large Copepods dominate at the onshore St L6(30 %) where their biomass reached up to 1727.49±340.8mg C. m<sup>-2</sup>  
382 d<sup>-1</sup> (**Table 2**). A surface peak of biomass was associated to OMZ-UB stratum during daytime condition, and a second peak  
383 associated to deeper stratum (OMZ-LW) also during daytime. Off Iquique they were the second dominant group, with a  
384 surface peak in OX-ML stratum during night at St. T5 and daytime at St. T3, and a second peak in deeper stratum (OMZ-  
385 LW), during daytime in both stations (**Fig. 4**).The biomass of Eucalanidae and *Acartia* copepods were lower than the other  
386 copepods in the whole area, but in general Eucalanidae was associated to the deeper stratum.

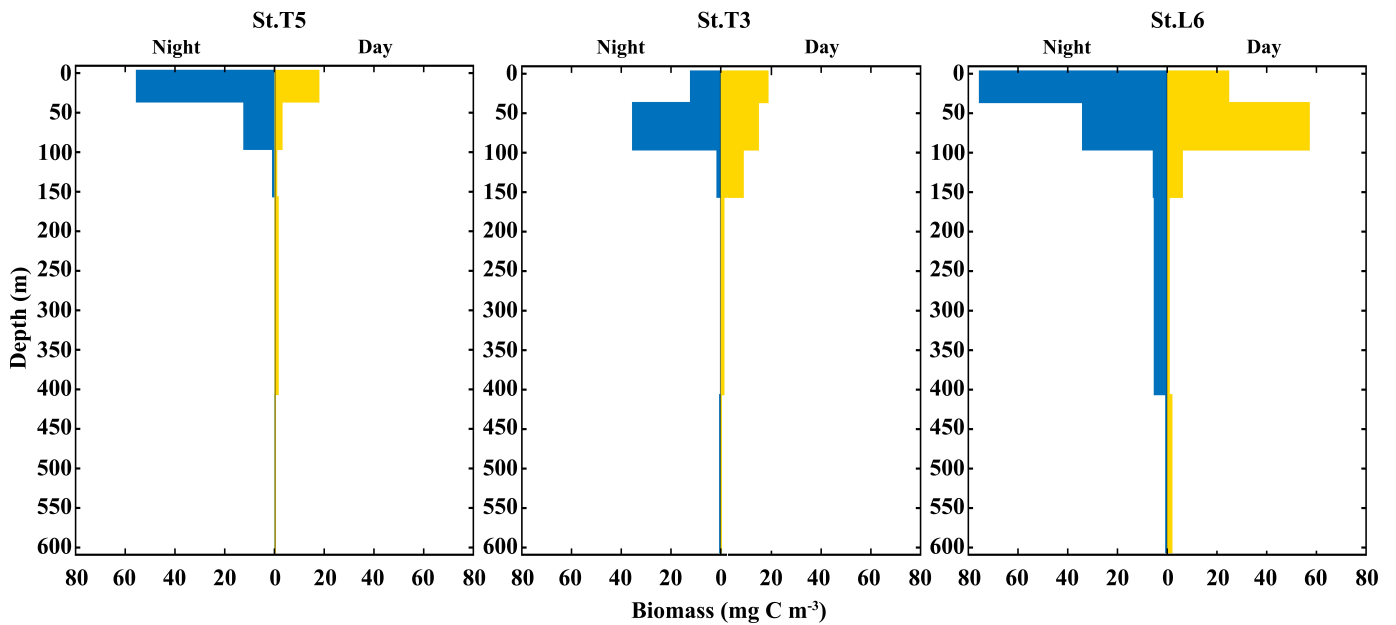

387 Following Copepods, Euphausiids were the second dominant group in term of biomass in the whole area. In general, their  
388 ascent from deep layers to the upper ones at night was also evidenced by increasing proportions of these group in the OMZ-  
389 UB stratum at night. The highest biomass was in St L6(19%) where reached up to  $1060.58 \pm 305.8 \text{ mg C. m}^{-2} \text{ d}^{-1}$ (**Table 2**). A  
390 surface peak of biomass was associated to OMZ-UB stratum during night condition, decreasing in the deep strata (**Fig. 4**).  
391 Across of the zonal section off Iquique two peak of biomass was in both stations. A surface peak was in OMZ-UB stratum  
392 during night condition followed by lower biomass within the OMZ core, then a second peak was in the OMZ-LC during  
393 daytime.

