22 **ABSTRACT**

23 In this study we have analyzed sediment trap time series from five tropical sites to assess seasonal
24 variations in concentrations and fluxes of long-chain diols (LCDs) and associated proxies with emphasis
25 on the Long chain Diol Index (LDI) temperature proxy. For the tropical Atlantic, we observe that
26 generally less than 2 % of LCDs settling from the water column are preserved in the sediment. The
27 Atlantic and Mozambique Channel traps reveal minimal seasonal variations in the LDI, similar to the
28 two other lipid-based temperature proxies TEX_{86} and $U^{K'}_{37}$. In addition, annual mean LDI-derived
29 temperatures are in good agreement with the annual mean satellite-derived sea surface temperatures
30 (SSTs). In contrast, the LDI in the Cariaco Basin shows larger seasonal variation, as do the TEX_{86} and
31 $U^{K'}_{37}$. Here, the LDI underestimates SST during the warmest months, which is likely due to summer
32 stratification and the habitat depth of the diol producers deepening to around 20 to 30 m. Surface
33 sediment LDI temperatures in the Atlantic and Mozambique Channel compare well with the average
34 LDI-derived temperatures from the overlying sediment traps, as well as with decadal annual mean SST.
35 Lastly, we observed large seasonal variations in the Diol Index, as indicator of upwelling conditions, at
36 three sites: in the Eastern Atlantic potentially linked to Guinea Dome upwelling, in the Cariaco Basin
37 likely caused by seasonal upwelling, and in the Mozambique Channel where Diol Index variations may
38 be driven by upwelling from favorable winds and/or eddy migration.

39

40 **1. Introduction**

41 Several proxies exist for the reconstruction of past sea surface temperature (SST) based on lipids. The
42 $U^{K'}_{37}$ is one of the most applied proxies and is based on the unsaturation of long-chain alkenones (LCAs),
43 which are produced by phototrophic haptophyte algae, mainly the cosmopolitan *Emiliania huxleyi*
44 (Volkman et al., 1980; Brassell et al., 1986; Prahl and Wakeham, 1987; Conte et al., 1994). This index
45 exhibits a strong positive correlation with SST (Müller et al., 1998; Conte et al., 2006). Another widely
46 used organic paleotemperature proxy is the TEX_{86} , as originally proposed by Schouten et al. (2002),
47 based on the relative distribution of archaeal membrane lipids, i.e. glycerol dialkyl glycerol tetraethers
48 (GDGTs), and in the marine realm are mainly thought to be derived from the phylum Thaumarchaeota.
49 Schouten et al. (2002) showed that the TEX_{86} index measured in marine surface sediments is correlated
50 with SST, and since then its application in paleoenvironmental studies has increased (see e.g. review by
51 Tierney, 2014). However, research showed that despite their highest abundance being recorded in the
52 upper 100 m of the water column, Thaumarchaeota can be present down to 5000 m depth (Karner et al.,
53 2001; Herndl et al., 2005). Accordingly, GDGTs may be found in high concentrations below 100 m
54 depth (e.g., Sinninghe Damsté et al., 2002; Wuchter et al., 2005) and several studies have indicated that
55 TEX_{86} might be more reflective of subsurface temperatures in some regions (e.g., Huguet et al., 2007;
56 Lopes dos Santos et al., 2010; Kim et al., 2012; 2015; Schouten et al., 2013; Chen et al., 2014; Tierney
57 et al., 2017; see Zhang and Liu, 2018 for review).

58 Most recently a SST proxy based on the distribution of long-chain diols (LCDs), called the Long-chain
59 Diol Index, or LDI was proposed (Rampen et al., 2012). This index is a ratio of 1,13- and 1,15-diols
60 (i.e., alcohol groups at position C-1 and C-13 or C-15), and the analysis of globally distributed surface
61 sediments revealed that this index strongly correlates with SST. Since then, the index has been applied
62 in several paleoenvironmental studies (e.g., Naafs et al., 2012; Lopes dos Santos et al., 2013; Jonas et
63 al., 2017; Warnock et al., 2017). However, large gaps still remain in the understanding of this proxy.
64 The largest uncertainty is that the main marine producer of LCDs is unknown. Although these diols have
65 been observed in cultures of certain marine eustigmatophyte algae (e.g. Volkman et al., 1992; 1999;
66 Méjanelle et al., 2003; Rampen et al., 2014b), the LCD distributions in cultures are different from those

67 observed in marine sediments. Furthermore, Balzano et al. (2018) combined lipid analyses with 18S
68 rRNA gene amplicon sequencing on suspended particulate matter (SPM) and did not find a significant
69 direct correlation between LCD concentrations and sequences of known LCD-producers. Rampen et al.
70 (2012) observed the strongest empirical relation between surface sediment derived LDI values and SSTs
71 for autumn and summer, suggesting that these are the main growth seasons of the source organisms.
72 Moreover, the strongest correlation was also observed for the upper 20 m of the water column,
73 suggesting that the LCDs are likely produced by phototrophic algae which thrive in the euphotic zone.
74 Nevertheless, LDI-temperatures based on surface sediments reflect an integrated signal of many years,
75 which complicates the interpretation of the LDI in terms of seasonal production and depth of export
76 production.

77 One way of resolving seasonality in LCD flux and LDI is to analyze time series samples from sediment
78 traps that continuously collect sinking particles in successive time intervals over periods of a year or
79 more. Such studies have been carried out for the $U^{K'_{37}}$ as well as for the TEX_{86} and associated lipids
80 (e.g., Müller and Fischer, 2001; Wuchter et al., 2006; Huguet et al., 2007; Fallet et al., 2011; Yamamoto
81 et al., 2012; Rosell-Melé and Prahl, 2013; Türich et al., 2013). However, very few studies have been
82 done for LCDs. Villanueva et al. (2014) carried out a sediment trap study in Lake Challa (East Africa)
83 and Rampen et al. (2008) in the upwelling region off Somalia. The latter study showed that 1,14-diols,
84 produced by *Proboscia* diatoms strongly increased early in the upwelling season in contrast to 1,13- and
85 1,15-diols and thus can be used to trace upwelling. However, neither of these sediment trap studies have
86 evaluated the LDI.

87 In this study, we assess seasonal patterns of the LDI for sediment trap series at five sites, i.e., in the
88 Cariaco Basin, the Mozambique Channel and three sites in the tropical North Atlantic and compared the
89 LDI values to satellite-derived SST, as well as results obtained for other temperature proxies, i.e. the
90 TEX^H_{86} and $U^{K'_{37}}$. Moreover, for the Atlantic and Mozambique Channel, we compare the sediment trap
91 proxy signals with those preserved in the underlying sediments, after settling and burial. Finally, we
92 assess the applicability of the Diol Index, based on 1,14-diols produced by *Proboscia* diatoms
93 (Sinninghe Damsté et al., 2003), as tracer of upwelling and/or productivity in these regions.

94 **2. Materials and methods**

95 **2.1 Study sites and sample collection**

96 **2.1.1 Tropical North Atlantic**

97 The ocean current and wind patterns of the tropical Atlantic are mostly determined by the seasonal
98 latitudinal shift of the intertropical convergence zone (ITCZ; Figure 1). The ITCZ migrates southward
99 during boreal winter, and northward during boreal summer. During summer, the south-east trade winds
100 prevail, whereas during winter the north-east trade winds intensify. The north-east trade winds drive the
101 North Equatorial Current (NEC) which flows westward. South of the NEC, the North Equatorial
102 Countercurrent (NECC) flows towards the east (Stramma and Schott, 1999). The South Equatorial
103 Current (SEC) flows westward and branches off in the north Brazil Current (NBC; Stramma and Schott,
104 1999). When the ITCZ is in the north, the NBC retroflects off the South American coast, and is carried
105 eastward into the NECC, and thus into the western tropical Atlantic (e.g., Richardson and Reverdin,
106 1987). North of the NBC, the Guiana Current (GC) disperses the outflow from the Amazon River
107 towards the Caribbean Sea. (Müller-Karger et al., 1988; 1995). However, during boreal summer the
108 NBC may retroflect, carrying the Amazon River plume far into the western Atlantic (e.g., Lefèvre et al.,
109 1998; Müller-Karger et al., 1998; Coles et al., 2013). In fact, every late summer/autumn, the Amazon
110 River outflow covers around 2×10^6 km² of the western North Atlantic, and the river delivers
111 approximately half of all freshwater input into the tropical Atlantic (see Araujo et al., 2017 and
112 references therein).

113 The eastern tropical North Atlantic is characterized by upwelling caused by the interaction between the
114 trade winds and the movement of the ITCZ. Cropper et al. (2014) measured upwelling intensity along
115 the NW African coastline between 1981 and 2012, in terms of wind speed, SST and other meteorological
116 data. They recognized three latitudinal zones: weak permanent annual upwelling north of 26° N, strong
117 permanent upwelling between 21° and 26° N and seasonal upwelling between 12° and 19° N related to
118 the seasonal migration of the trade winds. Southeast of Cape Verde, large-scale cyclonic circulation
119 forms the Guinea Dome (GD; Fig. 1), which centers around 10° N, 22° W (Mazeika, 1967), i.e., close to
120 mooring site M1. The GD is a thermal upwelling dome, formed by near-surface flow fields associated

121 with the westward NEC, the eastward NECC and the westward North Equatorial Undercurrent (NEUC)
122 (Siedler et al., 1992). It forms a cyclonic circulation as a result of the eastward flowing NECC and the
123 westward flowing NEC (Rossignol and Meyrueis, 1964; Mazeika, 1967). The GD develops from late
124 spring to late fall due to the northward ITCZ position and the resulting Ekman upwelling, but shows
125 significant interannual variability (Siedler et al., 1992; Yamagata and Iizuka, 1995; Doi et al., 2009)
126 judging from general ocean circulation models. According to Siedler et al. (1992), upwelling is most
127 intense between July and October when the ITCZ is in the GD region and the NECC is strongest.

