Abstract

30 The capacity of Amazon forests to sequester carbon is threatened by climate change-induced shifts in precipitation patterns. However, the relative importance of plant physiology, ecosystem structure, and trait composition responses in determining variation in gross primary productivity (GPP), remain largely unquantified, and vary among models. We evaluate the relative importance of key climate constraints to GPP, comparing direct plant physiological responses to water availability and indirect structural and trait responses (via changes to leaf area index (LAI), roots and photosynthetic capacity). To separate these factors we combined the Soil-Plant-Atmosphere model with forcing and observational data from seven intensively studied forest plots along an Amazon drought stress gradient. We also used machine learning to evaluate the relative importance of individual climate factors across sites. Our model experiments showed that variation in LAI was the principal driver of differences in GPP across the gradient, accounting for 33% of observed variation. Differences in photosynthetic capacity (V_{cmax} and J_{max}) accounted for 21% of variance, and climate (which included physiological responses) accounted for 16%. Sensitivity to differences in climate was highest where shallow rooting depth was coupled with high LAI. On sub-annual timescales, the relative importance of LAI in driving GPP increased with drought stress ($R^2=0.72$), coincident with decreased importance of solar radiation (40 $R^2=0.90$). Given the role of LAI in driving GPP across Amazon forests, improved mapping of canopy dynamics is critical, opportunities for which are offered by new satellite-based remote sensing missions such as GEDI, Sentinel and FLEX.

Keywords: Canopy Dynamics, Leaf Traits, Tropical Rainforests, Precipitation, Gross Primary
50 Productivity

55 1. Introduction

As the entry point for carbon into the biosphere, gross primary productivity (GPP) is central to the global carbon cycle. Tropical rainforests alone account for one third of total terrestrial GPP, assimilating ~41 Pg of carbon each year (Beer et al., 2010). Carbon fluxes across the tropics are tightly coupled to climate, and water availability is a principal driver of spatial and temporal variation in GPP (Fisher et al., 2007, Von Randow et al., 2013, Beer et al., 2010, Malhi et al., 2015, Guan et al., 2015). Across Amazon forests, GPP decreases linearly with increasing seasonal water deficit (Malhi et al., 2015). Shifts in precipitation patterns as a result of anthropogenic climate change are predicted to have a major impact on Amazon GPP (Phillips et al., 2009, Malhi et al., 2008, Meir and Woodward, 2010, Zhang et al., 2015, Meir et al., 2015a). Longer and more intense dry seasons are projected, together with an increased frequency and severity of drought events (Joetzjer et al., 2013, Boisier et al., 2015, Duffy et al., 2015). Given the biogeochemical influence of Amazon forests at regional and global scales (Liu et al., 2017), accurately predicting GPP response to drought stress is critical.

Dynamic global vegetation models (DGVMs) disagree on the effects of projected precipitation change on Amazon carbon dynamics. Galbraith et al. (2010) found future shifts in precipitation patterns had little effect on model estimates of biomass change (for two of the three models tested), reflecting poorly the observed sensitivity of Amazon forests to water availability illustrated by through-fall exclusion experiments and natural drought events (Rowland et al., 2015a, Nepstad et al., 2007, Phillips et al., 2009). Substantial progress has been made in model development to capture the impact of drought stress on plant physiology. By coupling stomatal conductance and plant hydraulic theory, models have proved better able to predict ecosystem functioning and mortality (Eller et al., 2018, Fisher et al., 2018, Fisher et al., 2006, Fisher et al., 2007, Bonan et al., 2014). However, the interactions between drought stress, ecosystem structure (e.g. canopy dynamics and rooting depth) and trait composition (e.g. V_{cmax} , J_{max} , leaf lifespan and leaf mass per unit area (LMA)), are typically absent from models, despite having a major impact on simulated GPP (Fauset et al., 2012, Sakschewski et al., 2016, Lee et al., 2013). Furthermore, changes in canopy dynamics have been identified as a likely cause for the disparity between field observations and model predictions (Restrepo-Coupe et al., 2017, Powell et al., 2013).

The relative importance of plant physiology, ecosystem structure, and trait composition responses in determining variation in GPP, remain largely unquantified in data-constrained analysis (Meir et al., 2015b). Plant physiological responses to drought stress include stomatal conductance, which is limited
85 by water availability and atmospheric demand. Stomatal conductance constrains GPP via changes in CO₂ supply, but is considered a short (varying on sub-hourly timescales), rather than long-term response to climate forcings (Sperry et al., 2002). Changes to both ecosystem structure and traits, such as leaf area index (LAI), rooting depth and carboxylation capacity, are expected to be more longstanding (Meir et al., 2015a).

90 Extensive evidence links spatial and temporal variation in drought stress with ecosystem structure (across sub-annual and annual timescales). LAI typically decreases with increasing drought stress (Iio et al., 2014, Meir et al., 2015b, Brando et al., 2008, Grier and Running, 1977, Wright et al., 2013). Across the wet-dry tropical forest transition, LAI declines on average $\sim 1.4 \text{ m}^2\text{m}^{-2}$ (Iio et al., 2014). Brando et al., (2008) report a 21-26% decline in LAI following five years of drought onset at the
95 Amazon throughfall exclusion experiment at Tapajós National Forest, Pará, Brazil. Growth of near surface root mass, length and surface area decline with seasonal drought stress (and increase during periods of high soil water availability to exploit available resources), whilst deep roots can support water supply during dry periods (Nepstad et al., 1994, Metcalfe et al., 2008). Root depth, mass and traits influence hydraulic supply and consequently stomatal conductance.

100 Leaf traits similarly exhibit spatial and temporal variation with changing water availability. Leaf nitrogen content (per unit mass), light- and CO₂-saturated photosynthetic rates (per unit mass) increase with drought stress across tropical precipitation gradients, as ψ_{50} (the water potential at which 50% of hydraulic conductivity is lost) declines (Wright et al., 2004, Santiago et al., 2004, Anderegg, 2015). Leaf traits affect GPP via photosynthetic capacity (V_{cmax} and J_{max}) (Bahar et al., 2017, Fyllas et al.,
105 2017), and through their influence on canopy carbon economics, via leaf growth and maintenance costs (Bloom et al., 1985).

Field observations show variation in Amazon GPP is correlated with physiological, ecosystem structure and trait composition responses to climate (Restrepo-Coupe et al., 2013, Goulden et al., 2004, Hutryra

et al., 2007, Wu et al., 2017, Wagner et al., 2017). Modelling approaches have similarly highlighted the
110 role of canopy dynamics and leaf traits in driving spatial and temporal variation in GPP (Mercado et
al., 2011, Castanho et al., 2013, Restrepo-Coupe et al., 2013, Rodig et al., 2018), however their relative
effects have not been explicitly isolated and quantified. Quantifying the direct effect of discrete
photosynthetic drivers has been limited by the need for detailed field measurements of carbon fluxes,
canopy dynamics and traits. A deserved research effort has focused on the importance of nutrient
115 availability in driving spatial variation in GPP (Mercado et al., 2011, Castanho et al., 2013), however
the role of ecosystem responses to water availability has received less attention (Green et al., 2019). In
light of projected changes in rainfall patterns across the basin, capturing responses to water availability
in ecosystem models is critical to reducing current uncertainty around Amazon climate-vegetation
feedbacks. We aim to reduce the uncertainty by assessing the relative effects of physiological, structural
120 and trait responses to water availability on GPP across monthly to annual timescales.

We apply an ecosystem model to plots across the Amazon, spanning a large drought stress gradient
(herein, the term drought stress refers to seasonal water deficit), and a range in forest types from moist
equatorial to seasonally dry tropical forests. Process modelling allows the links between climate,
ecosystem structure and leaf traits to be quantified explicitly, and separated, across timescales (Figure
125 1). The soil plant atmosphere model (SPA) (Williams et al., 1996, Williams et al., 1998, Fisher et al.,
2006, Fisher et al., 2007, Rowland et al., 2015b) is well suited to this investigation given its prior use
in accurately simulating carbon and water fluxes in Amazon tropical forests. We calibrate and validate
the model using field data gathered over multiple years (2009-2010) on permanent sample plots from
the Global Ecosystems Monitoring (GEM) network (Doughty et al., 2015a, Malhi et al., 2015). The
130 datasets comprise detailed measurements of carbon fluxes, carbon stocks and leaf traits. We simulate
the effect of forest structure and leaf trait distributions along the drought stress gradient, and explore
the covariation of observed leaf traits (leaf N content (a proxy for photosynthetic capacity) and LMA)
and those derived from model calibrations (leaf lifespan), before using SPA to address the following
questions:

- 135 1. Is spatial variation in GPP across the drought stress gradient principally driven by the direct effects of climate and soils, which include physiological responses to water availability via hydraulic transport and stomatal conductance? Alternatively, are indirect effects of climate, via structural and trait responses to water availability (LAI, rooting biomass, root depth and photosynthetic capacity i.e V_{cmax} and J_{max}), more important?
- 140 2. Does the sensitivity of GPP to differences in climate, LAI, photosynthetic capacity (V_{cmax} and J_{max}) and rooting depth vary across the drought stress gradient?
3. What drives seasonal variation in GPP across an Amazon forest drought stress gradient?

Linked to question one, we hypothesise that indirect effects of climate via structural and trait responses are more important than the direct effects (via physiological responses), in explaining spatial variation in GPP across the drought stress gradient (Figure 1). We further posit that LAI is the principal driver of differences in GPP among Amazon forests, effected through the observed increase in leaf area with decreasing drought stress.

For question two, we predict that the sensitivity of GPP to differences in climate, LAI, photosynthetic capacity (V_{cmax} and J_{max}) and rooting depth will vary dependent on water demand (via LAI and stomatal conductance) and supply (climate and root depth and biomass; Figure 1). We expect that forests under lower drought stress will be most sensitive to differences in LAI and photosynthetic capacity within the bounds of observations across the gradient. We predict that forests under higher drought stress will be more sensitive to differences in rooting depth. We expect forests with high LAI but shallow rooting depth will be most sensitive to differences in climate, due to their higher transpiration demand but low capacity for water supply.

For question three, we hypothesise that on monthly timescales, climate will be more important than canopy dynamics in driving GPP. Across the drought stress gradient, we expect that solar radiation will be relatively more important during the wet season. VPD will be more important during the dry season, reflecting seasonal shifts in light and water availability. Due to differences in dry season length, we predict that for forests experiencing lower drought stress, solar radiation will be most important in driving sub-annual variation in GPP. For forests under higher drought stress, VPD will be the dominant

driver.