394 Decapod Larvae clearly dominated over copepods in the St. T3 (39%). The high biomass was in OMZ-UB stratum during  
395 night condition followed by lower biomass within the OMZ Core. At the St L6 also was a second peak of biomass in the  
396 OMZ-LC during night. Chaetognaths and Annelids were other groups with an important vertical movement of biomass  
397 between day and night across strata, and like other groups with two peaks of biomass. The high biomass was at St. L6 in  
398 both groups (**Fig. 4**).

399 Total added biomass of zooplankton revealed more clearly DVM behaviour of the whole zooplankton community (**Fig. 5**).  
400 The vertical distribution and daytime vs. Night-time variability of zooplankton biomass showed distinctive features  
401 associated with the OMZ structure, with significant differences ( $p < 0.05$ ) between strata for both daytime and night-time  
402 samplings, as based on the ANOSIM test ( $p < 0.05$ ). In the whole area most of the biomass was concentrated in a narrow band  
403 within the OX-ML and OMZ UB strata, associated with more oxygenated surface waters, with reduced values in deeper  
404 waters associated with the OMZ core, in special at the onshore station off Iquique (St. T3) (Fig.5). Overall, we observed that  
405 highest values of biomass were during the night at the shallower sampling stratum (Ox-ML) and in the subsurface during the  
406 day. There was also an important increase in biomass at the deepest stratum (OMZ-LW) during the daytime and night  
407 condition.

408  
 409 **Fig.4.** Daytime vs. Night-time vertical distribution of biomass of dominant taxonomic groups at 3 stations off northern Chile:  
 410 off Iquique (StationsT5 and T3) and off Coquimbo (StationL6). Data are from night and day replicated samples during two  
 411 consecutive days in the austral spring 2015. Values represent means from sampling size n=4 for St.T5 and St. T3, and n=2  
 412 for St. L6.

413  
 414 **Fig. 5.** Vertical distribution of total zooplankton biomass during daytime and night-time conditions at 3 stations off northern  
 415 Chile: off Iquique (StationsT5 and T3) and off Coquimbo (StationL6) during two consecutive days in the austral spring  
 416 2015.).

417 **3.4.1 Migrant biomass of the zooplankton taxa**

418 The migrant biomass of the zooplankton taxa and the rate of migration (RM), represented by the proportion of biomass (%)  
 419 being vertically moved daily from the upper 90 m are shown in **Table 3**. Most dominant groups showed a high rate of  
 420 migration as reflected in the RM. In terms of migrant biomass, Decapod larvae, Euphausiids, Decapods, Copepods and  
 421 Chaetognaths accounted for a large proportion of total migrant biomass (81%), although high estimates of migrant biomasses  
 422 were also associated with high standard deviations, indicating a strong variation among replicated samples (**Table 3**).  
 423 Presence of zero values in **Table 3** represents absence of a given taxonomic group in the upper 90 m layer or extremely low  
 424 values of biomass under both conditions' day and night, so that such groups did not contribute, or they had a non-significant  
 425 contribution to total migrant biomass.

426

427

428 **Table3.** Migrant biomass (mg C m<sup>-2</sup>) and rate of migration (RM) (%) for taxonomic groups of zooplankton sampled at  
 429 northern Chile at 3 stations: off Iquique (Stations T5 and T3) and off Coquimbo (Station L6) during the austral spring 2015.  
 430 RM represents the proportion (%) of migrant biomass with respect to total biomass found at night in the 0-90 m for a given  
 431 taxonomic group. SD= Standard deviation of the migrant biomass estimated from n=4 (St. T5 and St. T3) and n=2 (St. L6).