128 At three sites, we analyzed five sediment trap series along a longitudinal transect in the North Atlantic
129 ($\sim 12^\circ$ N) to determine seasonal variations in the LDI. This transect has been studied previously for
130 Saharan dust deposition in terms of grain sizes (van der Does et al., 2016), as the tropical North Atlantic
131 receives approximately one third of the wind-blown Saharan dust (e.g., Duce et al., 1991; Stuut et al.,
132 2005), which might potentially act as fertilizer because of the high iron levels (e.g., Martin and
133 Fitzwater, 1988; Korte et al., 2017; Guirreiro et al., 2017; Goudie and Middleton, 2001 and references
134 therein). Furthermore, Korte et al. (2017) assessed mass fluxes and mineralogical composition,
135 Guerreiro et al. (2017) measured coccolith fluxes for two of the time series, while Schreuder et al.
136 (2018a; 2018b) measured long-chain *n*-alkanes, long-chain *n*-alkanols and fatty acids, and levoglucosan
137 for the same sediment trap samples and surface sediments as analyzed in this study.

138 At site M1 (12.00° N, 23.00° W), the sediment trap, referred to as M1U, was moored at a water depth
139 of 1150 m (Fig. 1). This mooring is located in the proximity of the Guinea Dome, and might therefore
140 potentially be influenced by seasonal upwelling. At station M2 (13.81° N, 37.82° W), two sediment
141 traps were recovered, i.e., an ‘upper’ (M2U) trap at a water depth of 1235 m, and a ‘lower’ (M2L) trap
142 at a depth of 3490 m. Lastly, at mooring station M4 (12.06° N, 49.19° W), also an upper and lower trap
143 series were recovered and analyzed (M4U and M4L), at 1130 and 3370 m depth, respectively. This
144 mooring site may seasonally be affected by Amazon River discharge (van der Does et al., 2016; Korte
145 et al., 2017; Guirreiro et al., 2017; Schreuder et al., 2018a). All sediment traps were equipped with 24
146 sampling cups, which sampled synchronously over 16-day intervals from October 2012 to November

147 2013, using HgCl_2 as a biocide and borax as a pH buffer to prevent in situ decomposition of the collected
148 material.

149

150 **2.1.2 Mozambique Channel**

151 The Mozambique Channel is located between Madagascar and Mozambique and is part of the Agulhas
152 Current system hugging the coast of South Africa (Lutjeharms, 2006). The Agulhas Current system is
153 an important conveyor in the transport of warm and salty waters from the Indian to the Atlantic Ocean
154 (Gordon, 1986; Weijer et al., 1999; Peeters et al., 2004). The northern part of the channel is also
155 influenced by the East African monsoon winds (Biaostoch and Krauss, 1999; Sætre and da Silva, 1982;
156 Malauene et al., 2014). Between September and March, these winds blow from the northeast, parallel
157 to the Mozambique coastline, favoring coastal upwelling. Additionally, the Mozambique Channel is
158 largely influenced by fast-rotating, mesoscale eddies which migrate southward towards the Agulhas
159 region. Using satellite altimetry, Schouten et al. (2003) observed on average 4 to 6 eddies, ca. 300 km
160 in diameter, propagating yearly from the central Mozambique Channel (15° S) toward the Agulhas area
161 (35° S) between 1995 and 2000. Seasonal upwelling occurs off Northern Mozambique (between ca. 15°
162 and 18° S) (Nehring et al., 1987; Malauene et al., 2014), from August to March with a dominant period
163 of about two months although periods of one to four weeks have also been observed (Malauene et al.,
164 2014).

165 The sediment trap was moored at 16.8° S and 40.8° E, at a water depth of 2250 m (Fig. 1; Fallet et al.,
166 2010, 2011) and of the same type as used for the North Atlantic transect. We analyzed the LCD proxies
167 for two respective time intervals: the first interval covers ca. 3.5 years, from November 2003 to
168 September 2007, with a sampling interval of 21 days. The second interval covers another year, between
169 February 2008 and February 2009, with a sampling interval of 17 days. Previously, Fallet et al. (2011)
170 published foraminiferal, U^{K}_{37} and TEX_{86} records for the first time interval, and the organic carbon
171 content for the follow-up time series. For further details on the deployments and sample treatments, we
172 refer to Fallet et al. (2011, 2012). The two surface sediments are located across the narrowest transect

173 between Mozambique and Madagascar, and were analyzed for U^{K}_{37} and TEX_{86} by Fallet et al. (2012)
174 and for LCDs by Lattaud et al. (2017b).

175

176 **2.1.3 Cariaco Basin**

177 The Cariaco Basin is one of the largest marine anoxic basins (Richards, 1975), located on the continental
178 shelf of Venezuela. The basin is characterized by permanent stratification and strongly influenced by
179 the migration of the intertropical convergence zone (ITCZ). During late autumn and winter, the ITCZ
180 migrates to the south which results in decreased precipitation and trade wind intensification which in
181 turn induces upwelling and surface water cooling. This seasonal upwelling is a major source of nutrients
182 that leads to strong phytoplankton growth along the Venezuelan coast (e.g., Müller-Karger et al., 2001;
183 Thunell et al., 2007). Between August and October, the ITCZ moves northward again, resulting in a
184 rainy season and diminishing of the trade winds inhibiting upwelling. During this wet season the
185 contribution of terrestrially derived nutrients is higher. Due to the prevalent anoxic conditions in the
186 basin, there is no bioturbation which has resulted in the accumulation of laminated sediments which
187 provide excellent annually to decadal resolved climate records (e.g., Peterson et al., 1991; Huguen et
188 al., 1996; 1998). Moreover, in November 1995, a time series experiment started to facilitate research on
189 the link between biogeochemistry and the downward flux of particulate material under anoxic and
190 upwelling conditions (Thunell et al., 2000). This project (CARIACO;
191 <http://imars.marine.usf.edu/cariaco>) involved hydrographic cruises (monthly), water column chemistry
192 measurements and sediment trap sampling (every 14 days). One mooring containing four automated
193 sediment traps (Honjo and Doherty, 1988) was deployed at 10.50° N and 64.67° W, at a bottom depth
194 of around 1400 m. These traps were moored at 275 m depth, just above the oxic/anoxic interface (Trap
195 A), 455 m (Trap B), 930 m (Trap C) and 1255 m (Trap D). All traps contain a 13-cup carousel which
196 collected sinking particles over 2 weeks, and were serviced every half year. For further details on trap
197 deployment and recovery, and sample collection, storage and processing we refer to Thunell et al. (2000)
198 and Goñi et al. (2004). In addition to the sediment trap sampling, the primary productivity of the surface
199 waters was measured every month using ^{14}C incubations (Müller-Karger et al., 2001; 2004). For this

200 study, we investigated two periods, i.e., May 1999–May 2000 and July 2002–July 2003 for Traps A and
201 B. These years include upwelling and non-upwelling periods, as well as a disastrous flooding event in
202 December 1999 (Turich et al., 2013). Turich et al. (2013) identified the upwelling periods, linked to the
203 migration of the ITCZ, as indicated by decreasing SST in the CTD (temperature at -1 m water depth)
204 and satellite-based measurements (indicated by grey boxes in figures 8 and 10), and shoaling of the
205 average depths of primary production and increased primary production. Moreover, Turich et al. (2013)
206 evaluated the $U^{K_{37}}$ and TEX_{86} proxies for the same two time series for which we analyzed the LCD
207 proxies.

208

209 **2.2 Instrumental data**

210 Satellite SST, precipitation and wind speed time series of the M1, M2 and M4 moorings in the Atlantic
211 derive from Guerreiro et al. (2017 and in revision) who retrieved these data from the Ocean Biology
212 Processing Group (OBPG, 2014) (Frouin et al., 2003), the Goddard Earth Sciences Data and Information
213 Services Center (2016) (Huffman et al., 2007; Xie and Arkin, 1997) and NASA Aquarius project (2015a;
214 2015b) (Lee et al., 2012) (see supplement of Guerreiro et al., 2017 for detailed references). The SST and
215 Chlorophyll *a* time series data for the Mozambique Channel were adapted from Fallet et al. (2011), who
216 retrieved these data from the Giovanni database (for details see Fallet et al., 2011). Surface sediment
217 proxy temperatures were compared to annual mean SST estimates derived from the World Ocean Atlas
218 (2013) (decadal averages from 1955 to 2012; Locarnini et al., 2013). Sea surface temperature data for
219 the Cariaco Basin were adopted from Turich et al. (2013) and combined with additional CTD
220 temperatures from the CARIACO time series data base for the depths of 2, 5, 10, 15 and 20 m
221 (<http://www.imars.usf.edu/CAR/index.html>); CARIACO time series composite CTD profiles; lead
222 principal investigator: Frank Müller-Karger).

223

224 **2.3 Lipid extraction**

225 **2.3.1 Tropical North Atlantic**

226 The 120 sediment trap samples were sieved through a 1 mm mesh wet-split into five aliquots (van der
227 Does et al., 2016), of which one was washed with Milli-Q water, freeze-dried and homogenized for
228 chemical analysis (Korte et al., 2017). For organic geochemistry, sub-aliquots (by weight) were
229 extracted as described by Schreuder et al. (2018a). Shortly, ca. 100 mg dry weight of sediment trap
230 residue, and between 1.5 and 10 g of dry weight of surface sediment were extracted by ultrasonication
231 using a mixture of dichloromethane:methanol (DCM:MeOH) (2:1; v/v), and dried over a Na₂SO₄
232 column. For quantification of LCDs, LCAs and GDGTs, we added the following internal standards to
233 the total lipid extracts (TLEs): 2.04 µg C₂₂ 7,16-diol (Rodrigo-Gamiz et al., 2015), 1.50 µg 10-
234 nonadecanone (C_{19:0} ketone) and 0.1 µg C₄₆ GDGT (Huguet et al., 2006), respectively. Subsequently,
235 the TLEs were separated into apolar (containing *n*-alkanes), ketone (containing LCAs) and polar
236 (containing LCDs and GDGTs) fractions over an activated (2h at 150 °C) Al₂O₃ column by eluting with
237 hexane/DCM (9:1; v/v), hexane/DCM (1:1; v/v) and DCM/MeOH (1:1; v/v), respectively. The apolar
238 fractions were analyzed by Schreuder et al. (2018a) for *n*-alkanes. Polar fractions were split for GDGT
239 (25 %) and LCD (75 %) analysis. The LCD fraction was silylated by the addition of BSTFA (*N,O*-
240 bis(trimethylsilyl)trifluoroacetamide) and pyridine, and heating at 60 °C for 20 min, after which ethyl
241 acetate was added prior to analysis. The ketone fraction was also dissolved in ethyl acetate, and analyzed
242 by GC and GC/MS. The GDGT fraction was dissolved in hexane:isopropanol (99:1, v/v), filtered
243 through a 0.45 µm polytetrafluoroethylene (PTFE) filter and analyzed by HPLC-MS.