By combining detailed plot-level timeseries data with a hydrodynamic terrestrial ecosystem model, we are able to use an innovative model experimentation approach to understand the drivers of spatial
165 variation in GPP, beyond correlative effects. We are able to apportion variation in GPP to the direct and indirect effects of climate (Figure 1), across sub-annual and annual timescales (Q1 and Q3). Furthermore, by performing a sensitivity analysis within the context of observed variation in parameters across the Amazon (Q2) we identify areas potentially more vulnerable to changes in precipitation regime.

170 2. Methods

Plot characteristics are summarised in Table 1, and detailed in full in the supplementary material. We characterise plot water status using mean Maximum Climatological Water Deficit (MCWD) and not annual precipitation, as water deficit is more closely linked to the mechanisms constraining GPP, than total water input. MCWD is the maximum cumulative water deficit reached within a year. A water
175 deficit estimate for each month is calculated as the difference between precipitation and transpiration (which ground measurements estimate at $\sim 100 \text{ mm month}^{-1}$, see Aragao et al. (2007)). Therefore, the forest is in water deficit if monthly precipitation falls below 100mm. Maximum cumulative water deficit is calculated as the sum of sequential monthly water deficits (for equations see supplementary material). More negative MCWD values indicate higher drought stress.

180

2.1 The Soil Plant Atmosphere model (SPA)

The Soil-Plant-Atmosphere model (SPA) is a hydrodynamic terrestrial ecosystem model, which has been calibrated and evaluated for moist tropical forests in Manaus and Caxiuanã (Williams et al., 1996, Williams et al., 1998, Fisher et al., 2007). In SPA, carbon and water fluxes are estimated through
185 process-based modelling of radiative transfer, boundary layer and stomatal conductance, plant and leaf ecophysiology and soil-plant energy and water balance (Smallman et al., 2013, Williams et al., 1996). Plant physiological responses to water availability are well represented in SPA due to the stomatal

conductance algorithm being coupled directly to plant water use (Fisher et al., 2006). As a result, higher evaporative demand under increased LAI drives increased root water uptake and consequently a depletion in soil moisture. Within SPA, C allocation between structural tissue and the non-structural C (NSC) pool is executed via the sub model DALEC_{canopy} (Bloom and Williams, 2015) (Figure 2). DALEC_{canopy} was updated on daily timesteps and in this study, forced using LAI observation data. Constraining simulated LAI was integral to the model experiments conducted. It allowed the quantification of direct effects of different LAI timeseries on GPP under different plot conditions. However, the capacity of SPA to accurately simulate canopy dynamics is demonstrated by both López-Blanco et al. (2018) and Sus et al. (2010). To force modelled LAI, LMA (gC m⁻²) and daily LAI estimates were used to calculate the foliar C stock. Leaf NPP was calculated as the difference between the foliar C stock of the current and previous timestep. Leaf NPP was allocated prior to other plant components, and if the leaf NPP requirement exceeded total NPP for the given timestep, the non-structural C pool was drawn upon (where total NPP was calculated as the difference between simulated GPP and autotrophic respiration) (see supplementary material). The NSC pool serves functions additional to the seasonal redistribution of C (e.g. phloem transport and osmoregulation; Dietze et al., 2014). As such, we assume the NSC pool is stable over time. If the NSC pool becomes depleted, a fraction of NPP is redirected towards NSC storage. Allocation towards NSC storage is executed in subsequent time steps when leaf NPP does not exceed total NPP. Root and wood NPP were calculated from the NPP remaining after leaf allocation. Leaf maintenance respiration was calculated as a function of leaf N content (Reich et al., 2008) and total leaf C stock (see supplementary material). Within SPA, wood and fine root maintenance respiration were simulated as a function of component C stock and a plot specific respiration coefficient. Growth respiration was calculated as fixed fraction of net primary productivity (NPP; 0.28) (Waring and Schlesinger, 1985). Model inputs and outputs are listed in Table 2.

2.2 Model Calibration

Following data collation to parameterise SPA, the model was calibrated and validated for each plot
215 prior to conducting model experiments. Measurements used to parameterise SPA include: soil texture,
soil C stock, leaf N content, LMA, photosynthetic capacity, the fraction of NPP allocated to fine roots
and wood, root depth, and foliar, wood and fine root C stocks (Table 2). Soil, wood and fine root C
stocks (single point measurements, not timeseries) were initial model inputs and allowed to vary
thereafter dependent on simulated C dynamics. Plot specific field measurements of leaf N content are
220 presented in Fyllas et al. (2009), or where absent were retrieved from trait databases using plot species
composition (Kattge et al., 2011; Poorter and Bongers, 2006). Photosynthetic capacity estimates (V_{cmax}
and J_{max}) were derived from leaf N content (Walker et al., 2014), or field measurements (Caxiuanã
only). Wood and root respiration measurements were used together with component C stocks to
estimate plot specific wood and root respiration coefficients.

225 The model was driven using hourly meteorological data, retrieved from local weather stations. The
number of missing hourly field meteorological measurements across the timeseries varied from 2-40%
across sites, whilst the frequency of gaps varied from 2-99 yr⁻¹. Gaps less than 6 hours in length
accounted for between 20-100% of total gaps across plots. Short gaps in air temperature, wind speed,
shortwave radiation and vapour pressure deficit measurements (<6 hours), were filled by spline
230 interpolation between existing data. Where local meteorological data was unavailable for a longer
period of time, or for gaps in precipitation measurements, hourly spline-interpolated ERA-Interim data
were used (Dee et al., 2011). The interpolation of solar radiation estimates accounted for the solar zenith
angle. MCWD was calculated for the years 2009-2010, and was consistent with previously published
estimates for all plots excluding Caxiuanã, which were calculated across different years (Malhi et al.,
235 (2015), Caxiuanã -203mm, Tambopata -259mm, Kenia -386mm, Tanguro -482mm; this study,
Caxiuanã -85±65mm, Tambopata -265±59mm, Kenia 342±146mm, Tanguro 451±73mm).

The simulation of soil water drainage in SPA was calibrated against timeseries of field measurements
of soil moisture. Initial investigations comparing modelled soil moisture to monthly field data
highlighted an overestimation by SPA. Pre-calibration, SPA soil moisture estimates were on average

240 11-68% higher than field measurements across plots. The difference between model and field soil moisture estimates increased significantly with MCWD ($R^2=0.69$, $p=0.04$). The empirical model used in SPA to relate soil texture to water retention (Saxton et al., 1986, eqn. 10) was then calibrated by adjusting the slope of the interaction to better represent soil moisture across tropical soils (to within standard error estimates of mean annual soil moisture).

245 Leaf litterfall parameters (day of peak leaf fall, leaf fall period and leaf lifespan) were calibrated against field data to accurately simulate litterfall period and amplitude (within standard error estimates of annual litterfall). Wood and fine root biomass turnover rates were assumed proportional to NPP, given the maturity of stands and their disturbance history:

$$turnover\ rate_i \propto \frac{NPP_i}{C\ stock_i}$$

250 Where i is wood or fine roots.

Local, monthly LAI estimates derived from hemispherical photographs were scaled to daily estimates via linear interpolation, and used to force simulated LAI. The vertical distribution of leaf area is kept constant, as current field data is insufficient to provide an accurate depiction of how vertical distributions change with canopy density across the MCWD gradient.

255 We calculate model uncertainty as a result of input parameters. SPA was forced with the observed LAI timeseries plus and minus the standard error for each plot. Model uncertainty estimates were limited to that derived from LAI as the availability of uncertainty estimates for leaf traits, root depth and root biomass were variable and plot dependent, and there were no uncertainty estimates for hourly meteorological data or soil properties. Model structural uncertainty was not calculated and we recognise
260 that the model error estimates presented are therefore underestimated. With respect to model structural uncertainty, we highlight that the stomatal conductance algorithm embedded within SPA is consistent with leaf and canopy scale observations, and surpasses the performance of the Ball-Berry model where soils experience moisture-stress (Bonan et al., 2014). However, model (and empirical) uncertainty remains around the role of non-structural carbon in regulating water-transport in large trees during

265 drought periods (O'Brien et al., 2014) Furthermore, SPA does not account for hydraulic lift and redistribution of water through the soil profile, which is known to impact water fluxes across the soil-plant-atmosphere continuum in Amazon trees (Oliveira et al, 2005; Wang et al., 2011).

2.3 Model Validation

Observation constrained SPA simulations were validated against biometric field measurements of C
270 fluxes (i.e. from infra-red gas analysers, dendrometers, root ingrowth cores litterfall traps etc.). Linear regression models were constructed to compare modelled estimates and independent field measurements of GPP, autotrophic respiration and total NPP. A comprehensive comparison of model estimates and independent field measurements of component NPP and respiration were also made. Validation of the SPA model against biometric data lent confidence to subsequent analyses, where the
275 model was used to explore C fluxes under non-observed conditions.

2.4 Model Experiments

Our aim was to isolate the direct effects of climate and soils (via physiological responses), and the indirect effects via ecosystem structure, and leaf traits, on simulated GPP. To avoid capturing the feedback effects of changing photosynthate supply (i.e. as a result of changes in climate, soils,
280 ecosystem structure or traits) on ecosystem structure, model experiments were conducted in the absence of C cycle feedbacks. Thus, within model experiments, C stocks for each component (leaves, wood, fine root, coarse root) were constrained to observations unless otherwise stated.

2.4.1 Experiment 1. Drivers of Spatial Variation in GPP

Through a series of model input alternations, we used SPA to quantify the effects of (i) climate, (ii) soil
285 properties, (iii) LAI, (iv) root biomass and (v) rooting depth, and (vi) trait responses driven by photosynthetic capacity (V_{cmax} and J_{max}), on simulated GPP. Model inputs for each driver were alternated at each plot, to that of all other plots, and annual GPP values for each of the two years retrieved. For example, plot CAX04 was simulated with the climate, soil properties, LAI, root biomass, root depth and photosynthetic capacity of CAX06, TAM05, TAM06, KEN01, KEN02, and Tanguro
290 etc. (Figure S1). SPA simulated GPP for a total of 462 combinations (for climate, 7 plots \times 3 alternations \times 2 years, plus for the remaining drivers, 5 drivers \times 7 plots \times 6 alternations \times 2 years) were combined

with 14 annual GPP estimates from observation constrained (control) runs (7 plots \times 2 years). A factorial ANOVA was applied to the difference between GPP from each model run and its control simulation (n=476, i.e. 462 +14) (Galbraith et al., 2010). The proportions of variation in GPP explained by climate, soil properties, LAI, photosynthetic capacity, root biomass and rooting depth, were then calculated as the conditional sum of square divided by the total sum of squares.