433

#### 434 **4 Discussion**

435 Studies on zooplankton DVM and the active transport of C mediated by zooplankton have been documented previously for  
436 the Pacific Ocean and for other areas of the world's ocean, as summarized in **Table 4**. However, downward C flux due to  
437 DVM in highly productive upwelling regions, such as northern Chile, which is also characterized by severe subsurface  
438 hypoxic conditions upon presence of a shallow OMZ, is still poorly understood. Some studies have shown that hypoxic  
439 conditions can interfere with DMV of many meso- and macrozooplankton species (Wishner *et al.*, 2013; Ekau *et al.*, 2010;  
440 Escribano *et al.*, 2009; Apablaza and Palma, 2006; Antezana, 2002; Escribano, 1998). These studies have shown that small  
441 differences in oxygen concentration can make a large difference for zooplankton behavior, physiology and adaptation  
442 (Wishner *et al.*, 2018; Kiko *et al.*, 2016; Seibel, 2011; Gonzalez and Quiñones, 2002; Escribano and McLaren, 1999).  
443 Therefore, it seems that the OMZ can play a very significant role influencing vertical distribution, DVM and ultimately the  
444 downward C flux mediated by zooplankton.

445 Our approach to assess downward C flux into the Oxygen Minimum Zone, based on estimates of the migrant biomass and  
446 our proposed migration indices, allowed us on one hand to examine the contribution that different zooplankton can have for  
447 vertical flux of C and hence export production, and in the other hand to assess zooplankton responses (e.g. vertical  
448 distribution and DVM performance) to changes in environmental conditions over the vertical gradient, such as temperature,  
449 water density and the abrupt changes in oxygenation levels. In this subtropical upwelling region, vertical gradients are much  
450 stronger than in temperate upwelling zones. For example, the coastal zone in this region is more stratified and with a very  
451 shallow OMZ (<50 m) with a weak seasonal signal and moderate upwelling throughout the year (Paulmier and Ruiz-Pino,  
452 2009; Fuenzalida *et al.*, 2009; Escribano *et al.*, 2004). This means that zooplankton must cope with hypoxic conditions  
453 during their entire life cycle, except for some species that may reside in near surface water (<30 m), such as *C. chilensis* and  
454 *C. brachiatus* which have been reported as mostly restricted to the upper layer without performing any substantial DVM  
455 (Escribano *et al.*, 2012, 2009; Escribano and Hidalgo, 2000; Escribano, 1998).

456 The vertical distribution and diurnal variability of zooplankton biomass seem to be disturbed by the OMZ, such that high  
457 biomass aggregates above the oxycline in a narrow band within the OX-ML and OMZ-UB layers, associated with more

458 oxygenated surface waters, whereas extremely low biomass reside in deeper waters, in particular within the OMZ core. This  
459 condition was more evident in the coastal station off Iquique (St. T3), characterized by the most intense OMZ in the whole  
460 study area. In the eastern tropical north Pacific, biomass distribution seemed different, exhibiting a secondary peak at depth  
461 during the daytime within the upper oxycline or OMZ core (Wishner *et al.*, 2013).

462 Regarding the estimates of biomass for each of the taxonomic groups, our approaches can certainly introduce variation,  
463 depending on selected regressions and conversion factors from highly diverse body shapes and body densities of the  
464 zooplankton taxa affecting the estimates of body area and volume, dry weight and C content. Various approaches have been  
465 adopted for converting sizes to body masses. For example, Lehet and Hernández-León (2009) provided some general  
466 regression equations for subtropical and Antarctic zooplankton describing the relationship between scanned area and body  
467 mass (C content). These authors also proposed two separate regressions for crustacean and gelatinous zooplankton, because  
468 of different body densities. In our study, we adopted more direct estimates of body masses by converting individual areas or  
469 volumes (from ZooScan) using published regressions for separate taxonomic groups. Also, in our samples there was a high  
470 diversity of taxonomic groups as identified by ZooScan, such that unique regressions for crustacean and gelatinous  
471 organisms may lead to strong biases in body mass estimates, because of high variability in C content, which is the key  
472 component of body mass needed to estimate C flux. Therefore, the use of taxa-specific conversion factors, as those detailed  
473 in our Table S3 (Supplemental Material) is strongly recommended.