244

245 **2.3.2 Mozambique Channel**

246 Aliquots of the sediment trap samples from the Mozambique Channel were previously extracted and
247 analyzed by Fallet et al. (2011) and Fallet et al. (2012), respectively. The sediment trap material was
248 extracted by ultrasonication using a mixture of DCM/MeOH (2:1; v/v), dried over Na₂SO₄, and
249 separated into apolar, ketone and polar fractions via alumina pipette column chromatography, by eluting
250 with hexane/DCM (9:1; v/v), hexane/DCM (1:1; v/v) and DCM/MeOH (1:1; v/v), respectively. These

251 existing polar fractions of the sediment trap material were silylated (as described above), dissolved in
252 ethyl acetate and re-analyzed for LCDs by GC-MS. Since no record was kept of the aliquoting of extracts
253 and polar fractions, we report the results in relative abundance rather than concentrations and fluxes of
254 diols.

255 **2.3.3 Cariaco Basin**

256 Sediment trap material was extracted as described by Turich et al. (2013). Briefly, 1/16 aliquots of the
257 trap samples were extracted by means of Bligh-Dyer extraction with sonication using a phosphate buffer
258 and a trichloroacetic acid (TCA) buffer, after which the extracts were separated by adding 5 % NaCl in
259 solvent-extracted distilled deionized water, and the organic phase was collected and the aqueous phase
260 was extracted two more times. The extracts were pooled and dried over Na₂SO₄ and separated by means
261 of Al₂O₃ column chromatography, eluting with hexane:DCM (9:1; v/v), DCM:MeOH (1:1; v/v) and
262 MeOH. For this study, the DCM:MeOH (1:1; v/v) fraction was silylated (as described above), dissolved
263 in ethyl acetate, and analyzed for LCDs using GC-MS. Similar to the Mozambique Channel samples,
264 no record was kept of the aliquoting of extracts and polar fractions, and thus we report the results in
265 relative abundance.

266 **2.4 Instrumental analysis**

267 **2.4.1 GDGTs**

269 The GDGT fractions of the surface sediments and sediment traps SPM samples of the tropical North
270 Atlantic were analyzed for GDGTs by means of Ultra High Performance Liquid Chromatography Mass
271 Spectrometry (UHPLC-MS). We used an Agilent 1260 HPLC, which is equipped with an automatic
272 injector, interfaced with a 6130 Agilent MSD, and HP Chemstation software according to Hopmans et
273 al. (2016). Compound separation was achieved by 2 silica BEH HILIC columns in tandem (150 mm x
274 2.1 mm; 1.7 μm; Waters Acquity) in normal phase, at 25 °C. GDGTs were eluted isocratically for 25
275 min with 18 % B, followed by a linear gradient to 35 % B in 25 minutes and finally a linear gradient to
276 100 % B in the last 30 min. A = hexane; B = hexane:isopropanol (9:1; v/v). The flow rate was constant
277 at 0.2 mL min⁻¹, and the injection volume was 10 μL. The APCI-MS conditions are described by

278 Hopmans et al. (2016). Detection and quantification of GDGTs was achieved in single ion monitoring
279 (SIM) mode of the protonated molecules ($[M+H]^+$) of the GDGTs. We used a mixture of crenarchaeol
280 and the C₄₆ GDGT (internal standard) to assess the relative response factor, which was used for
281 quantification of the GDGTs in the samples (c.f. Huguet et al., 2006).

282 Sea surface temperatures were calculated by means of the TEX₈₆^H as defined by Kim et al. (2010), which
283 is a logarithmic function of the original TEX₈₆ index (Schouten et al., 2002):

$$284 \quad \text{TEX}_{86}^H = \log \frac{[\text{GDGT-2}] + [\text{GDGT-3}] + [\text{Cren}']}{[\text{GDGT-1}] + [\text{GDGT-2}] + [\text{GDGT-3}] + [\text{Cren}']} \quad [1]$$

285 where the numbers indicate the number of cyclopentane moieties of the isoprenoid GDGTs, and *Cren'*
286 reflects an isomer of crenarchaeol, i.e. containing a cyclopentane moiety with a *cis* stereochemistry
287 (Sinninghe Damsté et al., 2018). The TEX₈₆^H values were translated to SSTs using the core-top
288 calibration of Kim et al. (2010):

$$289 \quad \text{SST} = 68.4 \times \text{TEX}_{86}^H + 38.6 \quad [2]$$

290 The Branched Isoprenoid Tetraether (BIT) index is a proxy for the relative contribution of terrestrial
291 derived organic carbon (Hopmans et al., 2004). We have calculated the modified version as reported by
292 de Jonge et al. (2014; 2015) which is based on the original index as proposed by Hopmans et al. (2004),
293 but includes the 6-methyl brGDGTs:

$$294 \quad \text{BIT} = \frac{[\text{brGDGT Ia}] + [\text{brGDGT IIa+IIa}'] + [\text{brGDGT IIIa+IIIa}']}{[\text{brGDGT Ia}] + [\text{brGDGT IIa+IIa}'] + [\text{brGDGT IIIa+IIIa}'] + [\text{Cren}]} \quad [3]$$

295 where the numbers reflect different branched GDGTs (see Hopmans et al., 2004) and *Cren* reflects
296 crenarchaeol. The branched GDGTs were always around the detection limit in the Atlantic samples,
297 implying a BIT index of around zero and thus minimal influence of soil organic carbon (Hopmans et al.,
298 2004), and thus the BIT index is not discussed any further.

299

300 **2.4.2 LCAs**

301 The ketone fractions of the surface sediments and sediment traps samples of the tropical North Atlantic
302 were analyzed for LCAs on an Agilent 6890N gas chromatograph (GC) with flame ionization
303 detection (FID) after dissolving in ethyl acetate. The GC was equipped with a fused silica column with
304 a length of 50 m, a diameter of 0.32 mm, and a coating of CP Sil-5 (film thickness = 0.12 μm). Helium
305 was used as carrier gas, and the flow mode was a constant pressure of 100 kPa. The ketone fractions
306 were injected on-column at a starting temperature of 70 $^{\circ}\text{C}$, which increased by 20 $^{\circ}\text{C min}^{-1}$ to 200 $^{\circ}\text{C}$
307 followed by 3 $^{\circ}\text{C min}^{-1}$ until the final temperature of 320 $^{\circ}\text{C}$ was reached. This end temperature was
308 held for 25 min.

309 The $U_{37}^{K'}$ index was calculated according to Prahl and Wakeham (1987):

$$310 \quad U_{37}^{K'} = \frac{[C_{37:2}]}{[C_{37:2}] + [C_{37:3}]} \quad [4]$$

311 The $U_{37}^{K'}$ values were translated to SST after the calibration of Müller et al. (1998):

$$312 \quad \text{SST} = \frac{U_{37}^{K'} - 0.044}{0.033} \quad [5]$$

313 We have also applied the recently proposed BAYSPLINE Bayesian calibration of Tierney and Tingley
314 (2018). They and others have shown that the $U_{37}^{K'}$ estimates substantially attenuate above temperatures
315 of 24 $^{\circ}\text{C}$ (e.g., Conte et al., 1998; Goñi et al., 2001; Sicre et al., 2002). The Bayesian calibration moves
316 the upper limit of the $U_{37}^{K'}$ calibration from approximately 28 to 29.6 $^{\circ}\text{C}$ at unity. Since our traps are
317 located in tropical regions with SSTs > 24 $^{\circ}\text{C}$, we have applied this calibration as well.

318

319 **2.4.3 LCDs**

320 The silylated polar fractions were injected on-column on an Agilent 7890B GC coupled to an Agilent
321 5977A MS. The starting temperature was 70 $^{\circ}\text{C}$, and increased to 130 $^{\circ}\text{C}$ by 20 $^{\circ}\text{C min}^{-1}$, followed by a
322 linear gradient of 4 $^{\circ}\text{C min}^{-1}$ to an end temperature of 320 $^{\circ}\text{C}$, which was held for 25 min. 1 μL was
323 injected, and separation was achieved on a fused silica column (25 \times 0.32 mm) coated with CP Sil-5
324 (film thickness 0.12 μm). Helium was used as carrier gas with a constant flow of 2 mL min^{-1} . The MS

325 operated with an ionization energy of 70 eV. Identification of LCDs was done in full scan mode,
 326 scanning between m/z 50–850, based on characteristic fragmentation patterns (Volkman et al., 1992;
 327 Versteegh et al., 1997). Proxy calculations and LCD quantifications were performed by analysis in SIM
 328 mode of the characteristic fragments (m/z 299, 313, 327 and 341; Rampen et al., 2012; m/z 187 for
 329 internal diol standard). For quantification of LCDs in the sediment traps and seafloor sediments of the
 330 tropical Atlantic, the peak areas of the LCDs were corrected for the average relative contribution of the
 331 selected SIM fragments to the total ion counts, i.e., 16 % for the saturated LCDs, 9 % for unsaturated
 332 LCDs and 25 % for the C_{22} 7,16-diol internal standard.