2.4.2 Experiment 2. Variation in Forest Sensitivity to Drivers of GPP

We quantified how the relative sensitivity of GPP to differences in LAI, climate, photosynthetic capacity and rooting depth varied across the MCWD gradient. For example, we tested whether forests occupying lower drought stress zones were more sensitive to differences in LAI than forests in higher drought stress zones, etc. We used model outputs generated in *Experiment 1* to calculate the sensitivity of GPP to drivers at each plot, within the bounds of observations across the MCWD gradient. Root biomass and soil properties were not included in the analysis as across the MCWD gradient they explained little variation in GPP (*Experiment 1*, Table 6). The sensitivity of GPP to drivers at each plot was calculated as the absolute range in simulated GPP values under each driver alternation i.e. the sensitivity of CAX04 to variation in LAI was calculated as the maximum GPP minus the minimum GPP simulated by alternating LAI to that of all other plots etc. Plots were grouped by location (Caxiuanã, Tambopata, Kenia and Tanguro) to compare how the sensitivity of GPP to LAI, climate, photosynthetic capacity and rooting depth varies across the MCWD gradient.

2.4.3 Experiment 3. Drivers of Sub-Annual Variation in GPP

We quantified the role of climate and LAI in explaining variation in sub-annual GPP. We used the random forest technique to compute the relative importance of LAI, VPD, solar radiation, precipitation and air temperature driving variation in monthly GPP (n=168; 7 plots \times 24 months), where GPP estimates were derived from SPA simulations. To quantify the effects of LAI and climate variables on monthly GPP we used the random forest machine learning technique applied by means of the Python Scikit-Learn module (Breiman, 2001, Pedregosa et al., 2011). The approach uses multiple mathematical decision tree predictors to describe a dependent variable as a function of selected independent variables. An importance value between 0 and 100 was assigned to each driver based on a tree-wise comparison

of explanatory power (Moore et al., 2018, López-Blanco et al., 2017). We calculated the average relative
320 importance of drivers at each plot to determine the principal drivers of variation in sub-annual GPP and
investigated the seasonality of driver importance.

3. Results

3.1 Model Calibration

Calibrated SPA soil water content corresponded well to field measurements from the GEM network
325 (Figure 3). Simulated mean annual soil moisture estimates were within field measurement standard
error for all plots. The timing of observed peak soil moisture was captured by SPA simulations
($R^2=0.98$, $p<0.001$, RMSE=1 month). A positive, but non-significant, correlation existed between
model and field estimates of seasonal soil moisture range ($R^2=0.35$, $p=0.21$, RMSE=5%). Notably, for
some plots such as Kenia, the magnitudes of seasonal peak soil water fluxes were not captured by SPA
330 simulations (up to 39% lower than field estimates). For Tanguro, peak soil water lasted 3 months longer
in SPA simulations than was measured in the field.

SPA was also successfully calibrated to simulate local leaf litterfall accurately. The calibration of leaf
fall cycle parameters in SPA using GEM leaf litterfall timeseries (Table 4), resulted in the magnitude
and timing of leaf litterfall being well represented by the model for all plots (monthly leaf litterfall range
335 for GEM measurements and SPA simulations $R^2=0.54$, $p=0.009$, RMSE= 11.2 gC m⁻² yr⁻¹; timing of
leaf litterfall peak $R^2=0.96$, $p<0.001$, RMSE=1.1 months) (Figure 4). SPA-simulated mean annual leaf
litterfall correlated significantly with GEM estimates ($R^2=0.99$, $p<0.001$, RMSE=9.0 gC m⁻² yr⁻¹).

3.2 Model Validation

Estimates of ecosystem-scale C fluxes from SPA model runs were validated against biometrically
340 derived estimates from the GEM network. GPP_{SPA} and GPP_{GEM} estimates were correlated across plots,
though not significantly ($R^2=0.36$, $p=0.15$; Figure 5a). Along the MCWD gradient, GPP_{SPA} estimates
varied across plots by 1137 gC m⁻² yr⁻¹, in line with GPP_{GEM} estimates which varied by 1202 gC m⁻² yr⁻¹.
Error bars overlap between GPP_{SPA} and GPP_{GEM} estimates for all plots except KEN01 and TAM06,

though marginally (difference KEN01 115 gC m⁻² yr⁻¹, TAM06 50 gC m⁻² yr⁻¹). GPP_{GEM} error bars are
345 field estimate standard error, and GPP_{SPA} error bars represent simulated GPP variance under LAI
standard error. Across plots, GPP_{SPA} estimates were 0.57% higher than GPP_{GEM} estimates. The
correlation between GPP and MCWD was similar for GPP_{SPA} (R²=0.64, p=0.03, slope=2.4) and GPP_{GEM}
estimates (R²=0.52, p=0.07, slope=2.00).

NPP_{SPA} estimates (the sum of model simulated root and wood NPP and data-constrained leaf NPP) were
350 also correlated with NPP_{GEM} measurements across plots (R²=0.38, p=0.14), though not significantly due
to differences in Kenia plots (on exclusion of Kenia plots R²=0.92, p= 0.01, RMSE=42 gC m⁻² yr⁻¹)
(Figure 5b). NPP_{SPA} estimates were 7.9% lower than field measurements across plots on average. Ra_{SPA}
(the sum of predicted leaf respiration, and parameterised root and wood respiration) were significantly
correlated with biometric measurements (Ra_{GEM}) across plots (R²=0.59, p=0.04; Figure 5c), though
355 were on average 5.3% higher.

Leaf respiration estimates simulated as a function of leaf nitrogen content were correlated with field
measurements, though not significantly (R²=0.47, p=0.09; Table 5). Parameterised wood and fine root
respiration, together with fine root NPP, correlated significantly with field measurements. SPA
estimates of wood NPP did not correlate significantly with GEM measurements due to underestimation
360 at KEN01 (on exclusion R²=0.78, p=0.02, RMSE=7.5 gC m⁻² yr⁻¹). Further comparisons of SPA
estimates and GEM measurements of component NPP and respiration are presented in Table 5.

3.4 LAI and Leaf Traits Trends along the MCWD gradient

Field estimated mean annual LAI ranged from 2.2 to 5.2 m² m⁻², and increased (though not significantly)
with MCWD across plots (R²=0.35, p=0.16; Table 3). A negative, non-significant correlation existed
365 between calibrated leaf lifespan and MCWD (R²=0.50, p=0.08). Photosynthetic capacity (V_{cm_{max}} and
J_{max}) estimates derived from measured leaf N content similarly exhibited a negative non-significant
correlation with MCWD (R²=0.51, p=0.07 and R²=0.53, p=0.06 respectively). A positive non-
significant correlation existed between model-calibrated leaf lifespan, measured LMA (log-log
R²=0.39, p=0.14), and LAI (R²=0.28, p=0.22). Model-calibrated leaf lifespan exhibited a negative, non-

370 significant correlation with photosynthetic capacity estimates (V_{cmax} $R^2=0.46$, $p=0.09$; J_{max} $R^2=0.47$,
375 $p=0.09$). A significant positive correlation existed between mean annual LAI and LMA ($R^2=0.85$,
 $p=0.003$).

3.5 Model Experiments

3.5.1 Experiment 1. Drivers of Spatial Variation in GPP

375 Structural and trait responses to water availability explained more variation in GPP across the MCWD
gradient than did climate. LAI accounted for the largest proportion of variance in mean annual GPP
across plots (32.8%, Table 6). Differences in photosynthetic capacity explained 21.3% of variance.
Photosynthetic capacity increased with decreasing MCWD; this relationship partially offset the
decrease in GPP linked to declining LAI. The direct effects of climate on GPP (which included
380 physiological responses to water availability including stomatal conductance) accounted for 16.2% of
plot variation in mean annual GPP. Rooting depth did not vary directionally with MCWD and
consequently only had a small effect on GPP (4.1%). Soil properties and root biomass accounted for a
very small fraction of variance (<2%).

3.5.2 Experiment 2. Variation in Forest Sensitivity to Drivers of GPP

385 The relative sensitivity of GPP to drivers varied across the MCWD gradient (Figure 6). GPP was most
sensitive to changes in LAI (per unit m^2 leaf area) for plots located at Caxiuanã, which experience the
least negative MCWD and have large rooting depth. The sensitivity of GPP to LAI exhibited a positive,
non-significant correlation with MCWD ($R^2=0.88$, $p=0.06$). Reflecting LAI trends, the sensitivity of
GPP to differences in photosynthetic capacity (per unit $\mu\text{mol C g s}^{-1}$) was similarly highest at Caxiuanã,
390 and decreased linearly (though not significantly) across the MCWD gradient ($R^2=0.83$, $p=0.09$).
Tambopata plots, which have high LAI but shallow rooting depth, were most sensitive to differences in
climate (per unit MCWD mm). Kenia plots, which have similarly shallow rooting depth but low LAI,
were the least sensitive. The sensitivity of GPP to differences in rooting depth (per m rooting depth)
was highest at Tanguro and Tambopata, and lowest at Caxiuanã and Kenia.

395 3.5.3 Experiment 3. Drivers of Sub-Annual Variation in GPP

In contrast to drivers of spatial variation in GPP, on a sub-annual timescale LAI had less explanatory power than climate (Tables 6 and 7). The relative importance of solar radiation in driving monthly GPP increased significantly with MCWD ($R^2 = 0.90$, $p < 0.001$), as the relative importance of LAI declined ($R^2 = 0.72$, $p = 0.015$). The relative importance of VPD did not vary directionally across the MCWD
400 gradient ($R^2 = 0.10$, $p = 0.49$). Both precipitation and air temperature had little effect on monthly GPP, though it is noted that a significant interaction existed between both precipitation and VPD ($p < 0.001$) and air temperature and shortwave radiation ($p < 0.001$). Furthermore, temperature varied least across plots in comparison to other climate forcings (standard deviation as a percentage of the mean; temperature 9.8%, VPD 73%, precipitation 192%, shortwave radiation 34%). As such, seasonal changes
405 in the relative importance of temperature and precipitation were not investigated further. The relative importance of LAI, VPD and solar radiation shifted seasonally, reflecting changes in the availability of light and water. Solar radiation was typically the most important driver of monthly GPP during the wet season, whilst VPD was more important during the dry season (Figure 7). The relative importance of LAI forcings peaked before dry season onset for forests under lower drought stress (Caxiuanã and
410 Tambopata), and during the dry season for forests under higher drought stress (Kenia and Tanguro). Notably, LAI was also more important during the dry season at KEN02, which occupies shallow soil (<1m) in comparison to KEN01.

