22 humidity

23 **Abstract**

24 Molecular fossils, like bacterial branched glycerol dialkyl glycerol tetraethers (brGDGTs), and  
25 the stable isotopic composition of biomarkers, such as  $\delta^2\text{H}$  of leaf wax-derived *n*-alkanes ( $\delta^2\text{H}_{n\text{-alkane}}$ ) or  $\delta^{18}\text{O}$  of hemicellulose-derived sugars ( $\delta^{18}\text{O}_{\text{sugar}}$ ) are increasingly used for the  
26 reconstruction of past climate and environmental conditions. Plant-derived  $\delta^2\text{H}_{n\text{-alkane}}$  and  
27  $\delta^{18}\text{O}_{\text{sugar}}$  values record the isotopic composition of plant source water ( $\delta^2\text{H}_{\text{source-water}}$  and  
28  $\delta^{18}\text{O}_{\text{source-water}}$ ), which usually reflects mean annual precipitation ( $\delta^2\text{H}_{\text{precipitation}}$  and  
29  $\delta^{18}\text{O}_{\text{precipitation}}$ ), modulated by evapotranspirative leaf water enrichment and biosynthetic  
30 fractionation ( $\varepsilon_{\text{bio}}$ ). Accuracy and precision of respective proxies should be ideally evaluated at  
31 a regional scale. For this study, we analysed topsoils below coniferous and deciduous forests,  
32 as well as grassland soils along a Central European transect in order to investigate the variability  
33 and robustness of various proxies, and to identify effects related to vegetation. Soil pH-values  
34 derived from brGDGTs correlate reasonably well with measured soil pH-values, but  
35 systematically overestimate them ( $\Delta\text{pH} = 0.6 \pm 0.6$ ). The branched vs. isoprenoid tetraether  
36 index (BIT) can give some indication whether the pH reconstruction is reliable. Temperatures  
37 derived from brGDGTs overestimate mean annual air temperatures slightly ( $\Delta T_{\text{MA}} = 0.5^\circ\text{C} \pm 2.4$ ). Apparent isotopic fractionation ( $\varepsilon_{n\text{-alkane/precipitation}}$  and  $\varepsilon_{\text{sugar/precipitation}}$ ) is lower for  
38 grassland sites than for forest sites due to “signal damping”, i.e. grass biomarkers do not record  
39 the full evapotranspirative leaf water enrichment. Coupling  $\delta^2\text{H}_{n\text{-alkane}}$  with  $\delta^{18}\text{O}_{\text{sugar}}$  allows to  
40 reconstruct the stable isotopic composition of the source water more accurately than without  
41 the coupled approach ( $\Delta\delta^2\text{H} = \sim-21\text{‰} \pm 22$  and  $\Delta\delta^{18}\text{O} = \sim-2.9\text{‰} \pm 2.8$ ). Similarly, relative  
42 humidity during daytime and vegetation period (RH<sub>MDV</sub>) can be reconstructed using the coupled  
43 isotope approach ( $\Delta\text{RH}_{\text{MDV}} = \sim-17 \pm 12$ ). Especially for coniferous sites, reconstructed RH<sub>MDV</sub>  
44 values as well as source water isotope composition underestimate the measured values. This  
45 can be likely explained by understory grass vegetation at the coniferous sites contributing  
46 significantly to the *n*-alkane pool but only marginally to the sugar pool in the topsoils.  
47 Vegetation-dependent variable “signal damping” and  $\varepsilon_{\text{bio}}$  (regarding  $^2\text{H}$  between *n*-alkanes and  
48 leaf water) along our European transect are difficult to quantify but likely contribute to the  
49 observed underestimation in the source water isotope composition and RH reconstructions.  
50 Microclimate variability could cause the rather large uncertainties. Vegetation-related effects  
51 do, by contrast, not affect the brGDGT-derived reconstructions. Overall, GDGTs and the  
52 coupled  $\delta^2\text{H}_{n\text{-alkane}}\text{-}\delta^{18}\text{O}_{\text{sugar}}$  approach have great potential for more quantitative paleoclimate  
53 reconstructions.  
54

56 **1 Introduction**

57 Information about the variability and consequences of past climate changes is a prerequisite for  
58 precise predictions regarding the present climate change. Molecular fossils, so called  
59 biomarkers, have great potential to enhance our understanding about variations of past climate  
60 and environmental changes. Lipid biomarkers in particular are increasingly used for  
61 paleoclimate and environmental reconstructions (e.g. Brincat et al., 2000; Eglinton and  
62 Eglinton, 2008; Rach et al., 2014; Romero-Viana et al., 2012; Schreuder et al., 2016). However  
63 strengths and limitations of respective proxies need to be known (Dang et al., 2016). For this,  
64 calibrations using modern reference samples are essential.

65 One famous and widely applied lipid biomarker group are terrestrial branched glycerol dialkyl  
66 glycerol tetraethers (brGDGTs). They are synthesized in the cell membranes of anaerobe  
67 heterotrophic soil bacteria (Oppermann et al., 2010; Weijers et al., 2010) have great potential  
68 for the reconstruction of past environmental conditions (e.g. Coffinet et al., 2017; Schreuder et  
69 al., 2016; Zech et al., 2012), although some uncertainties exist. Calibration studies suggest that  
70 the relative abundance of the individual brGDGTs varies with mean annual air temperature  
71 ( $T_{MA}$ ) and soil pH (Peterse et al., 2012; Weijers et al., 2007), at least across large, global climate  
72 gradients or along pronounced altitudinal gradients (Wang et al., 2017). However, in arid  
73 regions the production of brGDGT is limited, while isoprenoidal GDGTs (iGDGTs) produced  
74 by archaea provide the dominant part of the overall soil GDGT pool (Anderson et al., 2014;  
75 Dang et al., 2016; Dirghangi et al., 2013; Wang et al., 2013; Xie et al., 2012). The ratio of  
76 brGDGTs vs. isoprenoid GDGTs (BIT) can be used as indication whether a reconstruction of  
77  $T_{MA}$  and pH will be reliable. Moreover, Mueller-Niggemann et al. (2016) revealed an influence  
78 of the vegetation cover on the brGDGT producing soil microbes. From field experiments, it is  
79 known that vegetation type and mulching practice strongly effect soil temperature and moisture  
80 (Awe et al., 2015; Liu et al., 2014). Thus, multiple factors can be expected to influence soil  
81 microbial communities and GDGT production. So far, little is known about the variability of  
82 GDGT proxies on a regional scale, and a calibration study with small climate gradient but with  
83 different vegetation types might be useful.

84 Concerning paleohydrology proxies, compound-specific stable hydrogen isotopes of leaf wax  
85 biomarkers, such as long chain *n*-alkanes ( $\delta^2H_{n\text{-alkanes}}$ ) record the isotopic signal of precipitation  
86 and therefore past climate and environmental conditions (Sachse et al., 2004, 2006). However,  
87 various influencing factors are known e.g. the moisture source to leaf waxes (Pedentchouk and  
88 Zhou, 2018 and Sachse et al., 2012 for review). Next is the evapotranspiration of leaf water  
89 (Feehins and Sessions, 2010; Kahmen et al., 2013; Zech et al., 2015), which is strongly driven  
90 by relative air humidity (RH; e.g. Cernusak et al., 2016 for review). In addition, a strong  
91 precipitation signal is known to be incorporated into long chain leaf waxes (Hou et al., 2008;  
92 Rao et al., 2009; Sachse et al., 2004). In paleoclimate studies, it is often not feasible to  
93 disentangle between the evapotranspirative enrichment from the precipitation signal. Zech et  
94 al. (2013) proposed to couple  $\delta^2H_{n\text{-alkane}}$  results with oxygen stable isotopes of hemicellulose-  
95 derived sugars ( $\delta^{18}O_{\text{sugar}}$ ). Assuming constant biosynthetic fractionation ( $\varepsilon_{\text{bio}}$ ) for the different  
96 compound classes (*n*-alkanes and hemicellulose sugars), this coupling enables the  
97 reconstruction of the isotopic composition of leaf water, RH,  $\delta^2H$  and  $\delta^{18}O$  of plant source water  
98 ( $\approx \delta^2H$  and  $\delta^{18}O$  of precipitation; Tuthorn et al., 2015). So far, a detailed evaluation of this

99 approach on the European scale, as well as related effects concerning vegetation changes is  
100 missing.

101 We analysed topsoil samples under coniferous, deciduous and grassland vegetation along a  
102 Central European transect in order to estimate the variability of the biomarker proxies. More  
103 specifically, we aim to test whether:

104 (i) the vegetation type has an influence on the brGDGT proxies, the  $\delta^2\text{H}_{n\text{-alkane}}$  and the  $\delta^{18}\text{O}_{\text{sugar}}$   
105 stable isotopic composition, as well as on reconstructed  $\delta^2\text{H}_{\text{source-water}}$ ,  $\delta^{18}\text{O}_{\text{source-water}}$  and RH.

106 (ii) the published brGDGT proxies used for reconstructing mean annual temperature and soil  
107 pH are sensitive enough to reflect the medium changes in temperature and soil pH along our  
108 transect.

109 (iii) the coupled  $\delta^2\text{H}_{n\text{-alkane}}$ - $\delta^{18}\text{O}_{\text{sugar}}$  approach enables a  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  of precipitation and RH  
110 reconstruction along the transect.

111

## 112 **2 Material and methods**

### 113 **2.1 Geographical setting and sampling**

114 In November 2012, we collected 29 topsoil samples (0-5 cm depth) from 16 locations along a  
115 transect from Southern Germany to Southern Sweden (Fig. 1A). We distinguished between sites  
116 with coniferous forest (con, n = 9), deciduous forest (dec, n = 14) and grassland (grass, n = 6)  
117 vegetation cover (for more details see Schäfer et al. (2016) and Tab. S1).