333 Sea surface temperatures were calculated using the LDI, according to Rampen et al. (2012):

$$334 \quad LDI = \frac{[C_{30} \text{ 1,15-diol}]}{[C_{28} \text{ 1,13-diol}] + [C_{30} \text{ 1,13-diol}] + [C_{30} \text{ 1,15-diol}]} \quad [6]$$

335 These LDI values were converted into SSTs using the following equation (Rampen et al., 2012):

$$336 \quad SST = \frac{LDI - 0.095}{0.033} \quad [7]$$

337 Upwelling conditions were reconstructed using the Diol Index as proposed by Rampen et al. (2008):

$$338 \quad \text{Diol Index} = \frac{[C_{28} \text{ 1,14-diol}] + [C_{30} \text{ 1,14-diol}]}{[C_{28} \text{ 1,14-diol}] + [C_{30} \text{ 1,14-diol}] + [C_{30} \text{ 1,15-diol}]} \quad [8]$$

339 In 2010, Willmott et al. introduced an alternative Diol Index, which is defined as the ratio of 1,14-diols
 340 over 1,13-diols. Since the index of Rampen et al. (2008) includes the C_{30} 1,15-diol, it can be affected by
 341 temperature variation, and therefore we would normally prefer to use the index of Willmott et al. (2010).
 342 However, we often did not detect the C_{28} 1,13-diol, or it co-eluted with cholest-5-en-7-one-3 β -ol,
 343 compromising the calculation of the Diol Index of Willmott et al. (2010). Moreover, the temperature
 344 variations in all three sediment traps are minimal as recorded by the LDI. Accordingly, we chose to
 345 apply the Diol Index according to Rampen et al. (2008).

346 Potential fluvial input of organic carbon was determined by the fractional abundance of the C_{32} 1,15-
 347 diol (de Bar et al., 2016; Lattaud et al., 2017a):

$$348 \quad FC_{32} \text{ 1,15-diol} = \frac{[C_{32} \text{ 1,15-diol}]}{[C_{28} \text{ 1,13-diol}] + [C_{30} \text{ 1,13-diol}] + [C_{30} \text{ 1,15-diol}] + [C_{32} \text{ 1,15-diol}]} \quad [9]$$

349 The fractional abundance of the C₃₂ 1,15-diol was always lower than 0.23, suggesting low input of river
350 derived organic carbon (Lattaud et al., 2017a).

351

352 **3. Results**

353 **3.1 Tropical North Atlantic**

354 We have analyzed sediment trap samples from a longitudinal transect (~ 12°N) in the tropical North
355 Atlantic (two upper traps at ca. 1200 m water depth, and three lower traps at ca. 3500 m; Fig. 1), covering
356 November 2012–November 2013, as well as seven underlying surface sediments, for LCDs, LCAs and
357 GDGTs. Below we present the results for these lipid biomarkers and associated proxies.

358 **3.1.1 LCDs**

359 The LCDs detected in the sediment trap samples and surface sediments from the tropical North Atlantic
360 (Fig. 2) are the C₂₈, C₃₀ and C_{30:1} 1,14-, C₂₈ and C₃₀ 1,13-, the C₃₀ 1,15-, and C₃₂ 1,15-diols. We detected
361 the C₂₈ 1,14- diol and C₂₉-OH fatty acid in the traps from M1 and M4, in a few samples of the M2 traps
362 and in all surface sediments. For most samples from M2U and M2L, the C₂₈ 1,14-diol was often part of
363 a high background signal, making identification and quantification problematic. In these cases, 1,14-
364 diol fluxes and Diol Index were solely based on the (saturated and mono-unsaturated) C₃₀ 1,14-diol.

365 The average [1,13+1,15]-diol flux is 2.6 (± 1.0) μg m⁻² d⁻¹ at M1U, 1.4 (± 1.2) and 1.2 (± 1.1) μg m⁻² d⁻¹
366 for M2U and M2L, respectively, and 7.0 (± 7.8) and 2.2 (± 3.3) μg m⁻² d⁻¹ for M4U and M4L,
367 respectively (Fig. 3). The [1,13+1,15]-diol and 1,14-diol concentrations in the underlying sediments
368 vary between 0.05 μg g⁻¹ and 0.50 μg g⁻¹, and between 3 ng g⁻¹ and 0.06 μg g⁻¹, respectively. The 1,14-
369 diol flux for M1U averages 0.5 (± 0.8) μg m⁻² d⁻¹ with a pronounced maximum of 3.5 μg m⁻² d⁻¹ in late
370 April (Fig. 5a), irrespective of the total mass flux. The average 1,14-diol flux at M2 is much lower and
371 similar for the upper and lower traps, being around 0.01–0.02 (± 0.01) μg m⁻² d⁻¹. At M4, the average
372 1,14-diol fluxes are 0.3 (± 0.5) and 0.1 (± 0.2) μg m⁻² d⁻¹ for the upper and lower trap, respectively.
373 There are two evident maxima in the [1,13+1,15]-diols and 1,14-diol fluxes in late April and during
374 October/November, concomitant with maxima in the total mass flux (Fig. 3d and 3e). However, in the

375 lower trap this flux maximum is distributed over two successive trap cups, corresponding to late
376 April/early May (Fig. 3e and 3j).

377 The LDI ranged between 0.95 and 0.99 in all traps, corresponding to temperatures of 26.0 to 27.3 °C
378 with no particular trends (Fig. 4). For most M2 and M4 samples the C₂₈ 1,13-diol was below
379 quantification limit and, hence, LDI was always around unity, corresponding to 26.9 to 27.3 °C (Fig. 4),
380 whereas in others samples the C₂₈ 1,13-diol co-eluted with cholest-5-en-7-one-3β-ol, prohibiting the
381 calculation of the LDI and Diol Index (Fig. 4 and 5). The flux-weighted annual average LDI-derived
382 SSTs are 26.6 °C for M1U, and 27.1 °C for M2U, M2L, M4U and M4L. The underlying sediment is
383 very similar, with LDI values between of 0.95 and 0.98 corresponding to 26.0 and 26.9 °C (Fig. 6). The
384 Diol Index varied from 0.03 to 0.30 in M1U, showing a pronounced maximum during spring (Fig. 5a).
385 The Diol Index at M2 ranges between 0.01 and 0.05 without an evident pattern, while the Diol Index at
386 M4 ranges from 0.01 to 0.10 and shows the same pattern in the lower and upper trap, with highest values
387 during spring (ca. 0.1), followed by a gradual decrease during summer (Fig. 5d; 5e).

388

389 **3.1.2 LCAs**

390 We detected C₃₇, C₃₈ and C₃₉ long-chain alkenones in the sediment trap and surface sediments. The C_{37:3}
391 alkenone was generally around the limit of quantification for the M2L and M4L traps, and below the
392 limit of quantification for 4 out of the 7 surface sediment samples, while the C_{37:2} alkenone was always
393 sufficiently abundant. The annual mean fluxes of the C₃₇ LCAs are 4.3 (± 3.5) μg m⁻² d⁻¹ for M1U, 1.2
394 (± 0.9) μg m⁻² d⁻¹ and 0.4 (± 0.2) μg m⁻² d⁻¹ for M2U and M2L, respectively, and 2.8 (± 5.0) μg m⁻² d⁻¹
395 and 1.2 (± 2.0) μg m⁻² d⁻¹ for M4U and M4L, respectively. The concentrations of the C₃₇ LCAs in the
396 underlying surface sediments range between 0.02 and 0.41 μg g⁻¹. At M4, the two total mass flux peaks
397 at the end of April and during October/November are also clearly pronounced in the C₃₇ alkenone fluxes
398 (Fig. 3d, 3e and 5g), as well as the increased signal in the cup reflecting the beginning of May, which
399 follows the cup which recorded the peak in total mass flux at the end of April. The U^K₃₇ varied from
400 0.87 to 0.93, corresponding to 25.1 to 27.0 °C (Fig. 6c) for 3 out of 7 surface sediments in which the
401 C_{37:3} was above quantification limit. The flux-weighted average SSTs are 26.1 °C for M1U, 25.7 and

402 26.4 °C for M2U and M2L, respectively, and 28.2 and 27.5 °C for M4U and M4L, respectively (Fig. 6).
403 SST variations per sediment trap are generally within a 2–3 °C range (Fig. 4) with no apparent trends.

404

405 **3.1.3 GDGTs**

406 The main GDGTs detected were the isoprenoidal GDGT-0, -1, -2, -3, crenarchaeol and the isomer of
407 crenarchaeol. Branched GDGTs were typically around or below quantification limit. The average
408 iGDGT flux in M1U is 15.5 (\pm 4.6) $\mu\text{g m}^{-2} \text{d}^{-1}$, 2.4 (\pm 1.1) and 2.6 (\pm 0.3) $\mu\text{g m}^{-2} \text{d}^{-1}$ in M2U and M2L,
409 respectively, and 4.3 (\pm 1.5) and 2.9 (\pm 1.2) $\mu\text{g m}^{-2} \text{d}^{-1}$ in M4U and M4L, respectively (Fig. 3f). The
410 surface sediments exhibit iGDGT concentrations between 0.4 and 1.7 $\mu\text{g g}^{-1}$. Sediment $\text{TEX}^{\text{H}}_{86}$ values
411 vary between 0.62 and 0.69, corresponding to 24.3 to 27.4 °C. The $\text{TEX}^{\text{H}}_{86}$ flux-weighted average SSTs
412 are 25.2 °C for M1U, 27.3 and 26.6 °C for M2U and M2L, respectively, and 27.8 and 26.7 °C for M4U
413 and M4L, respectively. SSTs vary typically within a range of 1 and 2 °C. At M2U, the $\text{TEX}^{\text{H}}_{86}$
414 temperatures decrease slightly (ca. 1–2 °C) between January and July (Fig. 4b).

415

416 **3.2 Mozambique Channel**

417 For two time series (November 2003–September 2007 and February 2008–February 2009), we have
418 analyzed LCDs collected in the sediment trap at 2250 m water depth as well as nearby underlying surface
419 sediments (Fig. 1). The main LCDs observed in the sediment traps and surface sediments are the C_{28}
420 1,12-, 1,13- and 1,14-diols, the C_{30} 1,13-, 1,14- and 1,15-diols and the C_{32} 1,15-diol. We also observed
421 the $\text{C}_{30:1}$ 1,14 diol in some trap samples, and the C_{29} 12-OH fatty acid in all trap and sediment samples.
422 In 24 samples, the C_{28} 1,13-diol co-eluted with cholest-5-en-7-one-3 β -ol, and henceforth we did not
423 calculate the LDI for these samples. The C_{28} 1,14-diol was not affected by this cholest-5-en-7-one-3 β -
424 ol due to its much higher abundance compared to the C_{28} 1,13-diol and the Diol Index was therefore still
425 calculated. The LDI varied between 0.94 and 0.99, i.e., close to unity, corresponding to 25.5 to 27.2 °C,
426 without an evident trend (Fig. 7a). The Diol Index ranges between 0.11 and 0.69, showing substantial

427 variation, although not with an evident trend (Fig. 7b). The average LDI-derived temperature of two
428 underlying surface sediments is 26.0 °C.