4. Discussion

4.1 LAI and Leaf Traits along the MCWD gradient

415 Leaf trait parameters retrieved from SPA litterfall calibrations suggest a wide range of potential leaf lifespans across the MCWD gradient (~1-3 years), and are in accordance with estimates for Amazon tree species, reported by Reich et al. (1991) of between two months and four years (Table 4). Leaf trait estimates co-varied across the MCWD gradient, in line with leaf economic theory (Wright et al., 2004). However, the interactions were often not significant. We suggest that in instances where R^2 values
420 indicate a large proportion of variation is explained, high p-values may have occurred as a result of a

small sample size (i.e. 7 plots). As drought stress increased, a shift towards deciduous strategies resulted in reduced leaf lifespan, but higher photosynthetic capacity. The co-variation of leaf traits along the MCWD gradient shapes both the rate of carbon assimilation (via photosynthetic capacity), and the carbon economics of canopy dynamics (via LMA, leaf lifespan and metabolic rate). Coincident with changes in leaf traits, mean annual LAI increased with decreasing drought stress. Research efforts have focused on mapping LAI (Iio et al., 2014) and leaf trait (Kattge et al., 2011, Asner et al., 2015) distributions across climatic gradients, however their covariance has not yet been explored. Given the role of leaf traits in shaping canopy carbon economics, the mechanisms underpinning LAI and leaf trait distributions across the resource availability gradient could prove important in understanding the effect of changes in precipitation regime on future Amazon carbon dynamics.

4.2 Drivers of Spatial Variation in GPP

Indirect effects of climate via ecosystem structure and long-term trait responses to water availability accounted for 54% of variation in GPP (Q1; Figure 1). Direct effects of climate (which included physiological responses to water availability) accounted for only 16% of observed variance (Table 6). Our results are consistent with previous reports on the importance of ecosystem structure and traits in determining spatial variation in GPP (Rodig et al., 2018, van de Weg et al., 2013, Reichstein et al., 2014), but go further to quantify the direct contribution of discrete drivers to observed variation in carbon assimilation. LAI explained the greatest proportion of variation in GPP, followed by photosynthetic capacity. Root and soil properties had little explanatory power.

Evidence of changes in LAI in response to precipitation regime has been presented across multiple ecosystems and over time (Grier and Running, 1977, Schleppi et al., 2011, Iio et al., 2014, Dobbertin et al., 2010, Wright et al., 2013). Amazonian forest throughfall exclusion experiments identified a decline in LAI with the onset of reduced soil water (Fisher et al., 2007, Meir et al., 2008, Brando et al., 2008). At Caxiuanã, over a 4-year period, observed leaf area was 20-30% lower than the control stand (Meir et al., 2009), with long-term reductions estimated at between 10-15% (Rowland et al., 2015a). Investigations show that declines in LAI are not caused by increased leaf turnover due to drought stress, but instead are the result of lower leaf production (Nepstad et al., 2002, Schuldt et al., 2011), suggesting

an active response of plant allocation strategy to water availability. Concurrently, after 15 years under throughfall exclusion, Rowland et al. (2018) found that leaf litterfall still remained consistently lower. Reported trends in canopy dynamics are therefore in accordance with our findings, and indicate that LAI is a key response mechanism to precipitation regime. Other studies such as da Costa et al. (2018) have similarly pointed towards structural responses as the principal determinant of variation in GPP, however, they identify changes in sapwood area as the main driver, rather than LAI. We suggest that whilst sapwood area may be more important in shaping the response to short term changes in precipitation, over longer timescales emergent canopy properties (LAI) drive GPP trends.

Photosynthetic capacity also proved an important driver of spatial variation in GPP across the MCWD gradient. Our results are consistent with a number of Amazon-based studies linking leaf traits to productivity (Aragao et al., 2009, Cleveland et al., 2011, Castanho et al., 2013). Interestingly, the observed shifts in photosynthetic capacity along the gradient had a compensatory effect on the GPP-MCWD interaction. Reductions in GPP under high drought stress were alleviated by higher photosynthetic capacitance. Similarly, shifts in photosynthetic capacity in response to temperature have been reported to reduce spatial variation in GPP across a tropical elevation gradient (Bahar et al., 2017, van de Weg et al., 2013). Consistent with Fyllas et al. (2017), our results also show that the effect of climatic forcings on carbon fluxes can be successfully captured through spatial variation in canopy dynamics and leaf traits. However, as we have focused on the role of leaf traits in the absence of carbon cycle feedbacks, we do not take into account the effect of concurrent shifts in LMA and leaf lifespan, which together influence canopy carbon economics (Wright et al., 2004, Osnas et al., 2013, McMurtrie and Dewar, 2011).

Root depth, root biomass and soil properties had little direct effect on spatial variation in GPP. We recognise that the difficulty in measuring root depth and biomass (Metcalf et al., 2007) adds uncertainty to our results, however, the findings do not reflect the importance of belowground functioning highlighted by other studies (Fisher et al., 2007, Metcalfe et al., 2008, Baker et al., 2008, Phillips et al., 2009, Ichii et al., 2007). Notably, a number of GEM plots had hard pan layers (Quesada et al., 2012) so they may be acclimated to operate in shallow rooting zones, and are therefore not

475 necessarily representative of other Amazon forests under the same precipitation regime. Differences in
root depth and biomass can alleviate water constraints to photosynthesis via the direct physiological
pathway (i.e stomatal conductance). But in the absence of C cycle feedbacks, changes in root depth and
biomass do not drive changes in emergent canopy properties (i.e. LAI) which proved most important in
determining GPP. It is therefore likely that if feedbacks were enabled within analyses, root and soil
480 properties would prove to have a stronger effect.

4.3 Variation in Forest Sensitivity to Drivers of GPP

The sensitivity of GPP to differences in LAI, climate, photosynthetic capacity and rooting depth varied
across the MCWD gradient with evaporative potential and water uptake capacity (Q2; Figure 6). As the
model experiment was conducted in the absence of carbon cycle feedbacks, sensitivities reflect shorter
485 rather than long-term effects of changes in forcings. The sensitivity of GPP to differences in LAI and
photosynthetic capacity was greatest for forests occupying the lowest drought stress zone and declined
with increasing drought stress. Our results are in agreement with findings from Wright et al. (2013),
who reported that GPP was most sensitive to decreases in leaf area when water availability was highest.
Forests with a high LAI (and therefore high evaporative potential) but shallow rooting depth were most
490 sensitive to differences in climate. Our results suggest that where rooting depth is relatively shallow,
and unable to ameliorate the effects of drought stress as seen elsewhere (Nepstad et al., 2007, Malhi et
al., 2009a), forests with a high LAI could be more vulnerable to reduced precipitation. Investigations
into the vulnerability of Amazon forests to drought have put a deservedly large emphasis on the role of
physiological responses (Choat et al., 2012, Phillips et al., 2009, Bennett et al., 2015, Corlett, 2016).
495 However, our results indicate that the role of ecosystem structure could also prove important, and that
forests with a high evaporative potential (high LAI) but low water uptake capacity (shallow rooting
depth) should be a focus for future studies.

4.4 Drivers of Sub-Annual Variation in GPP

Seasonal (i.e. sub-annual) variation in GPP was driven by changes in solar radiation, VPD and LAI.
500 The relative importance of these factors was dependent on MCWD (Q3; Figure 7). Shortwave radiation

was the dominant driver of sub-annual variation in GPP across plots, but its relative importance was greater for moister forests (Table 7). The relative importance of LAI in driving sub-annual GPP increased with drought stress. In accordance with our findings, a number of studies report that for Amazon forests in higher rainfall zones, GPP increases in line with solar radiation, and for forests subject to significantly low annual rainfall GPP declines with increased VPD (Von Randow et al., 2013, Goulden et al., 2004, Hutrya et al., 2007, Saleska et al., 2003, Rowland et al., 2014, Carswell et al., 2002). Our results suggest that LAI is not the principal driver of sub-annual variation in GPP, in contrast to its role in driving spatial variation across the MCWD gradient. However, while other studies agree that leaf area alone does not drive variation in sub-annual GPP (Wu et al., 2017, Wu et al., 2016, Brando et al., 2010, Restrepo-Coupe et al., 2013, Bi et al., 2015), we do not account for potential shifts in photosynthetic capacity with leaf age. The coordination of leaf age (via leaf flushing and new leaf emergence) with climatic drivers such as solar radiation is thought to exceed the effects of LAI in non-water limited forests (Myneni et al., 2007). We further recognise the uncertainty introduced through using leaf N content to derive photosynthetic capacity estimates (for five of the seven plots), given the distribution of leaf N between photosynthetic and non-photosynthetic proteins is not fixed (Onoda et al., 2017). However, notwithstanding temporal variation in photosynthetic capacity, we demonstrate that the relative importance of LAI dynamics and climatic forcing driving variation in GPP shift with light and water availability.

Our results indicate that with respect to drought stress, annual GPP is constrained via indirect pathways (i.e. ecosystem structure and traits) across spatial scales, but is limited via direct pathways (i.e. physiology) across sub-annual timescales (Figure 1). In a study on net ecosystem exchange (NEE), Richardson et al., (2007) found that indirect pathways became progressively more important in driving NEE as the period of integration was lengthened (for a spruce-dominated forest in Maine, USA). The authors reasoned that the shift from direct to indirect pathways (as the period of integration transitions through day-week-month-seasonal-annual), reflected the timescales over which these processes operate. Stomata vary at hourly time scales with meteorology and soil conditions. The shift in direct to indirect pathways driving GPP variance reported here can similarly be explained by the difference in

timescales over which responses to drought stress operate. LAI varies over monthly timescales, constrained by C and nutrient investment requirements over years. As a result, over monthly timescales, up to one third of variation in GPP was explained by indirect effects of climate (i.e. LAI; Table 7), but direct effects (via physiological responses) remained the dominant driver (consistent with Richardson et al., 2007). Across the drought stress gradient, structural and trait responses to water availability (across annual to decadal timescales) result in indirect pathways dominating the GPP response, and the direct effects of climate are less important.

535 *4.5 Limitations and Opportunities*

As nutrient dynamics are not directly accounted for in SPA, we are unable to quantify the impact of soil nutrients on the GPP-MCWD interaction. Soil nutrient availability varied widely across plots (Table 1). We recognise that nutrient limitation likely impacts GPP across the MCWD gradient, effected through both nutrient availability and plants acquisition capacity (which is dependent on moisture-stress). However, there was no significant interaction between GPP and soil phosphorous (GEM $R^2=0.1$, $p=0.48$; SPA $R^2=0.01$, $p=0.81$) or soil nitrogen (GEM $R^2=0.37$, $p=0.14$; SPA $R^2=0.31$, $p=0.19$). Furthermore, we expect to capture soil nutrient effects via the inclusion of site specific leaf nutrient estimates as a model inputs (which influence simulated photosynthetic and metabolic rate).

We recognise that the lack of significant correlation between SPA and GEM GPP estimates could impact the interpretation of our results. However, we argue that five of the seven plot estimates were within the error bounds of field measurements, and that the inferential statistics used were limited by our small sample size ($n=7$). We also note that GEM GPP error estimates (calculated as the propagated standard error of component NPP and respiration measurements) do not account for assumptions used in scaling biometric measurements to plot level (e.g. uncertainty in using estimated total woody surface area to scale stem CO_2 efflux measurements).