118

### 119 **2.2 Database of instrumental climate variables and isotope composition of precipitation**

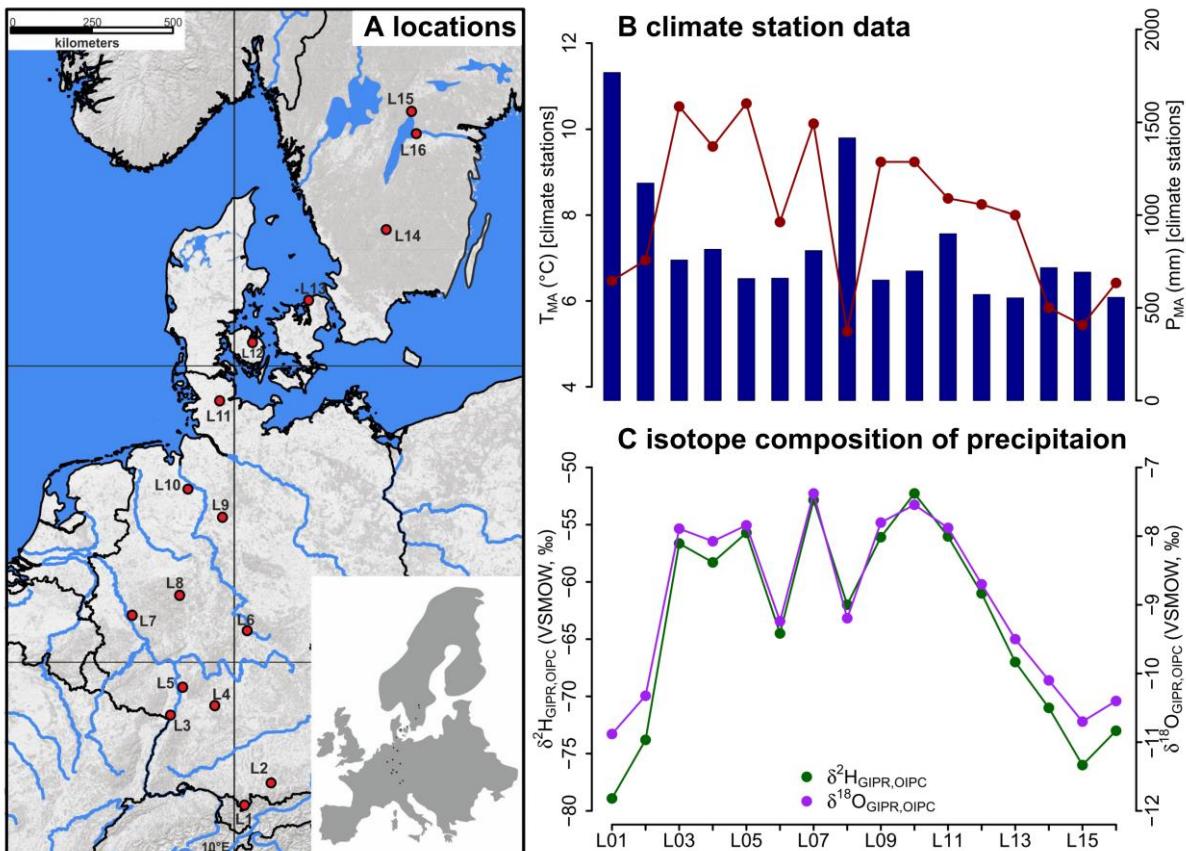

120 Climate data was derived from close-by weather observation stations operating by the regional  
121 institutions (Deutscher Wetterdienst (DWD) for Germany, Danmarks Meteorologiske Institut  
122 (DMI) for Denmark and the Sveriges Meteorologiska och Hydrologiska Institute (SMHI) for  
123 Sweden). The DWD provides hourly data for each station (DWD Climate Data Center, 2018b),  
124 enabling not only the calculation of  $T_{\text{MA}}$ , but also of the mean annual relative air humidity  
125 ( $\text{RH}_{\text{MA}}$ ), mean temperature and relative air humidity during the vegetation period ( $T$  and  
126  $\text{RH}_{\text{MV}}$ ), and of daytime temperature and relative humidity averages over the vegetation period  
127 ( $T$  and  $\text{RH}_{\text{MDV}}$ ). In addition, annual precipitation observations were used to derive the mean  
128 annual precipitation amount ( $P_{\text{MA}}$ ; DWD Climate Data Center, 2018b). From the DMI, the  
129 respective climate variables were derived from published technical reports (Cappelen, 2002;  
130 Frich et al., 1997; Laursen et al., 1999). The SMHI provides open data from which we derived  
131 the climate variables for the Swedish sites (Swedish Meteorological and Hydrological Institute,  
132 2018). For more details about the climate database used for calculations and comparisons, the  
133 reader is referred to Tab. S2.

134 For comprising German precipitation ( $\delta^2\text{H}$  and  $\delta^{18}\text{O}$ ) along the transect, we realized a  
135 regionalisation (called  $\delta^2\text{H}_{\text{GIPR}}$  and  $\delta^{18}\text{O}_{\text{GIPR}}$ ) using online available data from 34 German GNIP  
136 stations, 4 Austrian ANIP stations and the Groningen GNIP station (van Geldern et al., 2014;  
137 IAEA/WMO, 2018; Stumpp et al., 2014; Umweltbundesamt GmbH, 2018), following the  
138 approach of Schlotter (2007). However, instead of the multivariate regression procedure applied

139 by Schlotter (2007), we used a random forest approach (Hothorn et al., 2006; Strobl et al., 2007,  
 140 2008) to describe the relationship of squared latitude, latitude, longitude and altitude vs. long  
 141 term weighted means of precipitation  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$ , and realized the prediction for each site  
 142 (see supplementary method description for more information). For the Danish and Swedish  
 143 sites, such a procedure was not possible. Hence, the annual precipitation  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  values  
 144 were derived from the Online Isotopes in Precipitation Calculator (OIPC, version 3.1), therefore  
 145 called  $\delta^2\text{H}_{\text{OIPC}}$  and  $\delta^{18}\text{O}_{\text{OIPC}}$  (Bowen, 2018; Bowen and Revenaugh, 2003; IAEA/WMO, 2015).  
 146 The finally used  $\delta^2\text{H}_{\text{GIPR,OIPC}}$  and  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  data are given in Tab. S1.

147 The T<sub>MA</sub> along the transect ranges from 5.3 to 10.6°C, and P<sub>MA</sub> ranges from 554 to 1769 mm  
 148 (Fig. 1B). Precipitation  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  shows moderate changes along the transect,  $\delta^2\text{H}_{\text{GIPR,OIPC}}$   
 149 varies between -52 and -79‰, and  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  ranges from -7.4 to -10.9‰ (Fig. 1C).

150 Correlations between  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  and P<sub>MA</sub>, altitude of the locations, T<sub>MA</sub> are given in the  
 151 supplementary material (Fig. S1 to S3), along with a  $\delta^2\text{H}_{\text{GIPR,OIPC}}$  vs.  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  scatter plot  
 152 (Fig. S4).

153  
 154 **Fig. 1.** (A) Sample locations (red dots, map source: US National Park Service), (B) variations  
 155 of mean annual air temperature (T<sub>MA</sub>, red dots and line) and mean annual precipitation (P<sub>MA</sub>,  
 156 blue bars) derived from close-by climate station data, and (C) hydrogen and oxygen stable  
 157 isotope composition of precipitation ( $\delta^2\text{H}_{\text{GIPR,OIPC}}$  and  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$ , respectively) as derived for  
 158 the sampled transect locations (see section 2.2 GIPR  $\delta^2\text{H}$  and  $\delta^{18}\text{O}$  generation procedure). The  
 159 reader is referred to section 2.2 (and Tab. S1 and S2) for database and reference information of  
 160 data plotted in (B) and (C).

162 **2.3 Soil extractions and analysis**

163 **2.3.1 GDGTs and pH**

164 A detailed description of sample preparation for lipid analysis can be found in Schäfer et al.  
165 (2016). Briefly, 1–6 g freeze-dried and grounded soil sample was microwave extracted with 15  
166 ml dichloromethane (DCM)/methanol (MeOH) 9:1 (*v*:*v*) at 100°C for 1 h. Extracts were  
167 separated over aminopropyl silica gel (Supelco, 45 µm) pipette columns. The nonpolar fraction  
168 (including *n*-alkanes) was eluted with hexane and further purified over AgNO<sub>3</sub> coated silica  
169 pipette columns (Supelco, 60–200 mesh) and zeolite (Geokleen Ltd.). The GDGT-containing  
170 fraction was eluted with DCM:MeOH 1:1 (*v*:*v*), re-dissolved in hexane/isopropanol (IPA) 99:1  
171 (*v*:*v*) and transferred over 0.45 µm PTFE filters into 300 µl inserts. For quantification, a known  
172 amount of a C<sub>46</sub> diol standard was added after transfer. The samples were analysed at ETH  
173 Zurich using an Agilent 1260 Infinity series HPLC–atmospheric chemical pressure ionization  
174 mass spectrometer (HPLC-APCI-MS) equipped with a Grace Prevail Cyano column (150 mm  
175 × 2.1 mm; 3 µm). The GDGTs were eluted isocratically with 90% A and 10% B for 5 min and  
176 then with a linear gradient to 18% B for 34 min at 0.2 ml min<sup>-1</sup>, where A=hexane and  
177 B=hexane/isopropanol (9:1, *v*:*v*). Injection volume was 10 µl and single ion monitoring of  
178 [M+H]<sup>+</sup> was used to detect GDGTs.

179 The pH of the samples was measured in the laboratory of the Soil Biogeochemistry group,  
180 Institute of Agronomy and Nutritional Sciences, Martin-Luther-University Halle-Wittenberg,  
181 using a pH meter in a 1:3 soil:water (*w*:*v*) mixture.

182

183 **2.3.2 δ<sup>2</sup>H<sub>n</sub>-alkane**

184 The hydrogen isotopic composition of the highest concentrated *n*-alkanes (*n*-C<sub>25</sub>, *n*-C<sub>27</sub>, *n*-C<sub>29</sub>,  
185 *n*-C<sub>31</sub>, and *n*-C<sub>33</sub>) was determined using a TRACE GC Ultra Gas Chromatography connected to  
186 a Delta V Plus Isotope Ratio Mass Spectrometer via a <sup>2</sup>H pyrolysis reactor kept at 1420 °C (GC-  
187 <sup>2</sup>H-Py-IRMS; Thermo Scientific, Bremen, Germany) at ETH Zurich (Christoph et al., 2019).  
188 For more details about *n*-alkane quantification the reader is referred to Schäfer et al. (2016).  
189 The compound-specific <sup>2</sup>H/<sup>1</sup>H ratios were calibrated against an external standard with C<sub>15</sub>–C<sub>35</sub>  
190 homologues. External standard mixtures (A4 mix from A. Schimmelmann, University of  
191 Indiana) were run between the samples for multipoint linear normalization. The H<sup>+</sup><sub>3</sub> factor was  
192 determined on each measurement day and was constant throughout the periods of the sample  
193 batches. Samples were analysed in duplicates, and results typically agreed within 4% (average  
194 difference = 1.4%). All δ<sup>2</sup>H values are expressed relative to the Vienna Standard Mean Ocean  
195 Water (V-SMOW).