429

430 **3.3 Cariaco Basin**

431 We analyzed LCDs for two time series (May 1999–May 2000 and July 2002–July 2003) from the upper
432 (Trap A; 275 m) and the lower trap (Trap B; 455 m) in the Cariaco Basin. The main LCDs detected for
433 both time series are the C₂₈ 1,14-, C₃₀ 1,14-, C_{30:1} 1,14-, C₂₈ 1,13-, C₃₀ 1,15- and C₃₂ 1,15-diols, as well
434 as the C₂₉ 12-OH fatty acid. For some samples we did not compute the LDI, as the C₂₈ 1,13-diol co-
435 eluted with cholest-5-en-7-one-3β-ol. Similarly as for the Mozambique Channel, the C₂₈ 1,14-diol was
436 not affected by this co-elution due to its much higher abundance compared to the C₂₈ 1,13-diol and the
437 Diol Index was therefore still calculated. The calculated LDI values range between 24.3 and 25.3 °C
438 and 22.0 and 27.2 °C for Trap A and B of the 1999-2000 time series, respectively, with the lowest
439 temperature during winter, and the highest during summer. For the 2002-2003 time series, LDI
440 temperatures for Trap A range between 23.3 and 26.2 °C, and for Trap B between 22.5 °C and 26.5 °C.

441 For the May 1999–May 2000 time series, the Diol Index varies between 0.05 and 0.97 for Trap A, and
442 between 0.05 and 0.91 for Trap B (Fig. 8) with similar trends, i.e. the lowest values of around 0.1-0.2
443 just before the upwelling period during November, rapidly increasing towards values between ca. 0.8
444 and 1 during the upwelling season (January and February). For the time series of July 2002–July 2003,
445 the Diol Index shows similar trends, i.e. Diol Index values around 0.8-0.9 during July, which rapidly
446 decrease towards summer values of around 0.2-0.3. Similar to the 1999-2000 time series, the lowest
447 index values (ca. 0.2) are observed just before the upwelling period (during September), after which
448 they increase towards values of around 0.8-0.9 between December and March at the start of the
449 upwelling season. At the end of the upwelling season the Diol Index increases, followed by another
450 maximum of around 0.6 during May.

451 **4. Discussion**

452 **4.1 LCD sources and seasonality**

453 The 1,14 diols can potentially be derived from two sources, i.e. *Proboscia* diatoms (Sinninghe Damsté
454 et al., 2003; Rampen et al., 2007) or the dictyochophyte *Apedinella radians* (Rampen et al., 2011). The
455 non-detection of the C₃₂ 1,14-diol, which is a biomarker for *Apedinella radians* (Rampen et al., 2011),
456 and the detection of the C_{30:1} 1,14 diol and C₂₉ 12-OH fatty acid, which are characteristic of *Proboscia*
457 diatoms (Sinninghe Damsté et al., 2003), suggests that *Proboscia* diatoms are most likely the source of
458 1,14-diols in the tropical North Atlantic, the Mozambique Channel and the Cariaco Basin.

459 In the Cariaco Basin, the Diol Index shows a strong correlation (visually as correlation analysis was not
460 possible due to differently spaced data in time) with primary production rates, suggesting that *Proboscia*
461 productivity was synchronous with total productivity (Fig. 8), although for the 1999-2000 time series
462 there is a disagreement during January/February. Primary productivity in the Cariaco Basin is largely
463 related to seasonal upwelling which occurs between November and May when the ITCZ is at its southern
464 position. Hence, the Diol Index seems to be an excellent indicator of upwelling intensity in the Cariaco
465 Basin.

466 The index also shows considerable variation over time in the Mozambique Channel (Fig. 7b). Previous
467 studies have shown that upwelling occurs in the Mozambique Channel between ca. 15 and 18°S
468 (Nehring et al., 1987; Malauene et al., 2014), i.e. at the location of our sediment trap. Upwelling is
469 reflected by cool water events and slightly enhanced Chlorophyll *a* levels, and Malauene et al. (2014)
470 observed cool water events at ca. two month intervals although periods of 8 to 30 days were also
471 observed. The two main potential forcing mechanisms for upwelling in the Mozambique Channel are
472 the East African monsoon winds and the meso-scale eddies migrating through the channel. Fallet et al.
473 (2011) showed that subsurface temperature, current velocity and the depth of surface-mixed layer all
474 revealed a dominant periodicity of four to six cycles per year, which is the same frequency as that of the
475 southward migration of meso-scale eddies in the channel (Harlander et al., 2009; Ridderinkhof et al.,
476 2010), implying that eddy passage strongly influences the water mass properties. Wavelet analysis of
477 the Diol Index for the period 2003–2007 (supplemental Fig. S1) revealed short periods, occurring around

478 January of 2004, 2005, and 2006, of significant (above the 95 % confidence level) variability at about
479 bimonthly frequencies (60-day period). Both the frequency (bimonthly) and the timing (boreal winter)
480 of the observed time periods of enhanced Diol Index variability are similar to those of the cool water
481 events as observed by Malauene et al. (2014), associated with upwelling (Fig. 7b). The strongest
482 variability of the Diol Index at about bimonthly frequencies occurred in the first half of 2006. During
483 the same period, salinity time series showed the passage of several eddies that had a particularly strong
484 effect on the upper layer hydrography (Ullgren et al., 2012). Malauene et al. (2014) showed that neither
485 upwelling-favorable winds, nor passing eddies, can by themselves explain the observed upwelling along
486 the northern Mozambique coast. The two processes may act together, and both strongly influence the
487 upper water layer and the organisms living there, potentially including the LCD producers.

488 The least (seasonal) variation in the Diol Index is observed at M2 in the tropical North Atlantic (Fig. 5b
489 and 5c), which is likely due to its central open ocean position, associated with relatively stable,
490 oligotrophic conditions (Guerreiro et al., 2017). In contrast, M4 and M1 are closer to the south American
491 and west African coast, respectively, and thus are potentially under the influence of Amazon river runoff
492 and upwelling, respectively, and specific wind and ocean circulation regimes (see Sect. 2.1.1). However,
493 at M4, the Diol Index is also low (max. 0.1), suggesting low *Proboscia* productivity (Fig. 5d and 5e).
494 At M1, by contrast, we observe enhanced values for the Diol Index of up to ~0.3 during spring (Fig. 5a).
495 Most likely, an upwelling signal at this location is associated with the seasonal upwelling of the Guinea
496 Dome. This upwelling is generally most intense between July and October (Siedler et al., 1992), due to
497 the northward movement of the ITCZ and the resulting intensified Ekman upwelling. Specifically,
498 during this period, the trade winds are weaker, atmospheric pressure is lower, and the regional wind
499 stress is favorable to upwelling of the North Equatorial Undercurrent (Voituriez, 1981). Indeed, a
500 decrease in wind speed and increased precipitation during summer to autumn was observed (Fig. 5a)
501 which confirms that during these seasons the ITCZ was indeed at a northern position, and that during
502 2013 the upwelling associated with the Guinea Dome was most favored between July and October. The
503 timing of the Diol Index peak, i.e., between March and June is consistent with previous sediment trap
504 studies elsewhere which have shown that *Proboscia* diatoms and 1,14-diols are typically found during

505 pre-upwelling or early upwelling periods (Koning et al., 2001; Smith, 2001; Sinninghe Damsté et al.,
506 2003; Rampen et al., 2007). The surface sediment at 22° W just east of M1 also reveals the highest Diol
507 Index (0.53), likely due to its closer vicinity to the Guinea Dome center. Several studies have reported
508 *P. alata* diatoms offshore North West Africa (Lange et al., 1998; Treppke et al., 1995; Crosta et al.,
509 2012; Romero et al., 1999), pointing to *P. alata* as a plausible source organism. The sedimentary annual
510 diol indices compare well with the sediment trap indices (Fig. 6e), which is consistent with the results
511 of Rampen et al. (2008). Our results clearly show that the Diol Index reflects different things in different
512 regions. This is due to the ecology of *Proboscia* spp. where blooms occur during stratification to early
513 upwelling to postbloom, and from high nutrients to low nutrients (see Rampen et al., 2014; references
514 in Table 1). Therefore, the type of conditions reflected by the Diol Index is specific for every region.

515 To assess variations in seasonal production of 1,13- and 1,15-diols in the tropical Atlantic, for which we
516 have the most complete dataset, we calculated the flux-weighted 1,13- and 1,15-diol concentrations for
517 the different traps, and summed these per season (Fig. 9). Highest production is observed in autumn,
518 followed by summer and spring, with the lowest production during winter (~60 % compared to autumn).
519 This is in agreement with Rampen et al. (2012) who observed, for an extensive set of surface sediments,
520 the strongest correlation between LDI and SST for autumn, suggesting that production of the source
521 organisms of the LDI mainly occurs during autumn. At M4, there are two evident peaks in the 1,13- and
522 1,15-diol fluxes at the end of April and October 2013. These maxima correlate with peaks in other lipid
523 biomarker fluxes (i.e., 1,14-diols, C₃₇ alkenones and iGDGTs), total mass flux, calcium carbonate
524 (CaCO₃), OM and the residual mass flux which includes the deposition flux of Saharan dust (Korte et
525 al., 2017). According to Guerreiro et al. (2017), the maximum in total mass flux at the end of April 2013
526 is likely caused by enhanced export production due to nutrient enrichment as a result of wind-forced
527 vertical mixing. The peak at the end of October 2013, is likely associated with discharge from the
528 Amazon River. Moreover, both peaks are concomitant with prominent dust flux maxima, suggesting
529 that Saharan dust also acted as nutrient fertilizer (Korte et al., 2017; Guerreiro et al., 2017). Guerreiro
530 et al. (2017) suggested that during the October-November event the Amazon River may not only have
531 acted as nutrient supplier, but also as buoyant surface density retainer of dust-derived nutrients in the

532 surface waters, resulting in the development of algal blooms within just a few days, potentially
533 explaining the peak 1,13- and 1,15-diol fluxes, as well as the peak fluxes of the other lipid biomarkers.
534 However, they might also partially result from enhanced particle settling, caused by e.g. dust ballasting
535 or faecal pellets of zooplankton (see Guerreiro et al. 2017 and references therein). This agrees with the
536 results of Schreuder et al. (2018a) who show that the *n*-alkane flux also peaks concomitant with the
537 peaks in total mass flux and biomarkers, whereas *n*-alkanes are terrestrial derived (predominantly
538 transported by dust) and increased deposition can therefore not result from increased primary
539 productivity in the surface waters.