Given the importance of LAI in driving variation in GPP, data on canopy dynamics is critical to constrain carbon flux estimates across the Amazon basin. Our approach utilised field estimates of LAI from hemispherical photographs to constrain model simulations. The accuracy and spatial validity of

indirect estimates of LAI has been questioned at higher leaf areas (Bréda, 2003, Jonckheere et al., 2004,
555 Weiss et al., 2004). In this study, we expect that if field measurements of LAI were underestimated at
higher leaf areas, the proportion of spatial variation in GPP explained by LAI would increase, as a result
of increased variation in both field-measured and model simulated GPP. Yet, our highest estimates of
LAI (Caxiuanã $5.11 \pm 1.41 \text{ m}^2\text{m}^{-2}$) align with destructive sampling measurements from a terra-firme
Amazon forest (McWilliam et al. (1993) $5.7 \pm 0.5 \text{ m}^2\text{m}^{-2}$). Furthermore, a comparison of LAI estimation
560 approaches (Asner et al., 2003) suggested that indirect methods were appropriate for broadleaved
forests, and presented no statistical difference between destructive harvesting and indirect methods.
However, the use of ground measurements is limited to smaller spatial scales, and LAI estimates across
the basin are needed to constrain carbon flux estimates. Though the interpretation of forest responses
to drought stress through remote sensing approaches have caused controversy (Asner and Alencar,
565 2010, Saleska et al., 2007, Samanta et al., 2010), an increase in canopy mapping through satellite
missions could be instrumental to efforts aiming to better understand LAI dynamics. Current and
upcoming satellite missions including FLEX (FLuorescence EXplorer), GEDI (Global Ecosystem
Dynamics Investigation) and Sentinel will offer opportunity for new insights into changes in leaves in-
situ, vertical canopy structure, and temporal variability via repeat measurements (Morton, 2016, Drusch
570 et al., 2017, Pettorelli et al., 2018). Efforts to map trait distributions will also prove important (Kattge
et al., 2011, Asner et al., 2015) given their role in driving variation in GPP.

5. Conclusion

We show that indirect effects of climate (via ecosystem structure and trait responses) exceed direct
effects (via physiological responses) in driving spatial variation in GPP across an Amazon MCWD
575 gradient (Q1). Conversely, across sub-annual timescales, the reverse was true (Q3). The relative
sensitivity of GPP to changes in direct and indirect forcings shifted across the MCWD gradient and was
dependent on water availability, demand and acquisition potential (Q2). We identify the potential
vulnerability of forests with a high evaporative potential (i.e. high LAI), but low water uptake capacity
(i.e. shallow rooting depth), to changes in precipitation regime. Given the role of LAI in driving GPP
580 across the drought stress gradient, we highlight a requisite for improved mapping of canopy dynamics

(via remote sensing). We propose that ecosystem model development should focus on the integration of structural and trait responses to drought stress (alongside physiological responses). The inclusion of both direct and indirect effects of climate in ecosystem models, would reduce current uncertainty in predicted annual and sub-annual GPP for tropical forests.

585 **Supplementary Material**

Supplementary material is included in a separate document.

Authorship Contributions Sophie Flack-Prain, Mathew Williams and Patrick Meir conceived the research questions. Data used in model calibration and validation was collected by Yadvinder Malhi and associates. Model experiments were designed and conducted by Sophie Flack-Prain with
590 contributions from Mathew Williams and Thomas L. Smallman. Sophie Flack-Prain and Mathew Williams prepared the manuscript with active contributions from all co-authors.

Conflict of Interest Statement: There are no conflicts of interest to disclose.

Acknowledgements: The authors would like to thank the Global Ecosystems Monitoring network team for the field data used in this study, collected through funding from NERC and the Gordon and Betty
595 Moore Foundation, and an ERC Advanced Investigator Award to YM (GEM-TRAIT). The authors would also like to thank the PhD project funding body, the UK Natural Environment Research Council E3 DTP, the National Centre for Earth Observation, the UKSA project Forests 2020 and the Newton CSSP Brazil. The TRY trait database is thanked for the data used in model parameterisation.

1000 Table 1. Amazonian Forest Inventory Network (RAINFOR) site code and environmental characteristics of GEM network Amazon permanent sample plots across the MCWD gradient. Meteorological data is from local weather stations, gap filled with ERA interim data for the years 2009-2010 (Dee et al., 2011).

Plot name	Caxiuanã	Caxiuanã	Tambopata	Tambopata	Kenia	Kenia	Tanguro
	Control	Tower	V	VI	Wet	Dry	Control
RAINFOR- site code	CAX04	CAX06	TAM05	TAM06	KEN01	KEN02	---
Latitude	-1.716	-1.737	-12.831	-12.839	-16.016	-16.016	-13.077
Longitude	-51.457	-51.462	-69.271	-69.296	-62.73	-62.73	-52.386
Elevation (m.a.s.l)	47		223		384		385
Mean Maximum Climatological Water Deficit (mm)	-85.5		-256		-342		-498
Mean annual air temperature (°C)	26.1		24.6		23.4		25.4
Soil Type	Vetic Acrisol	Ferralsol	Cambisol	Alisol	Cambisol	Cambisol	Ferralsol
Soil N (%)	0.06	0.13	0.16	0.17	0.22	0.17	0.16
Soil P _{total} (mg kg ⁻¹)	37.4	178.5	256.3	528.8	447.1	244.7	147

Table 2. Summary of the relationship between model variables and field data. Values are either a SPA model parameter (input) or output. Model parameters may be initial conditions, a fixed value, or a time-series, whereby the parameter value at each time point is prescribed to the model. Model outputs are generated on either an hourly or daily time-step and are presented in the text as the mean annual sum (2009-2010), unless otherwise stated. Model outputs are calibrated or evaluated using field data. Values are specific to each of the seven GEM Amazonian permanent sample plots.

Value	Model Parameter or Output	Source of Value or Calibration/Validation Data
LMA	parameter (single fixed)	GEM plot-measured value or literature-based estimate from plot species list
V_{cmax}	parameter (single fixed)	(estimate from) GEM plot-measured value or TRY database estimate from plot species list
J_{max}	parameter (single fixed)	(estimate from) GEM plot-measured value or TRY database estimate from plot species list
Leaf N content	parameter (single fixed)	GEM plot-measured value or TRY database estimate from plot species list
LAI	parameter (timeseries fixed)	GEM monthly plot-measured value
Leaf NPP	output	model calibration to GEM plot-measured leaf litterfall and LAI

Wood NPP

fraction of total NPP parameter (single fixed) GEM plot-measured value

total wood NPP output simulated value validated against GEM field-measured total wood NPP

Root NPP

fraction of total NPP parameter (single fixed) GEM plot-measured value

total root NPP output simulated value validated against GEM field-measured total root NPP

Leaf turnover parameter (single fixed; function of three individual fixed parameters relating to the leaf litterfall cycle) model calibration to GEM plot-measured leaf litterfall

Root turnover parameter (single fixed) estimated using root NPP assuming steady state conditions

Wood turnover parameter (single fixed) estimated using wood NPP assuming steady state conditions

Foliar C stock parameter (timeseries fixed) product of LAI and LMA

Wood C stock	parameter	initial	condition;	initial condition uses GEM plot-measured DBH values converted to C stock using allometric equation
	thereafter	output		output calculated in SPA as simulated wood C stock plus NPP minus turnover
Root C stock	parameter	initial	condition;	initial condition used GEM plot-measured root stock values or literature-based estimate
	thereafter	output		output calculated in SPA as simulated root C stock plus NPP minus turnover
Leaf respiration		output		sum of leaf maintenance and growth respiration; maintenance respiration generated using measured leaf N content, foliar C stock and the Reich <i>et al.</i> , (2008) leaf respiration model, validated against GEM estimates; growth respiration calculated in SPA as leaf NPP × 0.28
Wood respiration		output		sum of wood maintenance and growth respiration; maintenance respiration calculated as a function of wood C stock, the coefficient being derived from GEM estimates; growth respiration calculated in SPA as wood NPP × 0.28

Root respiration	output	sum of root maintenance and growth respiration; maintenance respiration calculated as a function of root C stock, the coefficient being derived from GEM estimates; growth respiration calculated in SPA as $\text{root NPP} \times 0.28$
Respiration	output	sum of simulated leaf, wood and root respiration, evaluated against GEM data
GPP	output	generated through SPA process-based modelling of GPP using detailed parameters, evaluated against GEM data
NPP	output	calculated in SPA as GPP minus autotrophic respiration, evaluated against GEM data

1025 Table 3. Field estimated mean annual leaf area index (LAI), leaf traits, maximum rooting depth and fine root biomass for Amazon permanent sample plots along a MCWD gradient. LAI estimates were derived from monthly hemispherical photographs. LAI, leaf trait and rooting depth estimates were used to constrain SPA model runs. Estimate standard errors are presented in brackets. Fine root C stock estimates were absent for Tanguro plots.

	LAI (m ² m ⁻²)	LMA (g m ⁻²)	leaf N content (g m ⁻²)	Maximum Rooting Depth (m)	Fine Root C Stock (g C m ⁻²)
CAX04	4.99 (± 1.07)	93 (± 17)	1.82 (± 0.43)	8	345
CAX06	5.23 (± 0.92)	87 (± 54)	2.12 (± 0.7)	10	433
TAM05	4.85 (± 0.81)	101 (± 24)	2.38 (± 0.56)	1	770
TAM06	4.64 (± 0.77)	96 (± 21)	2.51 (± 0.64)	1	500
KEN01	2.77 (± 0.17)	53 (± 13)	2.12 (± 0.25)	2	818
KEN02	2.22 (± 0.14)	42 (± 13)	2.31 (± 0.31)	1	607
Tanguro	4.13 (± 1.01)	64 (± 13)	2.01 (± 0.52)	<10	-

1030

1035

Table 4. SPA calibrated leaf litterfall parameters for plots across an Amazon MCWD gradient. Peak leaf fall is the day of year leaf litterfall reaches its maximum, leaf lifespan reflects maximum lifespan of leaves and leaf fall period is the number of days over which systematic increases in leaf fall occur. Leaf litterfall parameters were calibrated against GEM field estimates to capture leaf litterfall and timing.

1040

	Peak Leaf Fall (day of year)	Leaf Lifespan (years)	Leaf Fall Period (days)
CAX04	210	3.00	150
CAX06	190	1.45	100
TAM05	220	1.30	130
TAM06	230	1.42	100
KEN01	200	1.05	100
KEN02	180	1.01	100
Tanguro	180	1.04	120

1045

1050 Table 5. A comparison of GEM field measurements and SPA process-based modelling estimates of component autotrophic respiration and NPP. We present the R^2 , p-value, and root mean square error (RMSE) of the interaction between SPA and GEM annual estimates, together with the range in GEM biometrically derived estimates across seven sample plots at four locations in the Amazon basin.