196

197 **2.3.3 δ<sup>18</sup>O<sub>sugar</sub>**

198 Hemicellulose sugars were extracted and purified using a slightly modified standard procedure  
199 (Amelung et al., 1996; Guggenberger et al., 1994; Zech and Glaser, 2009). Briefly, myoinositol  
200 was added to the samples prior to extraction as first internal standard. The sugars were released  
201 hydrolytically using 4M trifluoroacetic acid for 4 h at 105°C, cleaned over glass fibre filters and  
202 further purified using XAD and Dowex columns. Before derivatization with methylboronic acid  
203 (Knapp, 1979), the samples were frozen, freeze-dried, and 3-O-methylglucose in dry pyridine

204 was added as second internal standard. Compound-specific hemicellulose sugar  $^{18}\text{O}$   
 205 measurements were performed in the laboratory of the Soil Biogeochemistry group, Institute of  
 206 Agronomy and Nutritional Sciences, Martin-Luther-University Halle-Wittenberg, using GC-  
 207  $^{18}\text{O}$ -Py-IRMS (all devices from Thermo Fisher Scientific, Bremen, Germany). Standard  
 208 deviations of the triplicate measurements were 1.4‰ (over 29 investigated samples) for  
 209 arabinose and xylose, respectively. We focus on these two hemicellulose-derived neutral sugars  
 210 arabinose and xylose as they strongly predominate over fucose in terrestrial plants, soils and  
 211 sediments (Hepp et al., 2016 and references therein). Rhamnose concentrations were too low to  
 212 obtain reliable  $\delta^{18}\text{O}$  results. All  $\delta^{18}\text{O}$  values are expressed relative to the Vienna Standard Mean  
 213 Ocean Water (V-SMOW).

214

## 215 **2.4 Theory and Calculations**

216 2.4.1 Calculations used for the GDGT-based reconstructions

217 The branched and isoprenoid tetraether (BIT) index is calculated according to Hopmans et al.  
 218 (2004), for structures see Fig. S5:

$$219 \text{BIT} = \frac{\text{Ia+IIa+IIIa}}{\text{Ia+IIa+IIIa+crenarchaeol}}. \quad (1)$$

220 The cyclopentane moiety number of brGDGTs correlates negatively with soil pH (Weijers et  
 221 al., 2007), which led to the development of the cyclization of branched tetraethers (CBT) ratio.  
 222 CBT and the CBT based pH ( $\text{pH}_{\text{CBT}}$ ) were calculated according to Peterse et al. (2012):

$$223 \text{CBT} = -\log \frac{\text{Ib+IIb}}{\text{Ia+IIa}}, \quad (2)$$

$$224 \text{pH}_{\text{CBT}} = 7.9 - 1.97 \times \text{CBT}. \quad (3)$$

225 The number of methyl groups in brGDGTs correlates negatively with  $T_{\text{MA}}$  and soil pH (Peterse  
 226 et al., 2012; Weijers et al., 2007). Thus, the ratio of the methylation of branched tetraethers  
 227 (MBT) ratio and the CBT ratio can be used to reconstruct  $T_{\text{MA}}$ . We use the equation given by  
 228 Peterse et al. (2012):

$$229 \text{MBT}' = \frac{\text{Ia+Ib+Ic}}{\text{Ia+Ib+Ic+IIa+IIb+IIc+IIIa}}, \quad (4)$$

$$230 \text{T}_{\text{MA}} = 0.81 - 5.67 \times \text{CBT} + 31.0 \times \text{MBT}'. \quad (5)$$

231

232 2.4.2 Calculations and concepts used for the coupled  $\delta^2\text{H}$ - $\delta^{18}\text{O}$  approach

233 The apparent fractionation is calculated according to Cernusak et al. (2016):

$$234 \varepsilon_{n\text{-alkane/precipitation}} = \left( \frac{\delta^2\text{H}_{n\text{-alkane}} - \delta^2\text{H}_{\text{GIPR,OIPC}}}{1 + \delta^2\text{H}_{\text{GIPR,OIPC}}/1000} \right), \quad (6)$$

$$235 \varepsilon_{\text{sugar/precipitation}} = \left( \frac{\delta^{18}\text{O}_{\text{sugar}} - \delta^{18}\text{O}_{\text{GIPR,OIPC}}}{1 + \delta^{18}\text{O}_{\text{GIPR,OIPC}}/1000} \right). \quad (7)$$

236 The isotopic composition of leaf water ( $\delta^2\text{H}_{\text{leaf-water}}$  and  $\delta^{18}\text{O}_{\text{leaf-water}}$ ) can be calculated using  $\varepsilon_{\text{bio}}$   
 237 for  $\delta^2\text{H}_{n\text{-alkane}}$  (-160‰, Sachse et al., 2012; Sessions et al., 1999) and  $\delta^{18}\text{O}_{\text{sugar}}$  (+27‰, Cernusak  
 238 et al., 2003; Schmidt et al., 2001):

$$239 \delta^2\text{H}_{\text{leaf-water}} = \left( \frac{1000 + \delta^2\text{H}_{n\text{-alkane}}}{1000 + \varepsilon_{\text{bio}}(n\text{-alkane})} \right) \times 10^3 - 1000, \quad (8)$$

240 
$$\delta^{18}\text{O}_{\text{leaf-water}} = \left( \frac{1000 + \delta^{18}\text{O}_{\text{sugar}}}{1000 + \varepsilon_{\text{bio}} (\text{sugar})} \right) \times 10^3 - 1000. \quad (9)$$

241 Zech et al. (2013) introduced the conceptual model for the coupled  $\delta^2\text{H}_{n\text{-alkane}}-\delta^{18}\text{O}_{\text{sugar}}$  approach  
 242 in detail. Briefly, the coupled approach is based on the following assumptions (illustrated in  
 243 Fig. 8): (i) The isotopic composition of precipitation, which is set to be equal to the plant source  
 244 water, typically plots along the global meteoric water line (GMWL;  $\delta^2\text{H} = 8 \times \delta^{18}\text{O} + 10$ ) in a  
 245  $\delta^{18}\text{O}$  vs.  $\delta^2\text{H}$  space (Craig, 1961); (ii) Source water uptake by plants does not lead to any  
 246 fractionation (e.g. Dawson et al., 2002), and significant evaporation of soil water can be  
 247 excluded; (iii) Evapotranspiration leads to enrichment of the remaining leaf water along the  
 248 local evaporation line (LEL; Allison et al., 1985; Bariac et al., 1994; Walker and Brunel, 1990),  
 249 compared to the source water taken up by the plant; (iv) The biosynthetic fractionation is  
 250 assumed to be constant. In addition, isotopic equilibrium between plant source water (~  
 251 weighted mean annual precipitation) and the local atmospheric water vapour is assumed.  
 252 Further assumption concerns the isotope steady-state in the evaporating leaf water reservoir.  
 253 The coupled approach allows for reconstructing the isotopic composition of plant source water  
 254 ( $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$ ) from the reconstructed leaf water, by calculating the intercepts  
 255 of the LELs with the GMWL (Zech et al., 2013). The slope of the LEL ( $S_{\text{LEL}}$ ) can be assessed  
 256 by the following equation (Gat, 1971):

257 
$$S_{\text{LEL}} = \frac{\varepsilon_2^* + C_k^2}{\varepsilon_{18}^* + C_k^{18}}, \quad (10)$$

258 where  $\varepsilon^*$  are equilibrium isotope fractionation factors and  $C_k$  are kinetic fractionation factors.  
 259 The latter equals to 25.1‰ and 28.5‰, for  $C_k^2$  and  $C_k^{18}$ , respectively (Merlivat, 1978). The  
 260 equilibrium fractionation factors can be derived from empirical equations (Horita and  
 261 Wesolowski, 1994) by using  $T_{\text{MDV}}$  values. For two Danish sites  $T_{\text{MDV}}$  are not available, instead  
 262  $T_{\text{MV}}$  is used here (section 2.2 and Tab. S2).

263 In a  $\delta^{18}\text{O}$ - $\delta^2\text{H}$  diagram, the distance of the leaf water from the GMWL define the deuterium-  
 264 excess of leaf water ( $d_{\text{leaf-water}} = \delta^2\text{H}_{\text{leaf-water}} - 8 \times \delta^{18}\text{O}_{\text{leaf-water}}$ , according Dansgaard, (1964); Fig.  
 265 8). To convert  $d_{\text{leaf-water}}$  into mean RH during daytime and vegetation period ( $RH_{\text{MDV}}$ ), a  
 266 simplified Craig-Gordon model can be applied (Zech et al., 2013):

267 
$$RH = 1 - \frac{\Delta d}{\varepsilon_2^* - 8 \times \varepsilon_{18}^* + C_k^2 - 8 \times C_k^{18}}, \quad (11)$$

268 where  $\Delta d$  is the difference in  $d_{\text{leaf-water}}$  and the deuterium-excess of source water ( $d_{\text{source-water}}$ ).

269

## 270 2.5 Statistics

271 In the statistical analysis we checked sample distributions for normality (Shapiro and Wilk,  
 272 1965) and for equal variance (Levene, 1960). If normality and equal variances are given, we  
 273 perform an Analysis of Variance (ANOVA). If that is not the case, we conduct the non-  
 274 parametric Kruskal-Wallis Test. ANOVA or Kruskal-Wallis are used to find significant  
 275 differences ( $\alpha=0.05$ ) between the vegetation types (deciduous, conifer and grass).