540 The C₃₇ alkenone flux at M4U also reveals these two distinct maxima at the end of April and October
541 during 2013 (Fig. 5g). Interestingly, this flux, as well as the alkenone flux at M2U, is consistent with
542 coccolith export fluxes of the species *Emiliania huxleyi* and *Gephyrocapsa oceanica* (Guerreiro et al.,
543 2017). In fact, when we combine the coccolith fluxes of both species, we observe strong correlations
544 with the C₃₇ alkenone fluxes for both M2U and M4U (Fig. 5f and 5g, respectively; $r = 0.77$ and 0.92 for
545 M2U and M4U, respectively; p -values < 0.001). This implies that these two species are the main LCA
546 producers in the tropical North Atlantic, which agrees with previous findings (e.g., Marlowe et al., 1984;
547 Brassell, 2014; Conte et al., 1994; Volkman et al., 1995).

548

549 **4.2 Preservation of LCDs**

550 The sediment trap data from the North Atlantic can be used to assess the relative preservation of LCDs,
551 as well as other proxy lipid biomarkers, by comparing the flux-weighted concentration in the traps with
552 the concentrations in the surface sediments. For all four biomarker groups, i.e., C₃₇ alkenones, iGDGTs,
553 1,14-diols and 1,13- and 1,15-diols, we observe that in general the flux-weighted concentrations are
554 higher in the upper traps (ca. 1200 m) as compared to the lower traps (ca. 3500 m; Fig. 2) by a factor of
555 between 1.2 and 4.4, implying degradation during settling down the water column. The concentrations
556 in the surface sediments are 2 to 3 orders of magnitude lower in concentration (i.e., between 0.1–1.5 %
557 of upper trap signal), implying that degradation of lipids is mainly taking place at the water-sediment
558 surface rather than the water column. A similar observation was made for levoglucosan in these sediment

559 traps (Schreuder et al., 2018b). Both are functionalized polar lipids with alcohol groups and thus are
560 chemically relatively similar when compared to e.g. fatty acids (carboxyl group) or *n*-alkanes (no
561 functional groups). These degradation rates are likely linked to the extent of the oxygen exposure time
562 (Hartnett et al., 1998; Hedges et al., 1999) at the seafloor (Hartnett et al., 1998; Sinninghe Damsté et al.,
563 2002), since during settling the lipids are exposed to oxygen for weeks, whereas for surface sediments
564 this is typically decades to centuries. Our results compare well with several other sediment trap studies
565 which showed that LCDs, LCAs and iGDGTs generally have a preservation factor of around 1 %
566 (surface sediment vs. trap) (e.g., Prahl et al., 2000; Wakeham et al., 2002; Rampen et al., 2007;
567 Yamamoto et al., 2012).

568 We have also identified the C₃₀ and C₃₂ 1,15-keto-ol in the Atlantic as well as the Mozambique and
569 Cariaco sediment traps and surface sediments. These lipids are structurally related to LCDs and occur
570 ubiquitously in marine sediments (e.g., Versteegh et al., 1997; 2000; Bogus et al., 2012; Rampen et al.,
571 2007; Sinninghe Damsté et al., 2003; Wakeham et al., 2002; Jiang et al., 1994), and were inferred to be
572 oxidation products of LCDs (Ferreira et al., 2001; Bogus et al., 2012; Sinninghe Damsté et al., 2003).
573 We have not detected 1,14-keto-ols, which supports the hypothesis of Ferreira et al. (2001) and
574 Sinninghe Damsté et al. (2003) that the silica frustules of *Proboscia* diatoms sink relatively fast and thus
575 are exposed to oxygen for a shorter period than the producers of 1,13- and 1,15-diols, and thus less
576 affected by oxidation. Alternatively, the keto-ols are not oxidation products but are produced by
577 unknown organisms in the water column. In fact, Méjanelle et al. (2003) observed trace amounts of C₃₀
578 1,13- and C₃₂ 1,15-keto-ols in cultures of the marine eustigmatophyte *Nannochloropsis gaditana*. Thus,
579 an alternative explanation for the non-detection of 1,14-keto-ols is that, in contrast to the 1,15-keto-ols,
580 they were not produced in the water column.

581 For both the tropical Atlantic and the Cariaco Basin, we observe highly similar LDI values for the upper
582 and the lower traps. In the Atlantic there is no statistical difference between upper and lower trap that
583 are 2200 m apart (two-tailed $p > 0.8$), but we have too little data for the Cariaco Basin for statistical
584 comparison (Fig. 6b, 8c and 8f). This suggests that degradation in the water column does not affect the
585 LDI proxy. This is in agreement with the study of Reiche et al. (2018) who performed a short-term

586 degradation experiment (< 1 year) and found that the LDI index was not affected by oxic exposure on
587 short time scales. However, the oxygen exposure time on the seafloor is much longer, and Rodrigo-
588 Gámiz et al. (2016) showed for sediments in the Arabian Sea, deposited under a range of bottom water
589 oxygen conditions, that different LCDs had different degradation rates, which compromised the LDI
590 ratio. For the three sites in the tropical North Atlantic, we have calculated the flux-weighted average
591 proxy values for every sediment trap and compare these with the underlying surface sediments (Fig. 6b-
592 6e). For all indices, i.e., Diol Index, LDI, $U_{37}^{K'}$ and TEX_{86} , we observe very good correspondence
593 between the sediment trap and surface sediment values, implying minimal alteration of the proxies after
594 settling and during burial. Similarly, for the Mozambique Channel, the mean Diol Index and LDI from
595 the sediment trap (i.e., 0.41 and 0.97, respectively) are very similar to the surface sediment values (i.e.,
596 0.42 and 0.95, respectively). In agreement with the consistent diol indices, we observe that all individual
597 LCDs are also preserved relatively equally in the tropical Atlantic (1.2-4.3 % at station M1, 0.1-2.9 %
598 at station M2 and 0.03-0.16 % at station M4). This contrasts with the findings of Rodrigo-Gámiz et al.
599 (2016) who found that the 1,15-diols have the highest degradation rate, followed by the 1,14- and 1,13-
600 diols. Only the C_{32} 1,15-diol seems relatively better preserved than the other LCDs at all three North
601 Atlantic mooring sites (Fig. 2), suggesting that the C_{32} 1,15-diol is less impacted by degradation. The
602 C_{32} 1,15-diol likely partially derives from the same source as the other 1,13- and 1,15-diols, but is also
603 produced in fresh water systems (e.g., Versteegh et al., 1997; 2000; Rampen et al., 2014b; de Bar et al.,
604 2016; Lattaud et al., 2017a; 2017b). Hence, the different preservation characteristics might be the result
605 of a different source for this LCD.

606

607 **4.3 Relationship between LDI and SST**

608 In the tropical Atlantic and Mozambique Channel, the LDI-derived SSTs show minimal variability (<2
609 °C), while in the Cariaco Basin we observe much larger changes that range from 22.0 °C to 27.2 °C
610 (Fig. 8). Both time series in the Cariaco Basin show low temperatures between November and May
611 associated with the seasonal upwelling and surface water cooling, and significantly higher temperatures
612 during the rainy summer. However, during the warmest periods, the LDI temperatures are generally

613 lower than measured at the surface by CTD, whereas during the colder phases, the LDI agrees well with
614 the measurements. The LDI calibration reaches unity at 27.4 °C, and therefore it is not possible to resolve
615 the highest temperatures which are between ca. 28 and 30 °C. However, the LDI-derived temperatures
616 are sometimes well below 27.4 °C where the CTD data suggest SSTs > 28 °C. Consequently, the LDI-
617 based temperatures agree with CTD-based SSTs within calibration error for most of the record, but
618 during summer when SST is highest, are offset outside the calibration error ($\Delta T \sim 2.5\text{--}4.5$ °C).
619 Interestingly, the $U^{K'}_{37}$ - and TEX^H_{86} -derived temperature trends show the same phenomenon (Turich et
620 al., 2013; Fig. 8), where the proxy temperatures are cooler than the measured temperatures during the
621 warmer months. However, in contrast to the $U^{K'}_{37}$ and LDI, the TEX^H_{86} also overestimates SST during
622 the cold months. For $U^{K'}_{37}$, Turich et al. (2013) pointed out that a time lag between synthesis, export and
623 deposition could potentially explain the difference between the proxy and CTD temperatures. However,
624 previous analysis of plankton biomass, primary productivity, bio-optical properties and particulate
625 organic carbon fluxes for the same time period (Müller-Karger et al., 2004), as well as the total mass
626 and terrigenous fluxes assessed by Turich et al. (2013) showed best correlation at zero-time lag on the
627 basis of their 14-day sample interval. We compared our LDI temperature estimates with monthly CTD
628 measurements between 0 and 50 m depth, the temperature at depth of maximum primary productivity
629 and the temperature at the chlorophyll maximum (Turich et al., 2013; <http://www.imars.usf.edu/cariaco>)
630 (Fig. 10). During the upwelling season, temperatures are significantly lower due to the upward migration
631 of isotherms, whereas during the non-upwelling period, temperatures are higher, particularly in the upper
632 20 m, and the water column is more stratified (Fig. 10). LDI underestimates SST during stratification,
633 which suggests that the LCD producers may thrive at depths of ca. 20–30 m. During upwelling, LDI-
634 temperatures agree better with SST, implying that the habitat of the LCD producers potentially was
635 closer to the surface, coincident with the shoaling of the nutricline and thermocline (Fig. 10). However,
636 these absolute differences in LDI-temperatures are generally within the calibration error (2 °C), and
637 these seasonal variations in LDI-temperatures should thus be interpreted with caution. Turich et al.
638 (2003) found that the $U^{K'}_{37}$ -derived temperatures agreed reasonably well with the measured temperatures
639 at the chlorophyll maximum, which is generally found below 20 m depth (average 30–34 m depth;
640 ranging between 1 and 55 m) in the Cariaco Basin. The LDI temperatures are almost always higher than

641 the temperatures at the chlorophyll maximum (Fig. 10), and higher than the temperatures at 30 m depth,
642 implying that the LDI producers may reside in the upper 30 m of the water column, which is consistent
643 with the results of Rampen et al. (2012), who showed that LDI-derived temperatures have the strongest
644 correlation with temperatures of the upper 20 m of the water column. This also agrees with Balzano et
645 al. (2018) who observed highest LCD abundances within the upper 20 m of the water column in the
646 Tropical Atlantic.