Component	R^2	p-value	RMSE	Range in Field Estimates (gC m⁻² yr⁻¹)
Respiration				
Foliage	0.47	0.09	92.0	454-830
Wood	0.75	0.01	100.5	411-1054
Fine Root	0.91	<0.001	74.1	232-1041
NPP				
Foliage	0.99	<0.001	9.0	150-491
Wood	0.21	0.30	25.3	189-292
Fine Root	0.59	0.04	49.5	189-418

1055

1060

1065 Table 6. The proportion of variation in GPP across seven GEM Amazonian permanent sample plots explained by photosynthetic drivers in SPA. Model drivers were alternated individually at each plot to that of all other plots and the resultant change in GPP retrieved. Proportion of variance explained was calculated as conditional sum of squares divided by the total sum of squares (n=476; where the conditions were LAI, photosynthetic capacity, rooting depth, root biomass, climate and soil).

Driver	Percentage of Variation Explained (%)
LAI	32.8
Photosynthetic capacity	21.3
Climate	16.2
Root depth	4.1
Soil	1.2
Root biomass	0.7

1070

1075

1080 Table 7. The relative importance of LAI, VPD, solar radiation, precipitation and air temperature (T_{air})
 in driving monthly variation in GPP (%). Monthly GPP estimates are derived from calibrated SPA
 simulations for seven permanent sample plots across an Amazon MCWD gradient, constrained using
 monthly field LAI measurements. Relative importance values were derived from analyses using the
 random forest technique (n=168).

Plot	LAI	VPD	Solar Radiation	Precipitation	T_{air}
CAX04	13	17	58	8	5
CAX06	6	16	64	8	5
TAM05	17	22	53	3	5
TAM06	17	21	53	3	7
KEN01	16	21	45	10	8
KEN02	32	14	42	4	8
Tanguro	33	20	24	6	10