276 In order to describe the relation along a 1:1 line, the coefficient of correlation ( $R^2$ ) was  
 277 calculated as  $R^2 = 1 - \sum (\text{modeled} - \text{measured})^2 / \sum (\text{measured} - \text{measured mean})^2$ . The small  
 278  $r^2$  is taken as coefficient of correlation of a linear regression between a dependent ( $y$ ) and

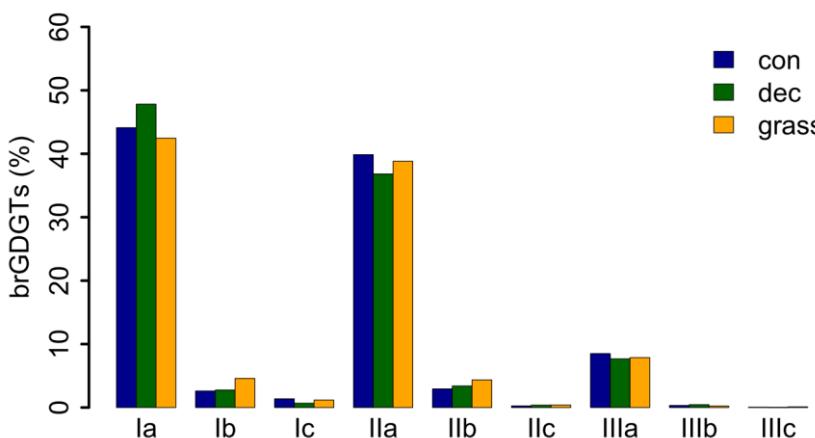

279 explanatory variable(s). The root mean square error (RMSE) of the relationships was calculated  
280 as  $RMSE = \sqrt{\left(\frac{1}{n} \cdot \sum (\text{modeled} - \text{measured})^2\right)}$ . All data plotting and statistical analysis was  
281 realized in R (version 3.2.2; R Core Team, 2015).

282

## 283 **3 Results and Discussion**

### 284 **3.1 GDGT concentrations**

285 GDGT Ia has the highest concentration under all vegetation types, followed by GDGT IIa and  
286 GDGT IIIa (Fig. 2). GDGT Ib, IIb and Ic occur in minor, GDGT IIc and IIIb only in trace  
287 amounts. GDGT IIIc was below the detection limit in most of the samples (Tab. S3). Although  
288 other studies document an influence of the vegetation cover on soil temperature and soil water  
289 content, which control the microbial community composition in soils (Awe et al., 2015; Liu et  
290 al., 2014; Mueller-Niggemann et al., 2016), we find no statistically different pattern of the  
291 individual brGDGTs.

292

293 **Fig. 2.** Mean concentrations of individual brGDGTs as percentage of all brGDGTs for the three  
294 investigated types. Abbreviations: con = coniferous forest sites (n=9); dec = deciduous forest  
295 sites (n=14); grass = grassland sites (n=6).

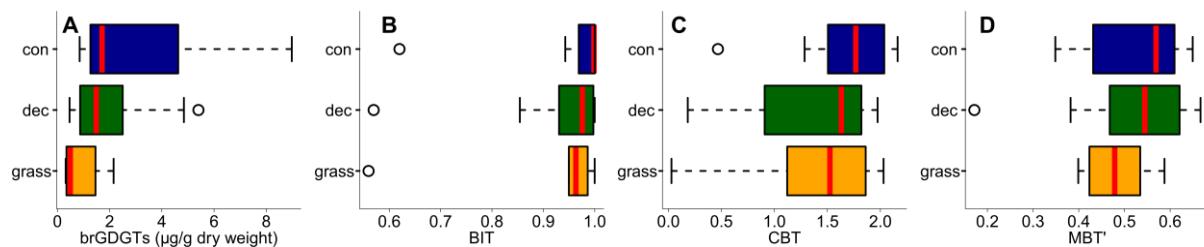

296 Total concentrations of brGDGTs range from 0.32 to 9.17 µg/g dry weight and tend to be  
297 highest for the coniferous samples and lowest for the grasses (Fig. 3A, Tab. S3). Bulk brGDGT  
298 concentrations lie within the range of other studies examining soils of mid latitude regions  
299 (Huguet et al., 2010b, 2010a; Weijers et al., 2011). Similar concentrations in coniferous and  
300 deciduous samples imply that brGDGT production does not strongly vary in soils below  
301 different forest types. The grass samples show lower brGDGT concentrations compared to the  
302 forest samples, but this is probably mainly due to ploughing of the grass sites in former times  
303 and hence admixing of mineral subsoil material. The differences in brGDGT concentrations are  
304 not significant (p-value = 0.06).

305

### 306 **3.2 BIT index**

307 Most of the samples have a BIT index higher than 0.9 (Fig 3B and Tab. S3). The BIT-values  
308 are typical for soils in humid and temperate climate regions (Weijers et al., 2006). However,

309 outliers exist. The most likely source of iGDGTs in soils are Thaumarchaeota, i.e. aerobic  
 310 ammonia oxidizing archaea producing Crenarchaeol and its regioisomer (Schouten et al., 2013  
 311 and references therein), when precipitation amount drops below 700-800 mm (Dang et al.,  
 312 2016; Dirghangi et al., 2013). The P<sub>MA</sub> data of our sampling sites mostly show precipitation >  
 313 550 mm (Fig. 1B), but one has to be aware that this data is based on the climate station nearest  
 314 to the respective sampling locations and microclimate effects, such as sunlight exposure,  
 315 canopy cover or exposition might have a pronounced influence on the brGDGT vs. iGDGT  
 316 distribution. Mueller-Niggemann et al. (2016) found higher BIT indices in upland soils  
 317 compared to paddy soils and stated that the management type also influences BIT values in  
 318 soils. Along our transect, grass sites tend to have slightly lower BIT-values than forest sites,  
 319 probably due to the absence of a litter layer and hence, no isolation mechanism preventing  
 320 evaporation of soil water. Differences between vegetation types are not significant (p-value =  
 321 0.32).

322 **Fig. 3.** (A) Total concentrations of brGDGTs in  $\mu\text{g g}^{-1}$  dry weight, as well as (B) BIT, (C) CBT  
 323 and (D) MBT'. Abbreviations: con = coniferous forest sites (n=9); dec = deciduous forest sites  
 324 (n=14); grass = grassland sites (n=6). Box plots show median (red line), interquartile range  
 325 (IQR) with upper (75%) and lower (25%) quartiles, lowest whisker still within 1.5IQR of lower  
 326 quartile, and highest whisker still within 1.5IQR of upper quartile, dots mark outliers.  
 327

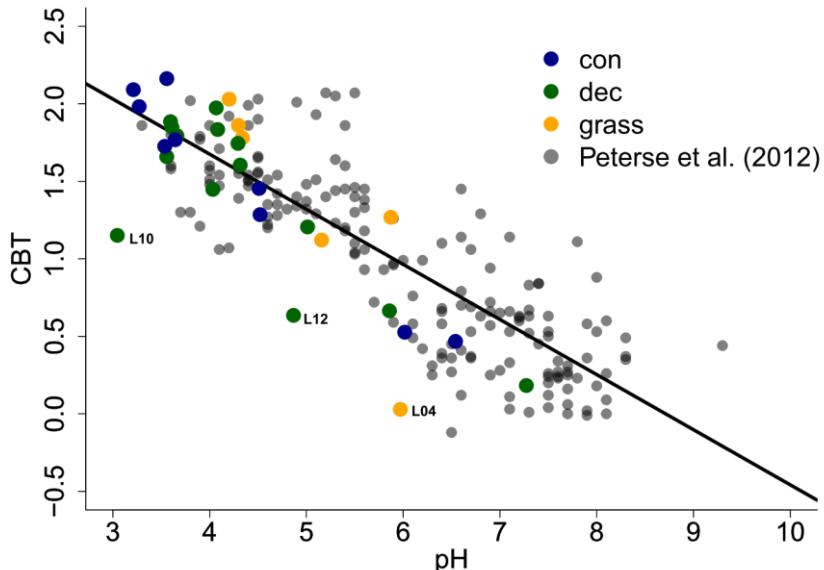

328

### 329 **3.3 CBT-derived pH**

330 The CBT ratio shows a pronounced variation independent of vegetation type with values  
 331 between 0.03 and 2.16 (Fig 3C). The coniferous samples tend to be highest, but the differences  
 332 between vegetation types are not significant (p-value = 0.48). The CBT index can be related to  
 333 pH in acidic and/or humid soils (e.g. Dirghangi et al., 2013; Mueller-Niggemann et al., 2016;  
 334 Peterse et al., 2012; Weijers et al., 2007) but might be an indicator of soil water content and  
 335 hence, precipitation in more arid and alkaline soils (e.g. Dang et al., 2016). There is a  
 336 pronounced correlation between CBT and soil pH (Fig. 4), which is in good agreement with  
 337 other studies from mid latitude regions where precipitation is relatively high (Anderson et al.,  
 338 2014 and references therein). Moreover, the CBT to pH relationship in terms of slope and  
 339 intersect in our dataset ( $\text{CBT} = -0.47 \times \text{pH} + 3.5$ ,  $r^2 = 0.7$ , p-value < 0.0001, n = 29) is well  
 340 comparable to the correlation described for the global calibration dataset of Peterse et al. (2012)  
 341 ( $\text{CBT} = -0.36 \times \text{pH} + 3.1$ ,  $r^2 = 0.7$ , p-value < 0.0001, n = 176).