474 Despite the apparently hostile oxygen-deficient habitat, associated with the OMZ, we found that most taxa were able to  
475 perform DVM in the upwelling zone withstanding severe hypoxia. Even, several zooplankton groups are strong migrants,  
476 exhibiting large DVM amplitude (~500 m). Among them, an important migrant group is comprised by the copepods  
477 Eucalanidae which have been described as even being able to enter the core of the OMZ, and then migrate downward to the  
478 lower limit of the OMZ, which is slightly more oxygenated (Hidalgo *et al.*, 2005). In our study however, their contribution to  
479 total migrant biomass was too small (ca. 0.4 mg C m<sup>-2</sup> d<sup>-1</sup>), as compared to the estimate made by Hidalgo *et al.*(2005). In  
480 fact, the migrant biomass and rate of migration of this group was non-significant when considering DVM between the upper  
481 90 m and below, suggesting a little or no contribution to downward flux of C for this group of copepods. However it seems  
482 that Eucalanidae remain below the oxycline or nearby the base of the oxycline day and night, as shown by their weighted  
483 mean depth (WMD) and therefore suggesting that they may still contribute to vertical flux by feeding at the base of the  
484 oxycline at night and then migrating into the OMZ during the day.

485 Other taxa, such as Euphausiids, *Acartia* spp., other copepods, Ctenophores, Decapods, Annelidae, Bryozoa L, Pteropods  
486 and Chaetognaths tended to concentrate their populations inside the OMZ core showing a strong link to the OMZ with  
487 important movement throughout the water column. Antezana (2010) showed that *E. mucronata*, an endemic and abundant  
488 euphausiid in the coastal upwelling zone off Chile, is a well-adapted species to vertically migrate into the core of the OMZ.  
489 In fact, the euphausiids studied here showed a large DVM amplitude (~250 m), descending into the core of the OMZ and  
490 below 250 m each day. In general, all strong migrants' taxa showed a strong interaction with the core of OMZ, remaining

491 there either temporarily or permanently during the day or night condition, contributing in this way to the release of C below  
 492 the thermocline, despite presence of hypoxic conditions.

493 Our estimates of DVM-mediated C flux showed that migrant biomass ( $958\pm778$  mg C m<sup>-2</sup> d<sup>-1</sup>) and C flux estimates  
 494 ( $71\pm64$ mg C m<sup>-2</sup> d<sup>-1</sup>) of the major taxa performing DVM, were greater than those reported for the Pacific Ocean, both in  
 495 oligotrophic, such as Hawaii, and mesotrophic waters, as the subarctic North Pacific(Steinberg *et al.*, 2008), and even greater  
 496 than that informed by Yebra *et al.* (2005) within eddies with enhanced biological production. Most of these previous  
 497 estimates however have not been done in regions with severe hypoxia or anoxia at mid water depths (e.g. Kiko *et al.*, 2016),  
 498 such as the highly productive upwelling region of the coastal zone off northern of Chile, where the oxygen concentrations  
 499 may fall below <1 μmol in the core of OMZ (Paulmier and Ruiz-Pino, 2009). Moreover, only few works have considered the  
 500 whole zooplankton community (**Table 4**). High productivity and strong aggregation of zooplankton in coastal areas of this  
 501 region (Escribano *et al.*, 2000; Escribano and Hidalgo, 2000) may promote greater amounts of migrant biomass. This  
 502 requires however that DVM should not be majorly constrained by presence of the OMZ and that most migrant taxa are  
 503 tolerant to low-oxygen. On the other hand, our estimates of downward C flux were substantially lower than previous ones  
 504 reported off northern Chile by Hidalgo *et al.* (2005) for *Eucalanus inermis* alone (14.1 mg C m<sup>-2</sup> d<sup>-1</sup>) and for copepods and  
 505 euphausiids by Escribano *et al.* (2009) (7200 mg C m<sup>-2</sup> d<sup>-1</sup>) (**Table 4**). Although, such previous estimates may be too high,  
 506 considering the level of primary production in the upwelling zone of Chile (~10000 mg C m<sup>-2</sup> d<sup>-1</sup>, the maximum estimated  
 507 value) (Daneri *et al.*, 2000), suggesting that previous works may have overestimated active transport of C. Although the  
 508 work of Escribano *et al.* (2009) was based on samples obtained with a Tucker Trawl net, which can be more efficient in  
 509 capturing large-sized zooplankton or macrozooplankton (Escribano *et al.*, 2007), as compared with the vertically towed  
 510 Multinet. This means that our estimates mainly based on mesozooplankton may not include the contribution of some  
 511 macrozooplankton, and therefore such values may be greater.