1085

1090

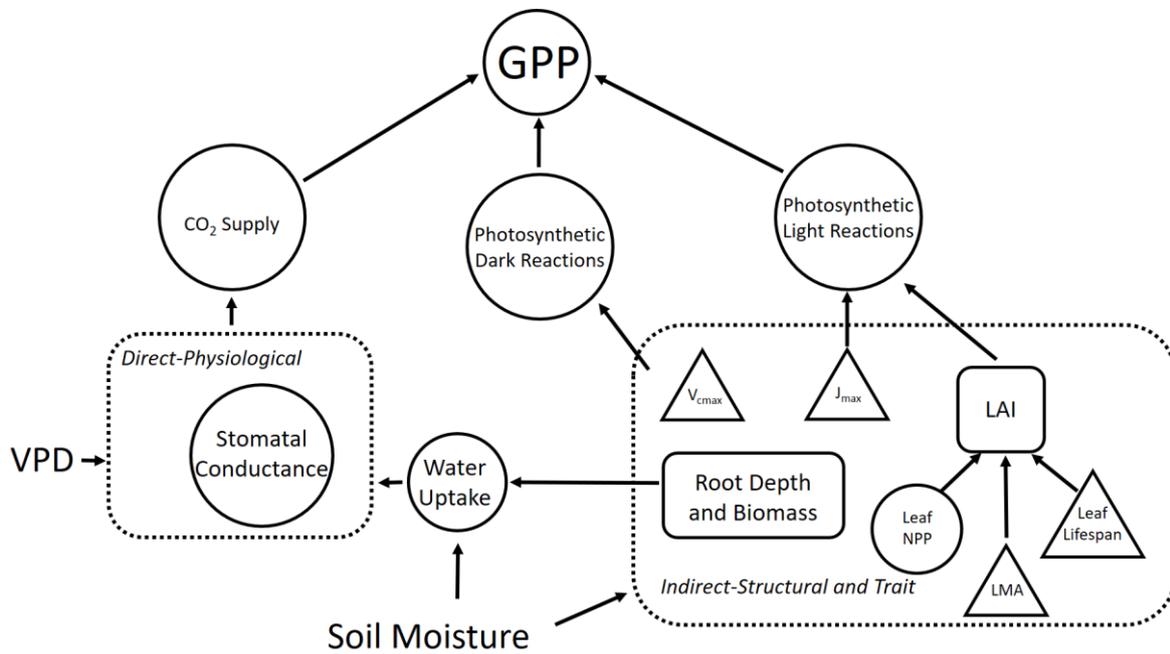

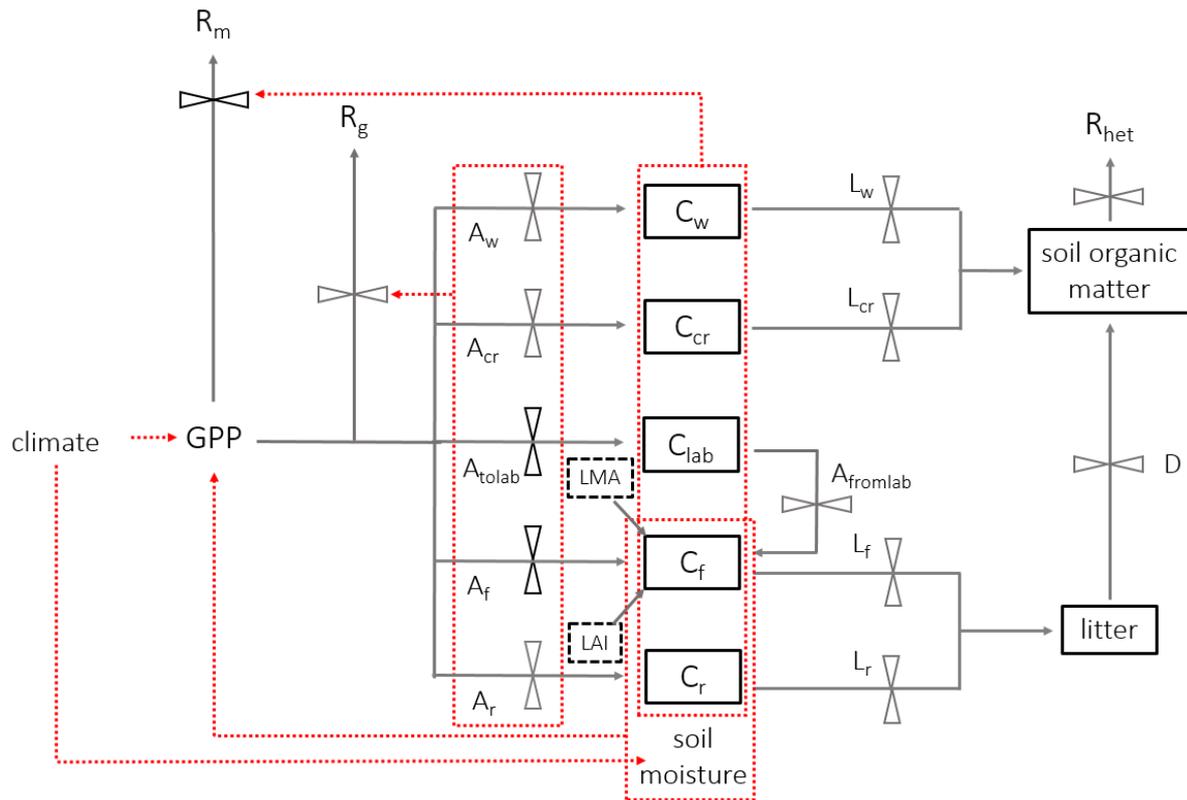

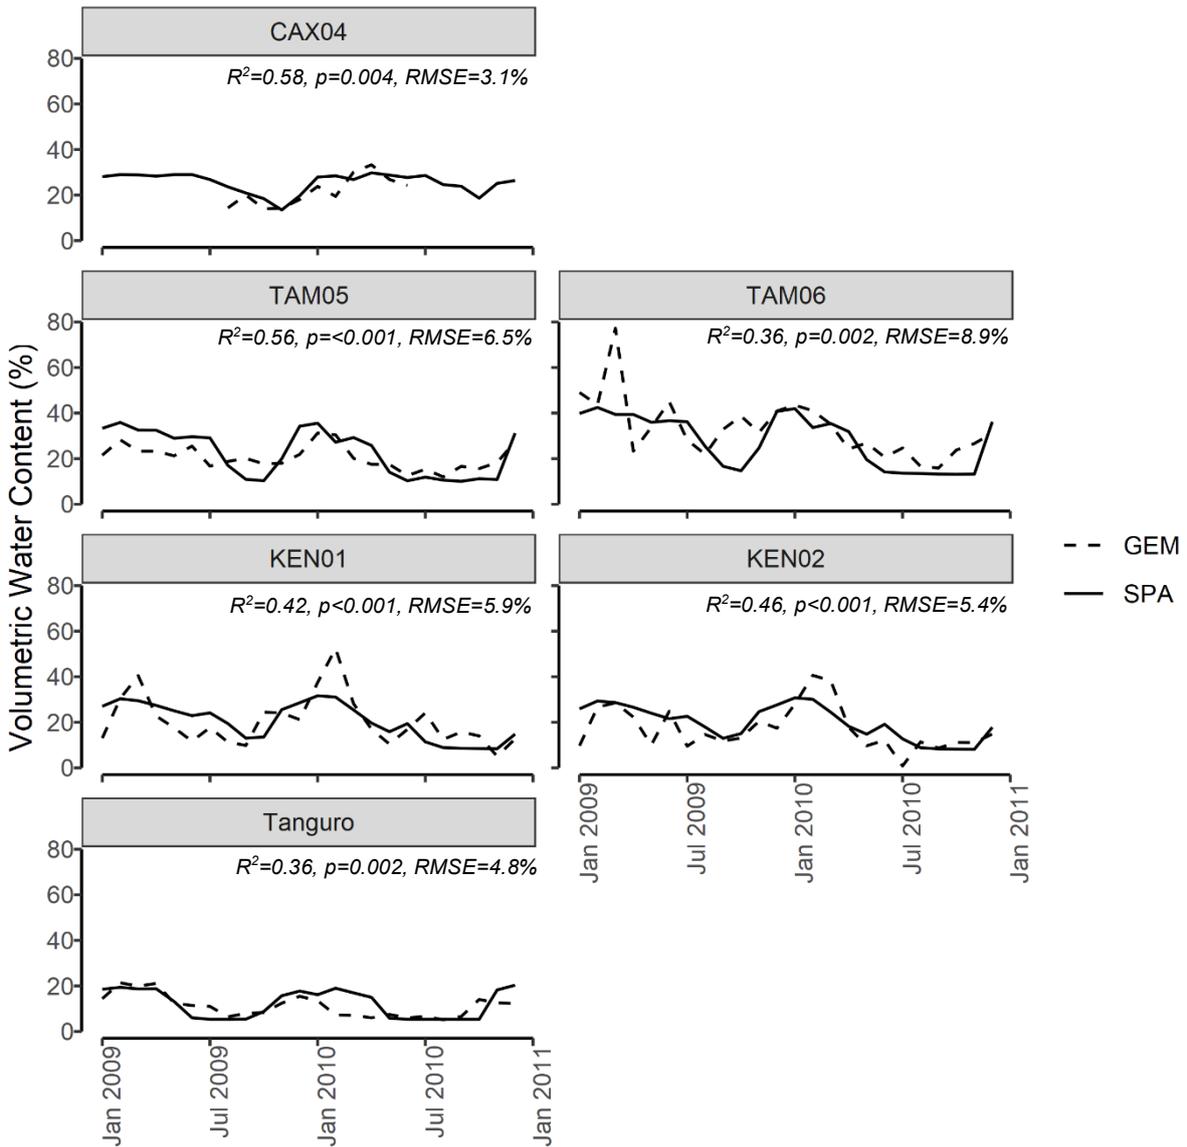

Figure 1. A schematic of the direct and indirect effects of drought stress via soil moisture and VPD on GPP. Drought stress affects GPP directly via stomatal conductance, and indirectly through its
 1100 determinant effect on plant traits and structural properties. Plant processes are represented by circles, traits are represented by triangles and vegetation properties (i.e. ecosystem structure) are represented by rectangles. Dashed boxes identify interactions driving the direct and indirect pathways through which drought stress impacts GPP. We note that other climate forcings (e.g. shortwave radiation and temperature) impact GPP but are not included here.

1105

1110 Figure 2. A schematic of DALEC_{canopy}, the carbon allocation sub-model integrated within the soil-plant-atmosphere model. Carbon moves between pools (solid boxes) via fluxes (solid arrows). Leaf carbon fluxes are constrained by field measurements (black dashed boxes). An effect of climate, carbon pools or fluxes on another carbon flux is shown by a red dashed arrow, whereby red dotted boxes indicate a collective impact of the contained carbon pools or fluxes. Black flux bars indicate that the carbon pathway is prioritised within the model above pathways from the same node. Climate is a model input, and soil moisture is simulated within SPA. Carbon pools (C), allocation (A) and litterfall (L) are separated by component: w = wood, cr = coarse roots, r = fine roots, f = foliage, lab = labile (or non-structural carbon), with to and from used for labile carbon.

1115

1120

Figure 3. SPA estimated soil volumetric water content compared to GEM measured values for six of the seven sample plots at four locations across the Amazon basin. Data presented is for the time period 2009-2010. Field data for CAX04 was limited to a shorter time period and for CAX06 was unavailable. R^2 , p -value and RMSE estimates presented are derived from linear regressions between monthly GEM measurements and SPA simulations.

1125

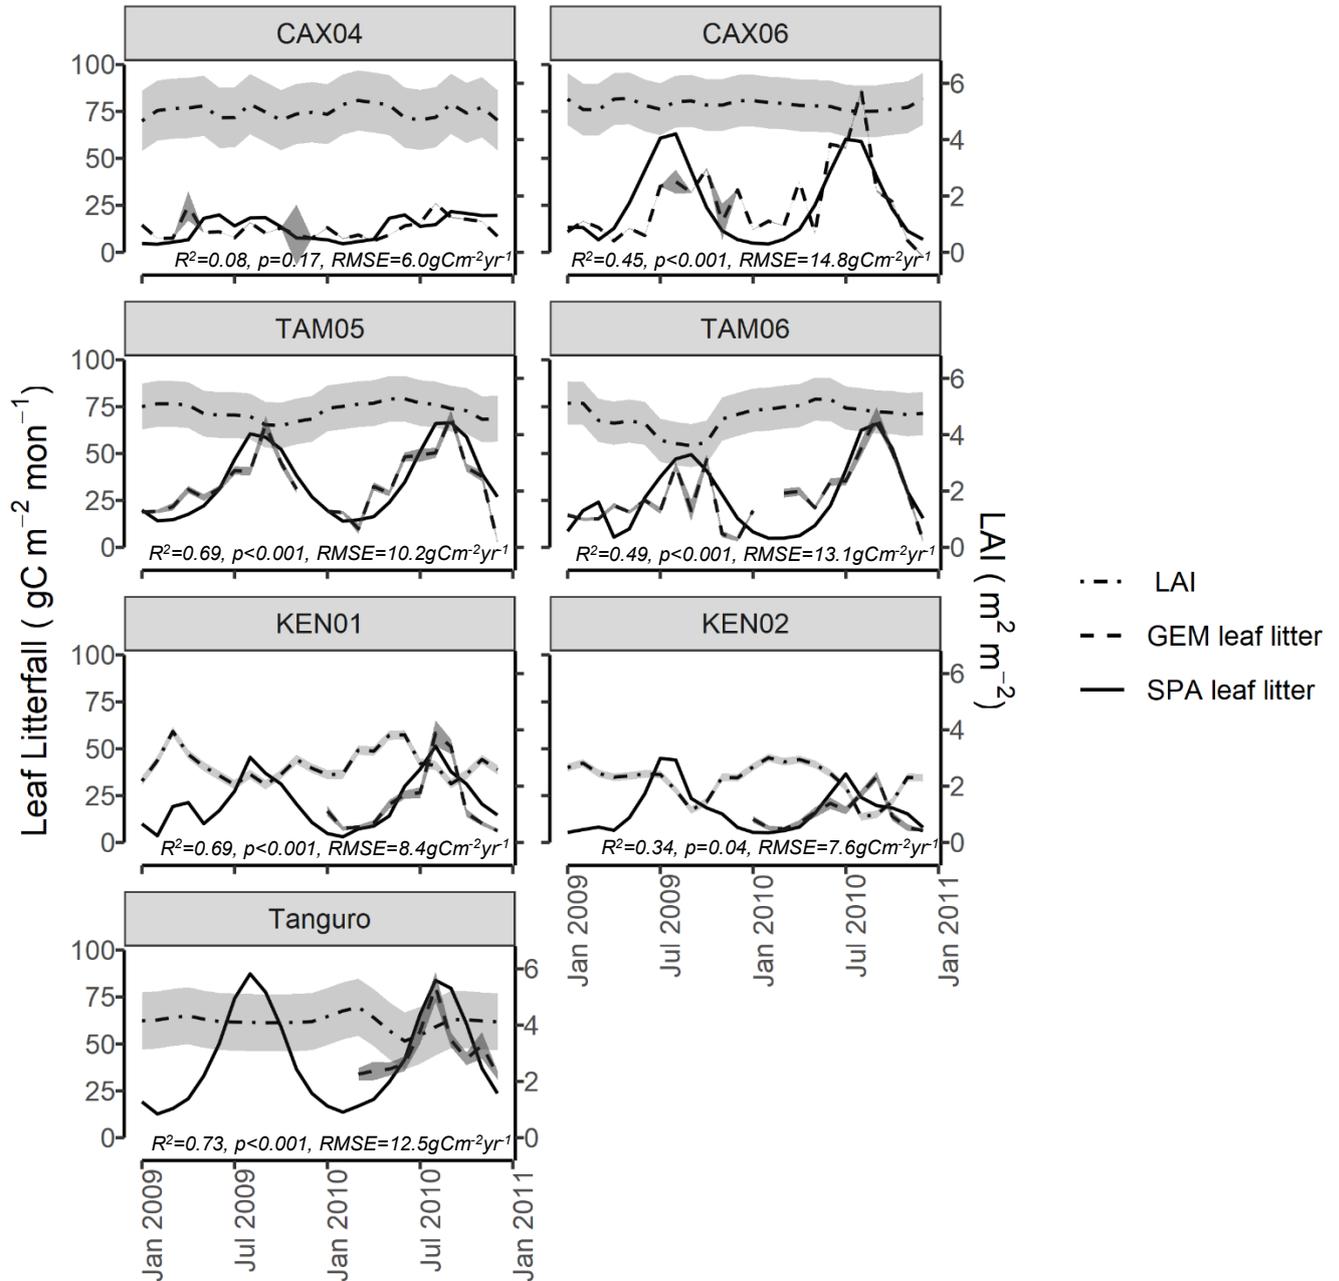

Figure 4. Field estimated monthly LAI, leaf litterfall (GEM), and standard error, compared with SPA simulated leaf litterfall for seven plots at four locations across the Amazon basin. SPA leaf litterfall was calibrated against GEM estimates to derive three fixed model drivers relating to the leaf cycle (peak leaf fall timing, leaf fall period and leaf lifespan). GEM leaf litterfall data was available for 2009-2010 for CAX04, CAX06, TAM05, TAM06 and for 2010 only for KEN01, KEN02 and Tanguro. R^2 , p-value and RMSE estimates presented are derived from linear regressions between monthly GEM measurements and SPA simulations.