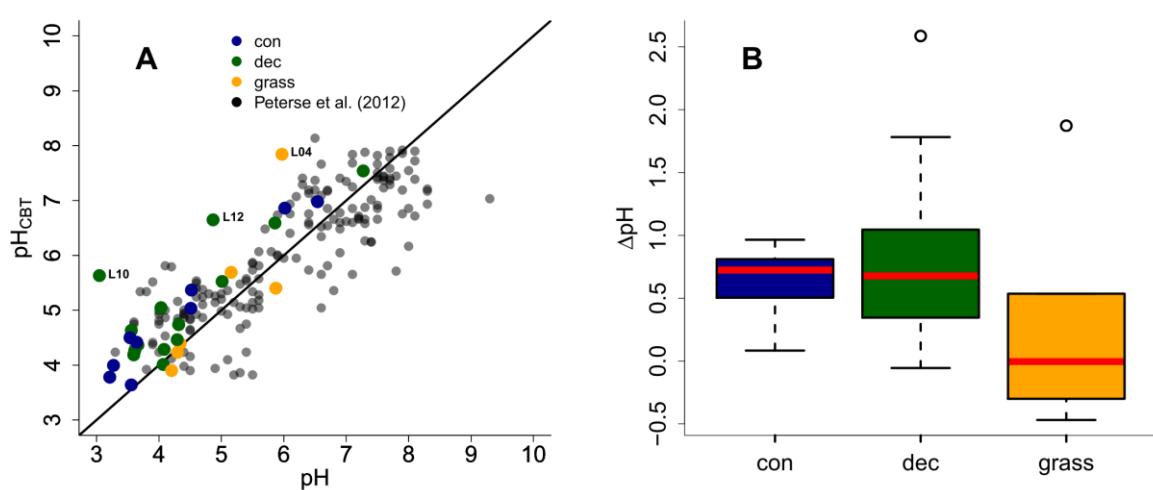

342 However, there are some outliers in the CBT-pH correlation, which need a further examination  
 343 (see locations grass L04, dec L10 and dec L12 as marked in Figs. 4 and 5). The outliers show  
 344 lower BIT indices (< 0.85, Tab. S3). Even though the data from the nearest climate station  
 345 suggest no abnormal P<sub>MA</sub>. Local effects such as differences in the amount of sunlight exposure,  
 346 nutrient availability for brGDGT producing organisms or, most likely soil water content might

347 influence the brGDGT production at these locations (Anderson et al., 2014; Dang et al., 2016).  
 348 A lower BIT index as well as a lower CBT occur when soil water content decreases (Dang et  
 349 al., 2016; Sun et al., 2016) or when aeration is high and less anoxic microhabitats for GDGT  
 350 producing microbes exist (e.g. Dirghangi et al., 2013).

351  
 352 **Fig. 4.** CBT to pH relationship in our dataset in comparison to the global calibration dataset  
 353 from Peterse et al. (2012) ( $CBT = -0.36 \times pH + 3.1$ ,  $r^2 = 0.7$ ,  $p$ -value < 0.0001,  $n = 176$ , black  
 354 line). Abbreviations: con = coniferous forest sites ( $n=9$ ); dec = deciduous forest sites ( $n=14$ );  
 355 grass = grassland sites ( $n=6$ ).

356  
 357 As the CBT and pH are similarly correlated in our dataset and the global dataset of Peterse et  
 358 al. (2012), the CBT-derived pH correlated well with the actual pH (Fig. 5A;  $R^2 = 0.3$ ).  
 359 Expressed as  $\Delta pH$  (CBT-derived pH - measured pH), there is a tendency that the GDGTs result  
 360 in an overestimation of the real pH for the forest sites (Fig. B). Yet a Kruskal-Wallis test shows  
 361 no statistically significant difference between the vegetation types, with a  $p$ -value of 0.13. The  
 362 overall  $\Delta pH$  of  $0.6 \pm 0.6$  shows that the reconstruction of soil pH using brGDGTs works well  
 363 along this transect.

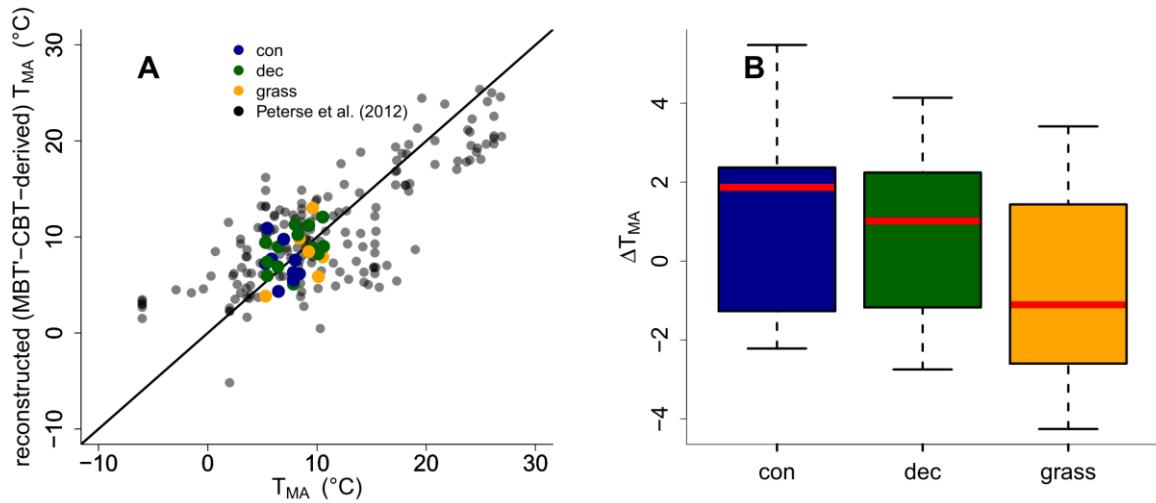

364

365 **Fig. 5.** (A) Correlation between measured pH and reconstructed soil pH ( $\text{pH}_{\text{CBT}}$ ) from our  
 366 transect data in comparison to the global calibration dataset from Peterse et al. (2012) ( $R^2 = 0.7$ ,  
 367 RMSE = 0.75,  $n = 176$ ). Black line indicates the 1:1 relationship. (B) Boxplots of  $\Delta\text{pH}$  (refers  
 368 to  $\text{pH}_{\text{CBT}}-\text{pH}$ ). Box plots show median (red line), interquartile range (IQR) with upper (75%)  
 369 and lower (25%) quartiles, lowest whisker still within 1.5IQR of lower quartile, and highest  
 370 whisker still within 1.5IQR of upper quartile, dots mark outliers. Abbreviations: con =  
 371 coniferous forest sites ( $n=9$ ); dec = deciduous forest sites ( $n=14$ ); grass = grassland sites ( $n=6$ ).

372

### 373 **3.4 MBT'-CBT-derived $T_{\text{MA}}$ reconstructions**

374 The MBT' shows high variability with values ranging from 0.17 to 0.67 no statistical  
 375 differences between vegetation types ( $p\text{-value} = 0.54$ ; Fig. 3D, Tab. S3). When comparing  
 376 reconstructed (MBT'-CBT-derived)  $T_{\text{MA}}$  with climate station  $T_{\text{MA}}$ , the data plot close to the 1:1  
 377 line, and fit well into the global dataset of Peterse et al. (2012) (Fig. 6A). The  $\Delta T_{\text{MA}}$  reveal an  
 378 overall offset of  $0.5^{\circ}\text{C} \pm 2.4$  and there is no statistically difference between vegetation types  
 379 (Fig. 6B). The standard deviation in  $\Delta T_{\text{MA}}$  of  $\pm 2.4$  is well in line with the RMSE of 5.0 for the  
 380 global calibration dataset (Peterse et al., 2012).

381

382 **Fig. 6.** (A) Correlation between climate station  $T_{\text{MA}}$  and reconstructed (MBT'-CBT-derived)  
 383  $T_{\text{MA}}$ . For comparison, the global calibration dataset from Peterse et al. (2012) is shown. The  
 384 black line indicates the 1:1 relationship. (B) Boxplots of  $\Delta T_{\text{MA}}$  (refers to reconstructed  $T_{\text{MA}}$ -  
 385  $T_{\text{MA}}$  from climate stations) in the different vegetation types from our transect study. Box plots  
 386 show median (red line), interquartile range (IQR) with upper (75%) and lower (25%) quartiles,  
 387 lowest whisker still within 1.5IQR of lower quartile, and highest whisker still within 1.5IQR of  
 388 upper quartile, dots mark outliers. Abbreviations: con = coniferous forest sites ( $n=9$ ); dec =  
 389 deciduous forest sites ( $n=14$ ); grass = grassland sites ( $n=6$ ).

390

### 391 **3.5 Potential impact of the used liquid chromatography method on pH and $T_{\text{MA}}$ 392 reconstructions**

393 The GDGT data presented in this study are not acquired on the up-to-date method (e.g. compare  
 394 De Jonge et al., 2014 vs. Zech et al., 2012c). De Jonge et al. (2014) presented a new liquid  
 395 chromatography method which enables the separation for the brGDGTs with  $m/z$  1036, 1034

396 and 1032, 1050, 1048 and 1046 into 6-methyl and 5-methyl stereoisomers. The old method did  
397 not allow such a separation (Zech et al., 2012c), thus in the calibration often the sum of 6 and  
398 5-methylated brGDGTs was used (see and compare De Jonge et al., 2014 vs. Peterse et al., 2012).  
399 This introduce scatter to the MBT'-CBT-based  $T_{MA}$  reconstructions and can cause a correlation  
400 between pH and MBT' (for more details see De Jonge et al., 2014). De Jonge et al. (2014)  
401 moreover show that the 6-methyl brGDGTs are ubiquitous abundant in soils from all over the  
402 world, based on reanalysing the dataset of Peterse et al. (2012). However, they also compare  
403 reconstructed  $T_{MA}$  values based MBT'-CBT calibration (Peterse et al., 2012) and their new  
404 developed  $T_{MA}$  calibration and state that they plot around a 1:1 line. They furthermore state,  
405 that especially for arid areas larger deviations can be expected. Finally, they conclude that the  
406 use of the new developed calibrations will improve the  $T_{MA}$  and pH reconstructions for areas  
407 with arid climate conditions. Because our study transect spans from southern Germany to  
408 southern Sweden, representing temperate and humid climate conditions, we argue that the usage  
409 of the older liquid chromatography method do not introduce a systematic error in our  $T_{MA}$  and  
410 pH reconstructions. Still, a higher variability/scatter could be associated with the calibration of  
411 Peterse et al. (2012) and therefore also present in our  $T_{MA}$  and pH reconstructions.