512

513 **Table 4.** Comparison of active transport of carbon (AC) (mg C m<sup>-2</sup> d<sup>-1</sup>) by vertically migratory taxa in Pacific Ocean. Diel  
 514 vertically migratory taxa (DVM), productivity primary (PP) (mg C m<sup>-2</sup> d<sup>-1</sup>), migrant biomass (MB) (mg C m<sup>-2</sup>), respiratory  
 515 loss (R) (mg C m<sup>-2</sup> d<sup>-1</sup>), faecal pellets production (F) (mg C m<sup>-2</sup> d<sup>-1</sup>) and mortality (M) (mg C m<sup>-2</sup> d<sup>-1</sup>). Where provided by  
 516 authors, estimated passive export (POC) is listed. Fluxes refer to carbon export beneath the epipelagic zone (150–200 m  
 517 depth, depending on the study) in mg C m<sup>-2</sup>d<sup>-1</sup>

518 Differences of our estimates with previous works may also be accounted by strong variability of zooplankton abundance in  
519 the upwelling zone. In fact, our estimates of migrant biomasses of the different taxonomic groups based on 2 days of  
520 sampling and two replicates for each condition (day and night) are strongly variables, as shown by the standard errors in  
521 **Table 3** which can be as much as 100% from the mean value. Therefore, comparisons must take caution upon strong time-  
522 space variation when assessing zooplankton abundance. Nevertheless, a strong spatial variation in migrant biomass was also  
523 evident when comparing the three sampling stations. For instance, St. L6 had more biomass than the other stations, but much  
524 less migrant biomass, and thus a very low contribution to vertical flux of C by DVM. At station L6, large copepods,  
525 Euphausiids, Annelids and Chaetognaths largely contributed to biomass, although they did not show significant DVM.  
526 Therefore, species composition and their DVM behaviour appear as a key factor to determine the downward flux of C  
527 mediated by active transport.

528 Even although the OMZ did not greatly prevent DVM migration, zooplankton behaviour appeared disrupted or exhibited  
529 reversed patterns, depending on vertical distribution of OMZ and on the taxonomic group being considered. This behaviour  
530 was more evident in the onshore stations (Stations T3 and L6), but in particular in the station off Iquique (St. T3) that also  
531 showed a higher migration rate (60%). According to Ekau *et al.* (2010), other indirect effects could also be caused by the  
532 hypoxia conditions, such as changes in prey availability, prey size or predation risk, as well as changes in species

533 composition, the strength of which depends on the duration and intensity of the hypoxic events. This could explain why  
534 individuals within a single population can perform reverse, normal, or non DVM, apparently depending on the more  
535 important source of mortality: predation by nocturnal feeding, normally migrating carnivorous zooplankton, or visually  
536 hunting planktivorous fish (Ohman, 1990). These kind of DVM behaviors can only be better assessed and understood when  
537 looking at the population level, although again time-space variation in zooplankton abundance in a highly heterogeneous  
538 upwelling zone should be kept in mind.