1130

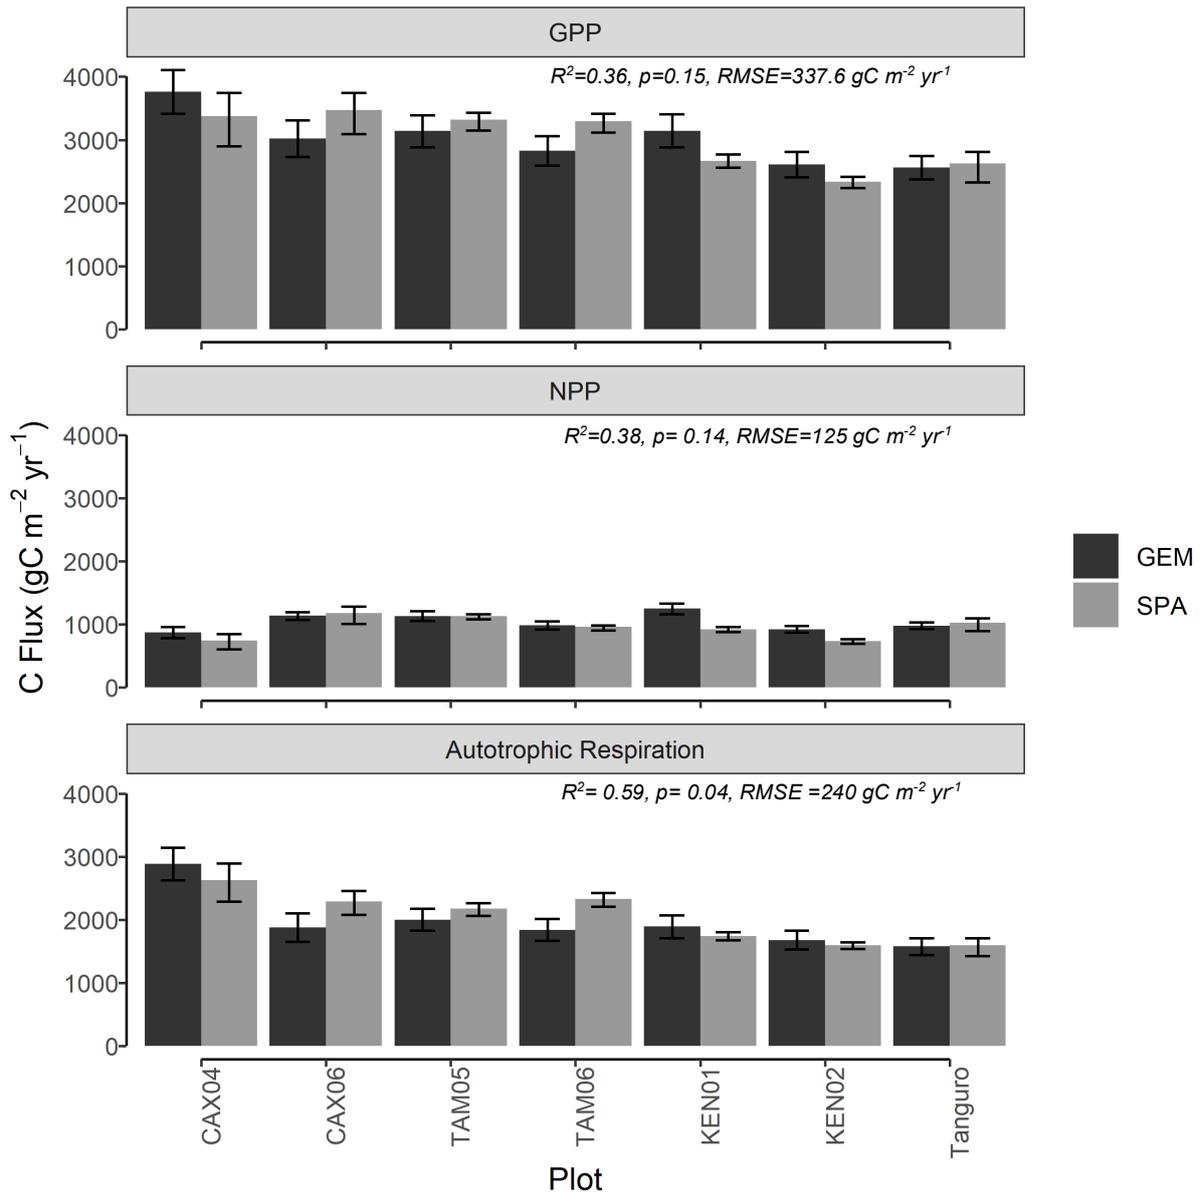

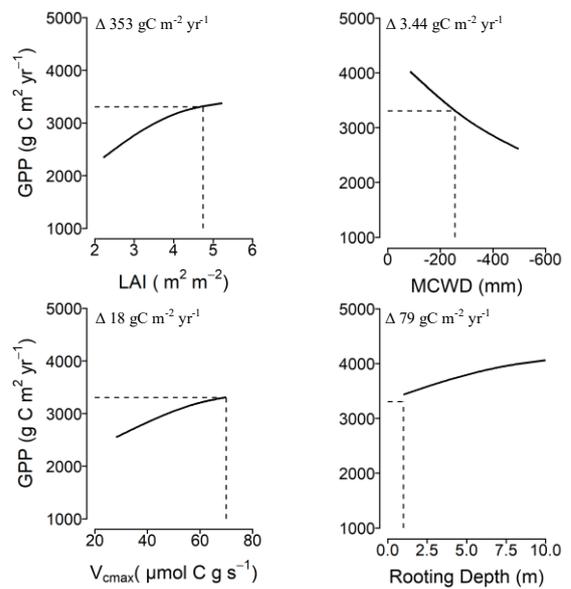

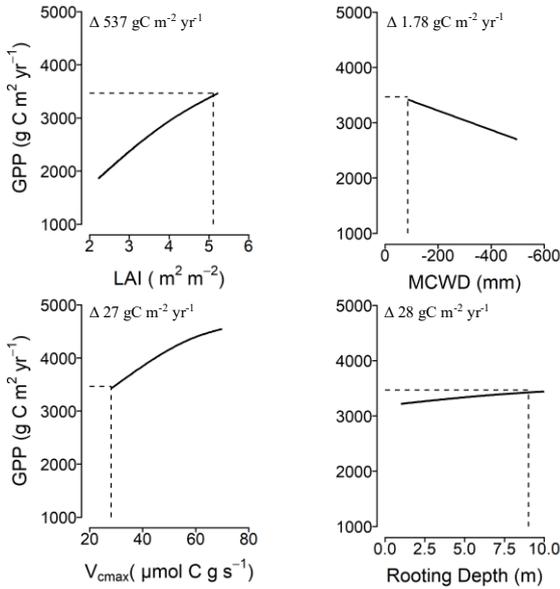

Figure 5. Carbon flux estimates (gC m⁻² yr⁻¹) of (a) GPP, (b) NPP and (c) autotrophic respiration, derived from process-based modelling (SPA) and biometric methods (GEM) for seven permanent sample plots at four locations across the Amazon basin. Estimates are mean annual values representative of the years 1140 2009-2010. GEM error bars represent standard error from field carbon flux measurements. SPA error bars represent simulated C fluxes under the upper and lower field LAI standard error. R^2 , p values and RMSE represent the interaction between SPA and GEM C flux estimates.

Figure 6. The sensitivity of GPP to model driver alternations in SPA at each location. Model drivers LAI, climate (characterised by MCWD), photosynthetic capacity (characterised by V_{cmax}) and rooting depth, derived from field observations, were alternated individually at each plot to that of all other plots and the resultant GPP retrieved. Solid lines represent SPA simulated GPP under the named driver alternations, and the dashed line represents the simulated value under observed conditions. SPA GPP

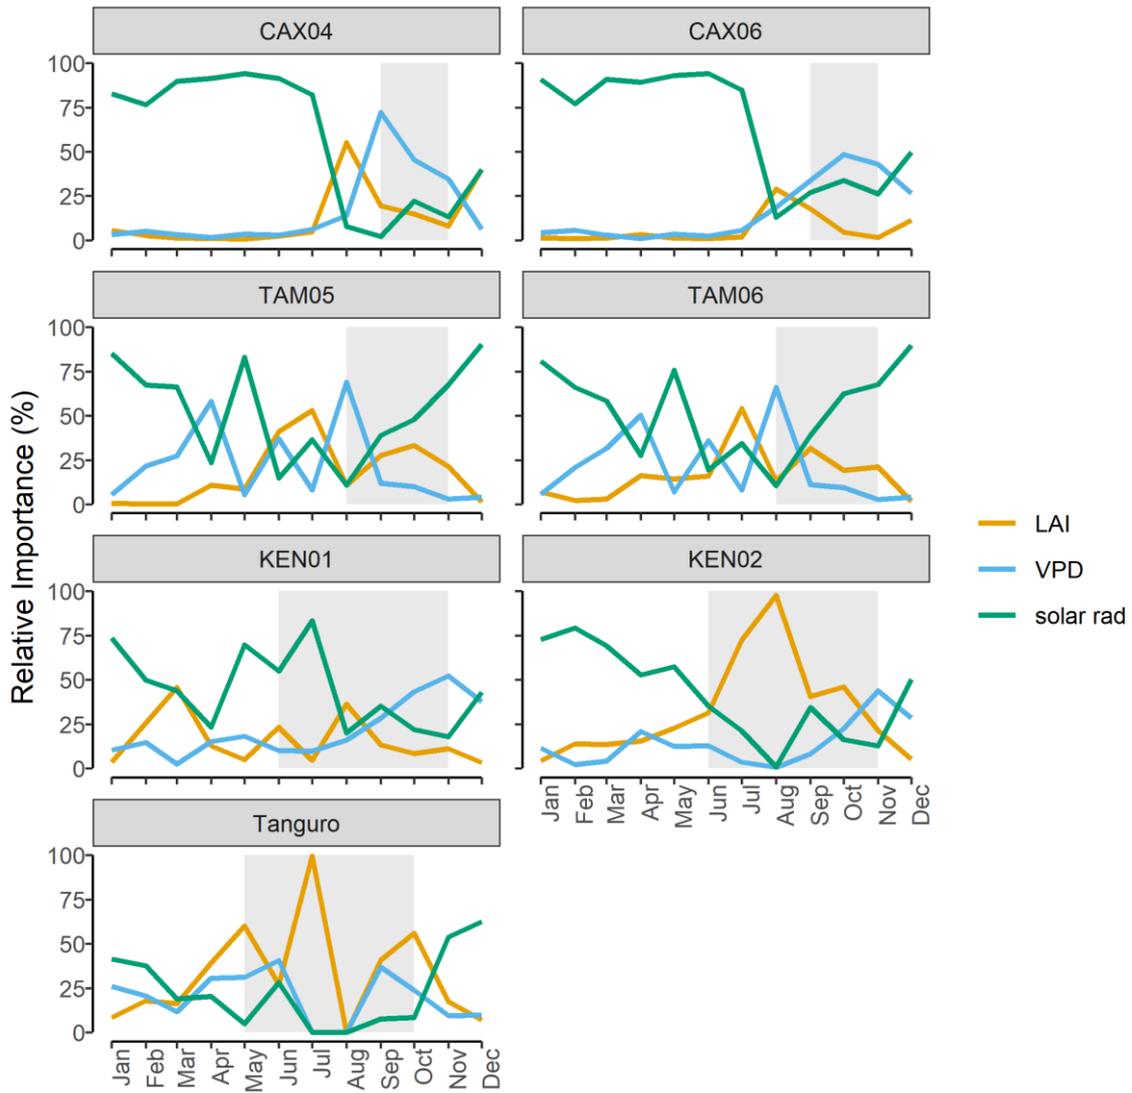

estimates presented are location averages. Climate and LAI were input to the model as timeseries. Photosynthetic capacity and rooting depth were fixed values. Plots are ordered to reflect soil moisture-stress which increases from Caxiuanã >Tambopata>Kenia>Tanguro. The range in GPP estimates under each set of driver alternations, for each location is presented (i.e. Δ values).

1175

Figure 7. The relative importance (%) of LAI, vapour pressure deficit (VPD) and solar radiation (solar rad) in driving SPA estimated monthly photosynthesis at permanent sample plots across an Amazon MCWD gradient. Relative importance was calculated using random forest machine learning. Shaded regions represent the dry season, where monthly precipitation was below 100mm. Plots are ordered to reflect drought stress which increased from Caxiuana to Tambopata to Kenia to Tanguro.