412

### 413 **3.6 Apparent fractionation of $\delta^2H$ and $\delta^{18}O$ in the different vegetation types**

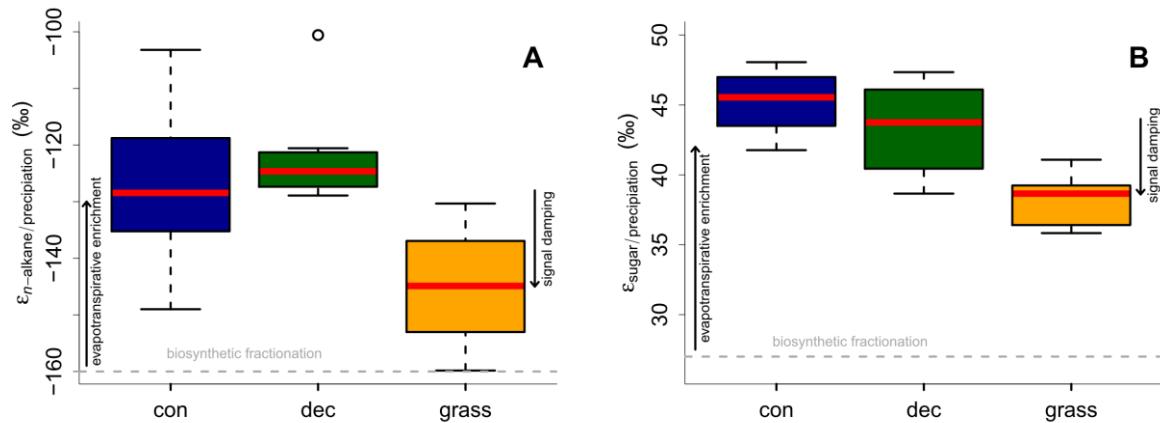

414  $\delta^2H$  values could be obtained for the *n*-alkanes C<sub>27</sub>, C<sub>29</sub> and C<sub>31</sub> in all samples and additionally  
415 at two locations for *n*-C<sub>25</sub> and *n*-C<sub>33</sub> at six other locations. The  $\delta^2H_{n\text{-alkane}}$  values, calculated as  
416 mean of *n*-C<sub>25</sub> to *n*-C<sub>31</sub>  $\delta^2H$ , range from -156 to -216‰. Pooled standard deviations show an  
417 overall average of 3.6‰. The  $\delta^{18}O_{\text{sugar}}$  values, calculated as the area weighted means for  
418 arabinose and xylose, range from +27.7 to +39.4‰. The average weighted mean standard  
419 deviation is 1.4‰. The compound-specific isotope data are summarized along with the  
420 calculations in Tab. S4.

421 Apparent fractionation ( $\epsilon_{n\text{-alkane/precipitation}}$ ) is on the order of -120 to -150‰, i.e. a bit less than  
422 the biosynthetic fraction of -160‰. This implies that evapotranspirative enrichment is ~ 10 to  
423 40‰ (Fig. 7A).  $\epsilon_{n\text{-alkane/precipitation}}$  is lower for grass sites compared to the forest sites. Differences  
424 are significant between deciduous and grass sites (p-value = 0.005). This finding supports the  
425 results of other studies (Kahmen et al., 2013; Liu and Yang, 2008; McInerney et al., 2011), and  
426 can be named “signal damping”. Grasses do not only incorporate the evaporatively-enriched  
427 leaf water but also unenriched xylem water in the growth and differentiation zone of grasses  
428 (Gamarra et al., 2016; Liu et al., 2017).

429 The grass-derived hemicellulose sugar biomarkers do not fully record the evapotranspirative  
430 enrichment of the leaf water, either, as indicated by lower apparent fractionation ( $\epsilon_{\text{sugar/precipitation}}$ )  
431 in Fig. 7B. The differences are significant between forest and grass sites (p-value < 0.005). This  
432 is in agreement with a study on cellulose extracted from grass blades (Helliker and Ehleringer,  
433 2002), and again, the “signal damping” can be explained with incorporation of enriched leaf  
434 water and non-enriched stem water.

435 Based on the comparison of evapotranspirative enrichment between forest and grass sites, the  
436 “signal damping” can be quantified to be ~ 31% for the hemicellulose sugars, and ~ 49% for  
437 the *n*-alkanes. This is in agreement with other studies that reported a loss of 22% of the leaf

438 water enrichment for hemicellulose sugars (Helliker and Ehleringer, 2002) and 39 to 62% loss  
 439 of the leaf water enrichment for *n*-alkanes (Gamarra et al., 2016).

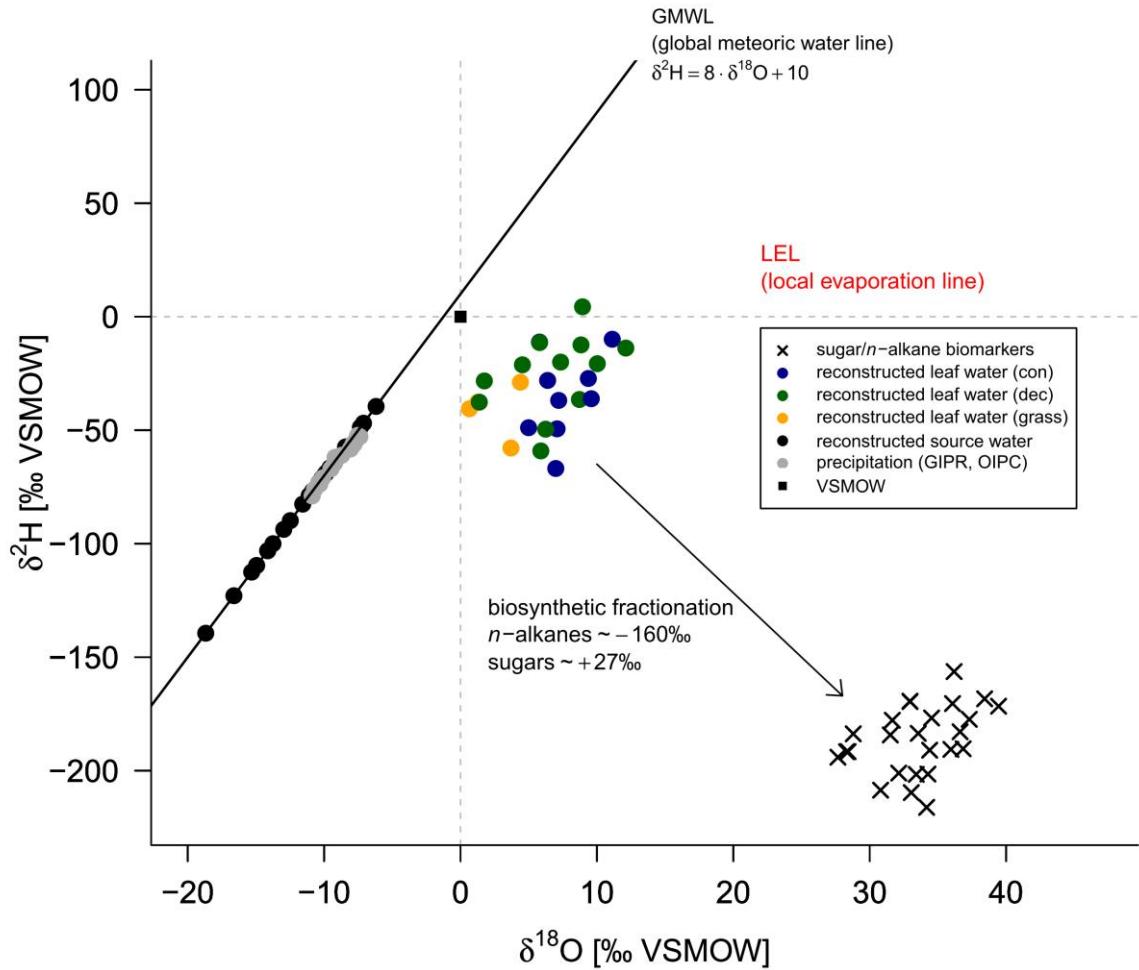

440

441 **Fig. 7.** Apparent fractionation (A)  $\varepsilon_{n\text{-alkane/precipitation}}$  and (B)  $\varepsilon_{\text{sugar/precipitation}}$ . Biosynthetic  
 442 fractionation factors according to section 2.4.2. Box plots show median (red line), interquartile  
 443 range (IQR) with upper (75%) and lower (25%) quartiles, lowest whisker still within 1.5IQR  
 444 of lower quartile, and highest whisker still within 1.5IQR of upper quartile, dots mark outliers.  
 445 Abbreviations: con = coniferous forest sites (n=9); dec = deciduous forest sites (n=11 and 14  
 446 for *n*-alkanes and sugars, respectively); grass = grassland sites (n=4 and 6 for *n*-alkanes and  
 447 sugars, respectively). The figure conceptually illustrates the effect of biosynthetic fractionation  
 448 and evapotranspirative enrichment as well as “signal damping”.

449

### 450 3.7 $\delta^2\text{H}_{\text{source-water}}$ and $\delta^{18}\text{O}_{\text{source-water}}$ reconstructions

451 The  $\delta^2\text{H}$  versus  $\delta^{18}\text{O}$  diagram shown in Fig. 8 graphically illustrates the reconstruction of  $\delta^2\text{H}_{\text{leaf-}}$   
 452 water and  $\delta^{18}\text{O}_{\text{leaf-water}}$  (colored dots) from  $\delta^2\text{H}_{n\text{-alkane}}$  and  $\delta^{18}\text{O}_{\text{sugar}}$  (crosses), as well as the  
 453 reconstruction of  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  (black dots). For reconstructing  $\delta^2\text{H}_{\text{source-water}}$   
 454 and  $\delta^{18}\text{O}_{\text{source-water}}$ , LELs with an average slope of  $2.8 \pm 0.1$  (Eq. 10) can be generated through  
 455 every leaf water point and the intercepts of these LELs with the GMWL.