647 In the Mozambique Channel, the LDI temperature variations are much smaller ($< 2\text{ }^{\circ}\text{C}$; Fig. 7a) than the
648 seasonal SST variation ranging between ca. 24.5 and 30.5 $^{\circ}\text{C}$. Accordingly, during the warmest months
649 of the year, the difference between LDI-derived and satellite-derived SST is outside of the calibration
650 error (i.e., $> 2\text{ }^{\circ}\text{C}$). However, this is similar to the $U^{K'}_{37}$ and $\text{TEX}^{\text{H}}_{86}$ which also did not reveal seasonal
651 variations. This lack of seasonality was explained by lateral advection and re-suspension of fine
652 sediment material by migrating meso-scale eddies and thus ending up in the deeply moored sediment
653 trap (Fallet et al., 2011; 2012). Most likely, this also explains the lack of seasonal variation in our LDI
654 record (Fig. 7a). Nevertheless, the average LDI temperature for the sediment trap of 26.4 $^{\circ}\text{C}$ agrees
655 reasonably well with the annual mean satellite-derived SST of 27.6 $^{\circ}\text{C}$ for the sampled years.
656 Additionally, there is a good agreement with the average LDI temperature of 26.0 $^{\circ}\text{C}$ for two underlying
657 surface sediments, as well as with the decadal average SST of 26.7 $^{\circ}\text{C}$ for 1955-2012 (Locarnini et al.,
658 2013) given by the World Ocean Atlas (2013). For the North Atlantic, we also observe rather constant
659 LDI temperatures during the year (Fig. 4) which contrasts with seasonal variations in satellite SSTs of
660 ca. 3 to 5 $^{\circ}\text{C}$. Nevertheless, differences are mostly within the calibration error, except at M1 and M2
661 where during winter and spring LDI-derived temperatures are between 0.5 and 2.8 $^{\circ}\text{C}$ higher than
662 satellite SSTs. Similar to the LDI, also the $\text{TEX}^{\text{H}}_{86}$ and $U^{K'}_{37}$ -derived SSTs for the tropical Atlantic
663 sediment traps do not reveal clear seasonal variation. As all three proxies show minimal seasonal
664 variability, this might indicate that the lipids are potentially allochthonous and partially derive from
665 distant regions, resulting in an integrated average temperature signal, similar to the Mozambique
666 Channel. Nevertheless, the flux-weighted annual LDI temperatures of the tropical Atlantic sediment
667 traps (26.6 for M1 and 27.1 $^{\circ}\text{C}$ for M2 and M4) agree well with the annual mean satellite-derived SSTs

668 of 26.1, 26.0 and 27.5 °C for M1, M2 and M4, respectively. Moreover, the LDI-derived temperatures in
669 the underlying sediments (26.5, 26.6 and 26.7 °C, respectively) do not only agree well with those found
670 in a single year in the sediment traps but also with the decadal average SSTs for 1955 to 2012 (26.2,
671 27.1 and 26.3 °C, respectively; Locarnini et al., 2013; Fig. 6b).

672

673 **5. Conclusions**

674 In this study we have evaluated LCD-based proxies, particularly the LDI, in sediment trap time series
675 from five sites in the tropical North Atlantic, the Cariaco Basin and the Mozambique Channel. For the
676 North Atlantic we found that in the water column ca. 25–85 % of the export of these lipid biomarkers is
677 preserved during settling from 1200m to 3500m, and that generally less than 2 % was preserved in the
678 surface sediments. Despite substantial degradation at the seafloor, likely linked to the prolonged oxygen
679 exposure time, LCD-derived temperatures from the sediments are generally very similar to the annual
680 mean LCD-derived temperatures in both the deep and shallow traps as well as to annual mean SST for
681 the specific sampling year and on decadal time scales for the specific sites. In the Cariaco Basin we
682 observe a seasonal signal in the LDI linked to the upwelling season reflecting temperatures of the upper
683 ca. 30 m of the water column. The LDI temperatures in the Mozambique Channel and the tropical
684 Atlantic reveal minimal seasonal change although seasonal SST contrasts amount to 3-5°C. For the
685 Mozambique Channel this is likely caused by lateral advection of re-suspended sediment by meso-scale
686 eddy migration, a signal not substantially altered by diagenesis. Seasonal variations in the Diol Index
687 are minimal in the central and western North Atlantic and 1,14-diol concentrations are rather low,
688 implying little *Proboscia* diatom productivity. However, in the eastern Atlantic closest to the African
689 continent, the Diol Index attains a clear spring maximum that is likely associated with upwelling in the
690 Guinea Dome during summer to autumn, suggesting the Diol Index reflects a pre-upwelling signal,
691 consistent with the current knowledge on *Proboscia* ecology. In the Cariaco Basin, controlled by
692 seasonal upwelling, the Diol Index reveals the same clear seasonal trend observed in primary
693 productivity, arguing that for this location the Diol Index is an excellent indicator of upwelling intensity.

1153

1154 **Fig. 1** (a) Location map showing the five sediment trap mooring sites in the Cariaco Basin, the tropical
 1155 North Atlantic (M1, M2 and M4) and the Mozambique Channel. Two of the moorings in the tropical
 1156 North Atlantic (M2 and M4) contain an upper ('U') and a lower ('L') trap, shown in the bathymetric
 1157 section below (b) with traps depicted as red triangles and surface sediments shown as black crosses. A
 1158 similar section profile is shown for the Mozambique Channel (c), where also the sediment trap and the
 1159 surface sediments are indicated. All maps/sections are generated in Ocean Data View (Schlitzer, 2015).
 1160 Indicated are the approximate seasonal positions of the ITCZ. NEC = North Equatorial Current; NECC
 1161 = North Equatorial Countercurrent; SEC = South Equatorial Current; MC = Mauritania Current; GD =
 1162 Guinea Dome; NBC = North Brazil Current; GC = Guiana Current.

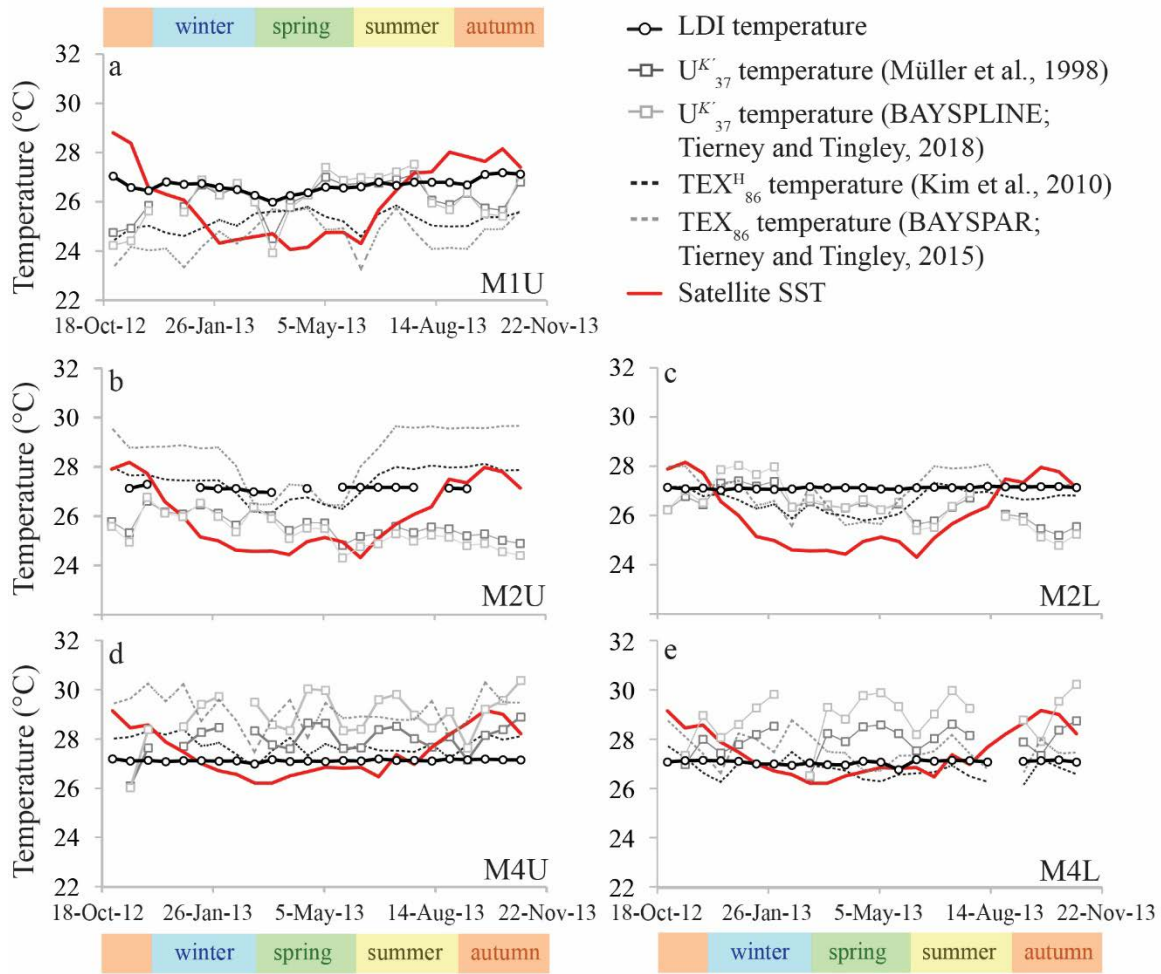

1163

1164 **Fig. 2** Relative concentrations of biomarker lipids for the mooring sites M1, M2 and M4 in the tropical
 1165 North Atlantic. Upper panel: percentages of lipid biomarkers in the lower traps ('L'; 3500 m) and the
 1166 surface sediments ('Sed.') relative to the annual flux-weighted concentrations in the upper traps ('U';
 1167 1200 m; set at 100%). The lower panel shows the preservation of the individual LCDs (sediments versus
 1168 upper trap flux-weighted concentration) for the three sediment trap sites. For M1 and M2 the
 1169 sedimentary LCD concentrations were based on the average of the two nearby underlying surface
 1170 sediments (Fig. 1). When no bar is shown then the LCD was not detected.