539 Concerning C fluxes, our estimates of active transport of carbon by zooplankton were greater than estimates of passive C  
540 sinking obtained off northern Chile at 60 m depth off Antofagasta (23°S) by Gonzalez *et al.* (1998) based on sediment traps  
541 (125 to 176 mg C m<sup>-2</sup> d<sup>-1</sup>). Regarding the question on how efficient is active C transport mediated by DVM, we obtained  
542 satellite-based (<http://science.oregonstate.edu.ocean.productivity>) estimates of net primary production (monthly means for  
543 November-December 2015) for the coastal area (Stations T3 and L6) and the coastal transition zone (Station T5), averaged  
544 for the months of November and December 2015. Our estimates of downward C flux represented a mean of ca. 4 % of  
545 export of Carbon resulting from net primary production in the upwelling region, estimated in the range of 1500-3500 mg C  
546 m<sup>-2</sup> d<sup>-1</sup> (**Table 5**). If we consider this is accounted only by mesozooplankton, then an important fraction of freshly produced  
547 C might be taken downward by zooplankton, and this DVM-mediated C flux ought to be taken into account when and  
548 analysing and modelling the C budget in the upwelling zone.

549

550 **Table5.** Mean net primary production rate and estimates of daily downward C flux due to passive sinking and mediated by  
 551 diel vertical migration (DVM) of mesozooplankton at three stations (T5, T3 and L6) in the coastal upwelling region off  
 552 northern Chile during the austral spring 2015. Primary production represents satellite-based estimates of monthly mean  
 553 (November–December 2015) at the 3 sampling stations. Passive C flux is a mean value estimated from sediment traps by  
 554 González et al. (2000) off Antofagasta (northern Chile, 23 °S) for January 1997. Total biomass and epipelagic biomass are  
 555 mean observed values from day-night conditions after 2 consecutive days of sampling.

556

Station	T5	T3	L6	Mean ± SD
Primary Production mg C m <sup>-2</sup> d <sup>-1</sup>	1500	3500	3500	2833 ± 1155

## 558 5. Conclusions

559 In the coastal upwelling zone off northern Chile the presence of a subsurface oxygen minimum zone (OMZ) can impose an  
 560 important constraint for diel vertical migration of zooplankton and so influencing the downward C export mediated by  
 561 zooplankton. We found that most of the zooplankton biomass aggregates above the oxycline, associated with more  
 562 oxygenated surface waters and this was evident upon presence of a more intense OMZ. Some taxonomic groups however,  
 563 were found closely associated with the OMZ and several taxa were able to perform DVM in the upwelling zone withstanding  
 564 severe hypoxia. Also strong migrants, such as large sized copepods and copepod of the group Eucalanidae and Euphausiids,  
 565 can exhibit a large migration amplitude (~500 m), remaining either temporarily or permanently during the day or night  
 566 condition within the core of the OMZ, and so contributing to the release of C below the oxycline (and thermocline). Our  
 567 estimates of DVM-mediated C flux suggested that a mean migrant biomass of 957.7 mg C m<sup>-2</sup> d<sup>-1</sup> may contribute with about  
 568 71.1 mg C m<sup>-2</sup> d<sup>-1</sup> to the OMZ system through respiration, mortality, and C excretion a at depth, accounting for ca, 4% of the  
 569 net primary production, and so implying the existence of a efficient mechanism to incorporate freshly produced C into the  
 570 OMZ. This downward C flux mediated by zooplankton DVM is however strongly depending on the taxonomic structure due

571 to variable migration amplitude and DVM behavior. These estimates should also consider the strong temporal-spatial  
572 variation in zooplankton abundance in the upwelling zone for comparison purposes.

573

#### 574 **Acknowledgements**

575 This work has been funded the Millennium Institute of Oceanography (IMO) (Grant IC 120019) and the CONICYT Project  
576 Grant No PCHA 21160038 through which the LowpHox I cruise was conducted. We are thankful to two anonymous  
577 reviewers who greatly contributed to improve the work. We are also grateful to D. Toledo for assistance during field work.  
578 The work is a contribution to IMBeR Program and SCOR EBUS WG 155.