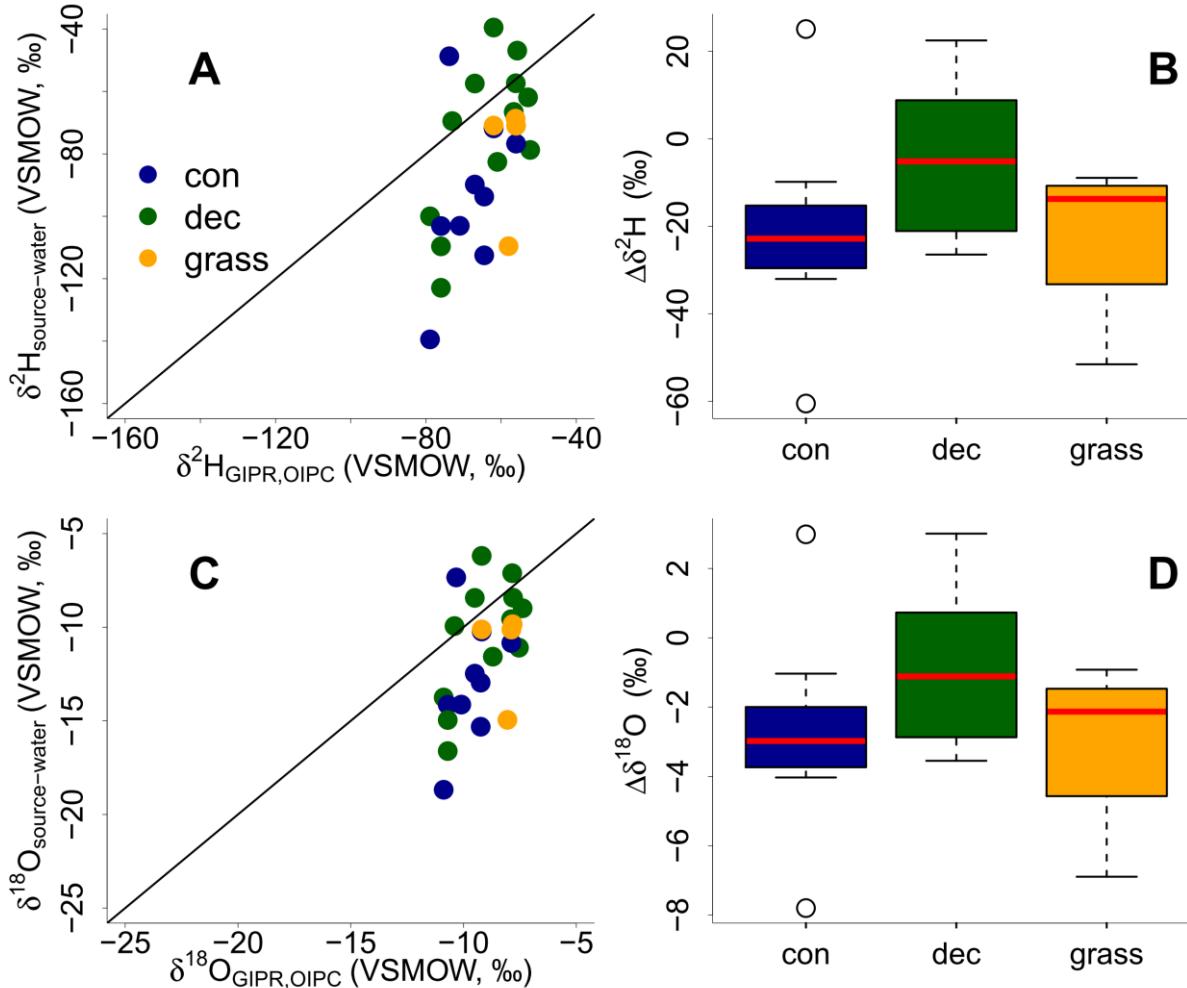

456  
 457 **Fig. 8.**  $\delta^2\text{H}$  vs.  $\delta^{18}\text{O}$  diagram illustrating the coupled  $\delta^2\text{H}_{n\text{-alkane}}$ - $\delta^{18}\text{O}_{\text{sugar}}$  approach: measured  
 458  $\delta^2\text{H}_{n\text{-alkane}}$  and  $\delta^{18}\text{O}_{\text{sugar}}$  values, reconstructed  $\delta^2\text{H}_{\text{leaf-water}}$  and  $\delta^{18}\text{O}_{\text{leaf-water}}$  (according Eqs. 8 and  
 459 9) and reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  in comparison to GIPR and OIPC-based  
 460  $\delta^2\text{H}_{\text{precipitation}}$  and  $\delta^{18}\text{O}_{\text{precipitation}}$ . Abbreviations: con = coniferous forest sites (n=9); dec =  
 461 deciduous forest sites (n=11); grass = grassland sites (n=4).

462  
 463 The reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  results can be compared with the  $\delta^2\text{H}_{\text{GIPR,OIPC}}$   
 464 and  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  data (Fig. 9). This comparison reveals that the coupled  $\delta^2\text{H}_{n\text{-alkane}}$ - $\delta^{18}\text{O}_{\text{sugar}}$   
 465 approach yields more accurate  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  compared to single  $\delta^2\text{H}_{n\text{-alkane}}$   
 466 approaches. However, the range of the reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  values is  
 467 clearly larger than in  $\delta^2\text{H}_{\text{GIPR,OIPC}}$  and  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  values.  $\delta^2\text{H}$  is systematically underestimated  
 468 by  $\sim 21\text{‰} \pm 22$  (Fig. 9B) and  $\delta^{18}\text{O}$  by  $\sim 2.9\text{‰} \pm 2.8$  (Fig. 9D). The type of vegetation seems to  
 469 be not particularly relevant (p-value = 0.18 for  $\Delta\delta^2\text{H}$  and p-value = 0.34 for  $\Delta\delta^{18}\text{O}$ ).  
 470 Nevertheless, the systematic offsets tend to be lowest for the deciduous sites ( $\Delta\delta^2\text{H}$  and  $\Delta\delta^{18}\text{O}$  is  
 471 closer to zero with  $\sim -5\text{‰} \pm 15$  and  $\sim -1.1\text{‰} \pm 2.1$ ), followed by grass sites ( $\sim -14\text{‰} \pm 20$  and  $\sim$   
 472  $2.1\text{‰} \pm 2.6$ ). In comparison, the coniferous sites show the largest offsets ( $\sim -23\text{‰} \pm 26$  for  $\Delta\delta^2\text{H}$   
 473  $\sim -3.0\text{‰} \pm 3.3$  for  $\Delta\delta^{18}\text{O}$ ). Differences are, however, not statistically significant. The systematic  
 474 offset and the large variability might have more specific reasons, and we suggest that this is  
 475 related to the type of vegetation. Deciduous trees produce lots of leaf waxes and sugars (e.g.  
 476 Prietzel et al., 2013; Zech et al., 2012a), and all biomarkers reflect and record the

477 evapotranspirative enrichment of the leaf water (e.g. Kahmen et al., 2013; Tuthorn et al., 2014).  
478 By contrast, coniferous trees produce quite low amounts of *n*-alkanes (Diefendorf and Freimuth,  
479 2016; Zech et al., 2012a), while sugar concentrations are as high as in other vascular plants (e.g.  
480 Hepp et al., 2016; Prietzel et al., 2013). For the coniferous soil samples this means that the *n*-  
481 alkanes stem most likely from the understory whereas the sugars originate from grasses and  
482 coniferous needles. When the understory is dominated by grass species then the *n*-alkane  
483 biomarkers do not record the full leaf water enrichment signal, whereas the sugars from the  
484 needles do. The reconstructed leaf water for the coniferous sites is therefore too negative  
485 concerning  $\delta^2\text{H}$ , and reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  values thus also become too  
486 negative (Fig. 8). Concerning the grass sites, the following explanation can be found. Correcting  
487 for “signal damping” makes the reconstructed leaf water points more positive and shifts them  
488 in Fig. 8 up and right. As the “signal damping” is stronger for  $\delta^2\text{H}$  than for  $\delta^{18}\text{O}$  the corrected  
489 leaf water points would now plot above the uncorrected ones. The corrected leaf water points  
490 lead to more positive reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  values for the grass sites.  
491 However, Gao et al. (2014) and Liu et al. (2016) showed that the  $\varepsilon_{\text{bio}}$  (regarding  $^2\text{H}$  between *n*-  
492 alkanes and leaf water) of monocotyledon plants could be larger than those of dicotyledonous  
493 ones. This would therefore also cause a more negative  $\varepsilon_{n\text{-alkane/precipitation}}$  for grasses compared to  
494 trees. We observe that the  $\varepsilon_{n\text{-alkane/precipitation}}$  is indeed more negative for the grass sites compared  
495 to the forest sites (Fig 7 and section 3.6). Therefore, effects of “signal damping” vs. variable  
496  $\varepsilon_{\text{bio}}$  along with vegetation types are indistinguishable here. As an outlook for a future study, we  
497 therefore strongly recommend a comparison between the here measured  $\delta^2\text{H}_{n\text{-alkane}}$  values with  
498 modelled ones using e.g. the new available model approach from Konecky et al. (2019), which  
499 could provide insights if such vegetation effects on  $\varepsilon_{\text{bio}}$  of  $^2\text{H}$  in *n*-alkanes are describable.

500

501 Vegetation type specific rooting depths could partly cause the overall high variability in  
502 reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$ . Deep rooting species most likely use the water  
503 from deeper soil horizons and/or shallow ground water, which is equal to the (weighted) mean  
504 annual precipitation (e.g. Herrmann et al., 1987). Shallow rooting plants take up water from  
505 upper soil horizons, which is influenced by seasonal variations in  $\delta^2\text{H}_{\text{precipitation}}$  and  $\delta^{18}\text{O}_{\text{precipitation}}$   
506 and by soil water enrichment (Dubbert et al., 2013). Thus, the overall assumption that the source  
507 water of the plants reflects the local (weighted) mean precipitation might be not fully valid for  
508 all sites. Moreover, a partly contribution of root-derived rather than leaf-derived sugar  
509 biomarkers in our topsoil samples is very likely. This does, by contrast, not apply for *n*-alkanes,  
510 which are hardly produced in roots (Zech et al., 2012b and the discussion therein).

511  
 512 **Fig. 9.** Correlation of reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  vs. precipitation  $\delta^2\text{H}_{\text{GIPR,OIPC}}$   
 513 and  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  (A and C). Black lines indicate 1:1 relationship. Differences between  
 514 reconstructed source water and precipitation ( $\Delta\delta^2\text{H}$ ,  $\delta^{18}\text{O} = \delta^2\text{H}_{\text{source-water}} - \delta^2\text{H}_{\text{GIPR,OIPC}}$ ,  
 515  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$ ) for the three different vegetation types (B and D). Box plots show  
 516 median (red line), interquartile range (IQR) with upper (75%) and lower (25%) quartiles, lowest  
 517 whisker still within 1.5IQR of lower quartile, and highest whisker still within 1.5IQR of upper  
 518 quartile. Abbreviations: con = coniferous forest sites (n=9); dec = deciduous forest sites (n=11);  
 519 grass = grassland sites (n=4).