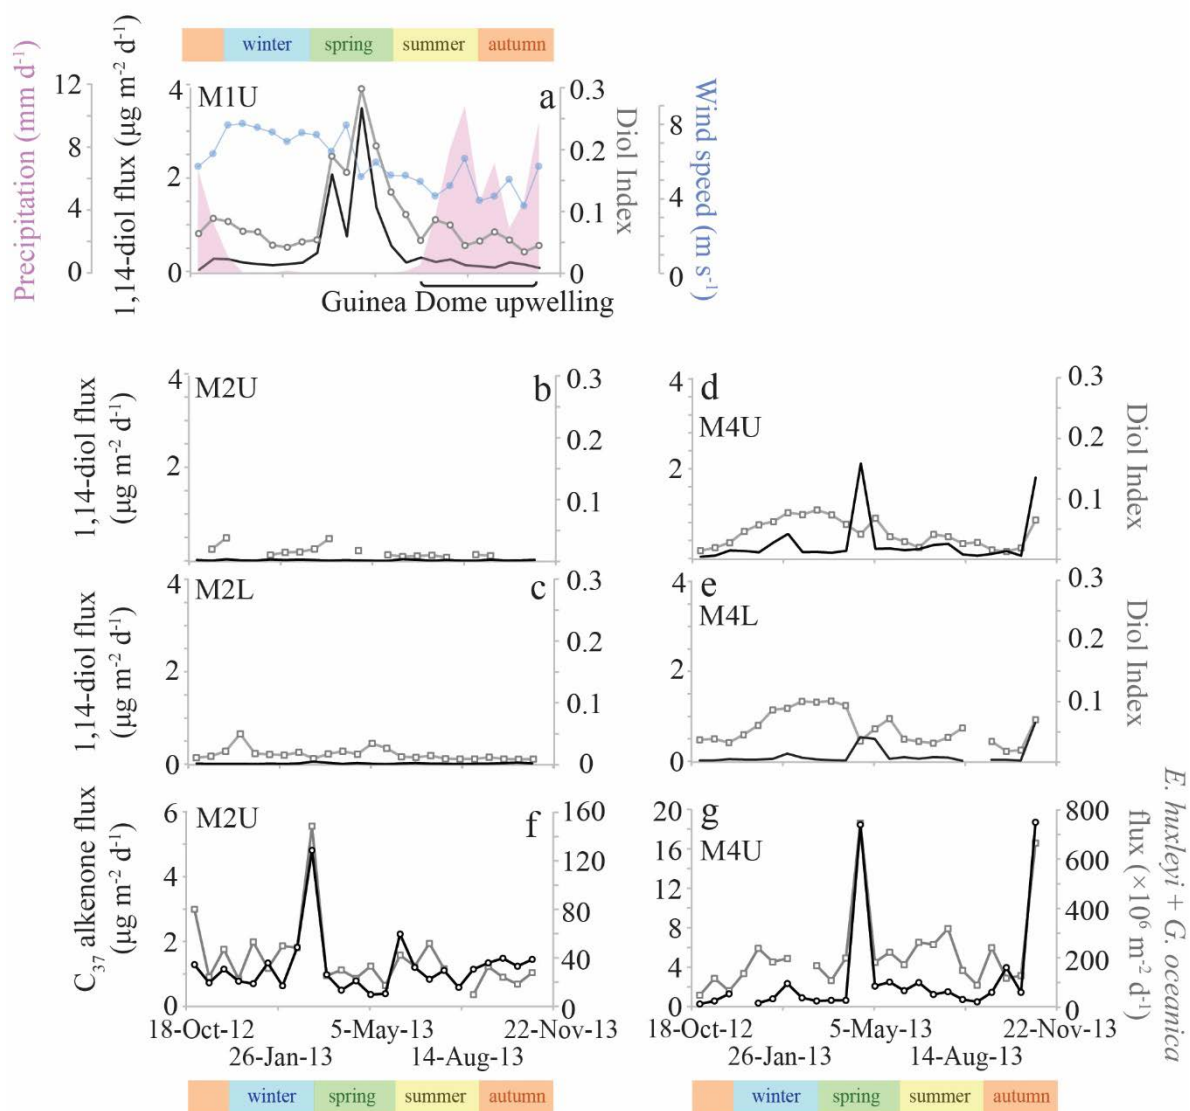

1171 **Fig. 3** Lipid biomarker fluxes for the tropical North Atlantic sediment traps, i.e., M1, upper and lower
 1172 M2, and upper and lower M4 in panels (a) to (e). Lipid biomarker fluxes (iGDGTs in purple; C_{37}
 1173 alkenones in orange; 1,13- and 1,15-diols in black; 1,14-diols in red) are indicated on the left y-axis, and
 1174 the total mass flux (grey stack; Korte et al., 2017) on the right y-axis. Lipid biomarker concentrations
 1175 are plotted in panels (f) to (j), with biomarker concentrations on the left y-axis, and the total mass flux
 1176 on the right y-axis. Note that the y-axes are different per sediment trap site, but identical for upper (U)
 1177 and lower (L) traps.

1178
 1179 **Fig. 4** Temperature proxy records for the tropical North Atlantic. Panel (a) shows upper trap station
 1180 M1, (b) upper trap station M2 and (c) lower trap M2, respectively, (d) upper trap station M4 and (e)
 1181 lower trap station M4, respectively.

1182

1183

1184 **Fig. 5** Phytoplankton productivity records for the tropical North Atlantic. Panels (a) – (e) show the 1,14-
 1185 diol fluxes (left y-axis; black) and the Diol Index (right y-axis; grey) for sediment traps. The y-axes are
 1186 the same for these panels. Wind speed and precipitation data were adapted from Guerreiro et al. (in
 1187 revision); for references regarding remote sensing parameters, see Guerreiro et al. (2017). Panels (f) and
 1188 (g) show the C₃₇ alkenone fluxes (left y-axis; black) and combined fluxes of *E. huxleyi* and *G. oceanica*
 1189 (from Guerreiro et al., 2017; right y-axis; grey) for the upper traps of M2 and M4.

1193

1194

1195

1196 **Fig. 6** Flux-weighted average (annual) proxy results for the sediment traps compared with the underlying
 1197 sediments (crosses) and annual mean SST (red line; specific for coordinates of the surface sediments;
 1198 World Ocean Atlas 2013 $\frac{1}{4}$ grid resolution). Panel (a), (b) and (c) show the LDI, $U^{K'}_{37}$ and TEX_{86}
 1199 temperature results, respectively. Triangles reflect sediment trap results (red = upper/~1200 m; blue =
 1200 lower/~3500 m), and crosses represent surface sediments. In case of the $U^{K'}_{37}$ and TEX_{86} , the green and
 1201 purple triangles and grey crosses reflect the temperatures calculated using the BAYSPLINE and
 1202 BAYSPAR models (Tierney and Tingley, 2014; 2015; 2018), whereas the other temperatures were
 1203 calculated by means of the Müller et al. (1998) and Kim et al. (2010; TEX^H_{86}) calibrations, respectively.
 1204 Panel (d) shows the flux-weighted average Diol Index values for the sediment traps, and the Diol Index
 1205 estimates for the surface sediments.

1212 **Fig. 7** The LDI-derived temperatures, together with the $\text{TEX}^{\text{H}}_{86}$ and U^{K}_{37} -derived temperatures and
 1213 satellite SST (Fallet et al., 2011) (a) and the Diol Index (b) for the Mozambique Channel sediment trap.
 1214 The black cross in panel (a) reflects the average LDI temperature of two underlying surface sediments,
 1215 with the LDI calibration error. The chlorophyll *a* data is from Fallet et al. (2011).

1216

1217

1218

1219 **Fig. 8** Seasonal proxy derived temperature and upwelling/productivity records for the sediment traps in
 1220 the Cariaco Basin. Panels (a), (b) and (c) show the May 1999 – May 2000 time series $\text{TEX}^{\text{H}}_{86}$, $U^{K'}_{37}$ -
 1221 and LDI-derived temperature reconstructions for Trap A (275 m depth; solid symbols) and Trap B (455
 1222 m depth; dashed symbols), respectively. Panels (d), (e) and (f) show the proxy data for the July 2002 –
 1223 July 2003 time series, with CTD-temperatures (1 m depth) in red. The $U^{K'}_{37}$, $\text{TEX}^{\text{H}}_{86}$ and CTD
 1224 temperatures are adopted from Turich et al. (2013). The horizontal lines reflect the average proxy-
 1225 derived temperatures (Trap A = solid; Trap B = dashed). Panel (g) and (h) show the 1,14-diol based
 1226 Diol Index (Rampen et al., 2008) for the 1999-2000 and 2002-2003 time series, respectively, for Trap
 1227 A (275 m depth; solid symbols) and Trap B (455 m depth; dashed symbols). Primary productivity in mg
 1228 $\text{C m}^{-3} \text{h}^{-1}$ is plotted in green (data adopted from Turich et al., 2013). The shaded area reflects the period
 1229 of upwelling.