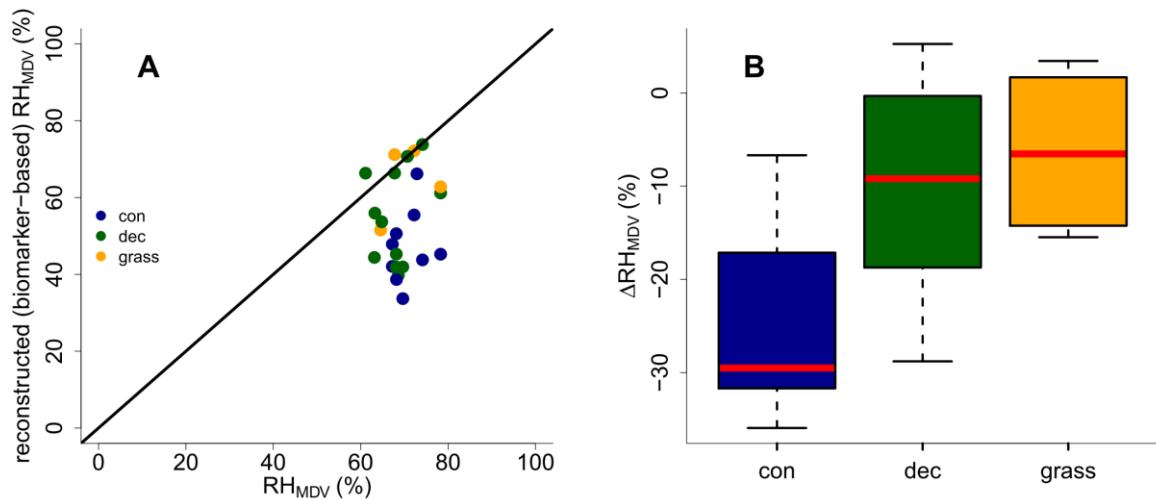

520 Moreover, the high variability within the vegetation types could be caused by variability in  $\varepsilon_{\text{bio}}$   
 521 of  $^2\text{H}$  in  $n$ -alkanes, as well as  $^{18}\text{O}$  in sugars. There is an ongoing discussion about the correct  
 522  $\varepsilon_{\text{bio}}$  for  $^{18}\text{O}$  in hemicellulose sugars (Sternberg, 2014 vs. Zech et al., 2014), and  $\varepsilon_{\text{bio}}$  is probably  
 523 not constant over all vegetation types. This translates into errors concerning leaf water  
 524 reconstruction and thus for reconstructing  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  values (Eq. 9 and Fig.  
 525 8). Likewise, the  $\varepsilon_{\text{bio}}$  values reported in the literature for  $^2\text{H}$  of  $n$ -alkanes can be off from -160‰  
 526 by tens of permille (Feakins and Sessions, 2010; Tipple et al., 2015; Feakins et al., 2016;  
 527 Freimuth et al., 2017). The degree to which hydrogen originates from NADPH rather than leaf  
 528 water is important, because NADPH is more negative (Schmidt et al., 2003). The wide range  
 529 in biosynthetic  $^2\text{H}$  fractionation factors, which can be even larger, is therefore also related to  
 530 the carbon and energy metabolism state of plants (Cormier et al., 2018).

531 **3.8 RH reconstruction**

532 Reconstructed RH<sub>MDV</sub> ranges from 34 to 74%, while RH<sub>MDV</sub> from climate station data range  
 533 from 61 to 78% (Fig. 10A). Biomarker-based values thus systematically underestimate the  
 534 station data ( $\Delta\text{RH}_{\text{MDV}} = -17\% \pm 12$ ). Yet the offsets are much less for deciduous tree and grass  
 535 sites ( $\Delta\text{RH}_{\text{MDV}} = -10\% \pm 12$  and  $-7\% \pm 9$ , respectively; Fig. 10B). The offsets for the coniferous  
 536 sites are  $-30\% \pm 11$ , and significantly larger than for the deciduous and grass sites (p-values <  
 537 0.05).

538 Too low reconstructed RH<sub>MDV</sub> values for the coniferous sites make sense in view of the  
 539 previously discussed option that soils contain *n*-alkanes from the understory (which is  
 540 dominated by grass species), while sugars stem from needles and grasses. As explained earlier  
 541 already, the “signal damping” leads to too negative reconstructed  $\delta^2\text{H}_{\text{leaf-water}}$  (whereas  $\delta^{18}\text{O}$  is  
 542 affected less by the “signal damping”), and too negative  $\delta^2\text{H}_{\text{leaf-water}}$  translates into  
 543 overestimated d-excess and underestimated RH values. In Fig. 8, a correction for this requires  
 544 moving the coniferous leaf water data points upwards towards more positive  $\delta^2\text{H}$  values, thus  
 545 the distance between the leaf water and the source water is reduced. It should be noted that also  
 546 here variable  $\epsilon_{\text{bio}}$  (regarding  $^2\text{H}$  between *n*-alkanes and leaf water) along with vegetation types  
 547 could not be distinguished from “signal damping” effects.

548 The underestimation of RH for the deciduous and grass sites could be partly associated with the  
 549 use of the GMWL as baseline for the coupled  $\delta^2\text{H}_{n\text{-alkane}}-\delta^{18}\text{O}_{\text{sugar}}$  approach. The deuterium-  
 550 excess of the LMWLs is generally lower than the  $+10\text{\textperthousand}$  of the GMWL, while the slopes of the  
 551 LMWLs are well comparable to the GMWL (Stumpp et al., 2014). In addition, if soil water  
 552 evaporation occurred before water uptake by the plants, this would lead to an underestimation  
 553 of biomarker-based RH<sub>MDV</sub> values, too. It can be furthermore assumed that plant metabolism is  
 554 highest during times with direct sunshine and high irradiation, i.e. during noon at sunny days.  
 555 The relevant RH could therefore be lower than the climate station-derived RH<sub>MDV</sub>. Indeed,  
 556 already climate station RH<sub>MDV</sub> is considerably lower than RH<sub>MA</sub> and RH<sub>MV</sub> (Tab. S1).

557 **Fig. 10.** (A) Comparison of reconstructed (biomarker-based) RH<sub>MDV</sub> values and climate station  
 558 RH<sub>MDV</sub> data. The black line indicates the 1:1 relationship. (B) Differences between  
 559 reconstructed and climate station RH<sub>MDV</sub> values ( $\Delta\text{RH}_{\text{MDV}} = \text{reconstructed} - \text{climate station}$   
 560 RH<sub>MDV</sub>) for the three different vegetation types along the transect. Abbreviations: con =  
 561 coniferous forest sites (n=9); dec = deciduous forest sites (n=11); grass = grassland sites (n=4).

563 The uncertainty of reconstructed  $\text{RH}_{\text{MDV}}$  values are large for all three investigated vegetation  
564 types, and again these uncertainties are probably also related to  $\varepsilon_{\text{bio}}$ , which is most likely not  
565 constant as assumed for our calculations. Moreover, microclimate variability is underestimated  
566 in our approach. As mentioned in the sections 2.4.2 and 3.7, in the coupled approach not only  
567 the source water of the plants is equated with (weighted) mean annual precipitation, but also an  
568 isotopic equilibrium between the source water and the (local) atmospheric water vapour is  
569 assumed. However, in areas with distinct seasonality this might be not fully valid. To account  
570 for this lack of equilibrium between precipitation and local atmospheric water vapour, apparent  
571  $\varepsilon$  values can be calculated with data from Jacob and Sonntag (1991). As shown by Hepp et al.  
572 (2018) those values can be used to achieve alternative RH reconstructions based on the coupled  
573  $\delta^2\text{H}_{n\text{-alkane}}-\delta^{18}\text{O}_{\text{sugar}}$  approach. Such calculated  $\text{RH}_{\text{MDV}}$  values are on average 1.5% more  
574 negative than the original values. However, this difference in RH is far below the analytical  
575 uncertainties of the compound-specific biomarker isotope analysis.

576 Finally, the integration time of the investigated topsoils has to be discussed. Unfortunately, no  
577  $^{14}\text{C}$  dates are available for the soil samples. However, most likely the organic matter has been  
578 built up over a longer timescale than the available climate data, which is used for comparison.  
579 In combination with vegetation changes/management changes throughout that period, this  
580 could surely lead to a less tight relationship of the reconstructions compared to the climate  
581 station data. Root input of arabinose and xylose seems to be of minor relevance in our topsoil  
582 samples. Otherwise, the reconstructed  $\delta^{18}\text{O}_{\text{sugar}}$  values would be too negative resulting in  
583 RH<sub>MDV</sub> overestimations, which is not observed.

584

## 585 4 Conclusions

586 We were able to show that

- 587 (i) the vegetation type does not significantly influence the brGDGT concentrations and  
588 proxies, yet the coniferous sites tend to have higher brGDGT concentrations, BIT  
589 indices and CBT-MBT' ratios, while grass sites tend to be lowest.
- 590 (ii) CBT faithfully records soil pH with a median  $\Delta\text{pH}$  of  $0.6 \pm 0.6$ , The CBT  
591 overestimates the real pH particularly at the forest sites.
- 592 (iii) CBT-MBT'-derived  $T_{\text{MA}}$  reflect the climate station-derived  $T_{\text{MA}}$  values with a  
593 median  $\Delta T_{\text{MA}}$  of  $0.5^{\circ}\text{C} \pm 2.4$ , but again slightly too high reconstructions for the forest  
594 sites were observed.
- 595 (iv) differences in the apparent fractionation between the investigated vegetation types  
596 can be explained with “signal damping”.
- 597 (v) the reconstructed  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  reflect the  $\delta^2\text{H}_{\text{GIPR,OIPC}}$  and  
598  $\delta^{18}\text{O}_{\text{GIPR,OIPC}}$  with a systematic offset for  $\delta^2\text{H}$  of  $\sim -21\% \pm 22$  and for  $\delta^{18}\text{O}$  of  $\sim -2.9\% \pm 2.8$  (based on overall medians of  $\Delta\delta^2\text{H}$ ,  $\Delta\delta^{18}\text{O}$ ). This is caused by too negative  
600 reconstructions for coniferous and grass sites. For coniferous sites, this can be  
601 explained with *n*-alkanes originating from understory grasses. As for the grass sites,  
602 the “signal damping” or variable  $\varepsilon_{\text{bio}}$  along with vegetation types effect  $\delta^2\text{H}$  more  
603 than  $\delta^{18}\text{O}$ . This leads to too negative reconstructed  $\delta^2\text{H}_{\text{leaf-water}}$  values and thus to too  
604 negative  $\delta^2\text{H}_{\text{source-water}}$  and  $\delta^{18}\text{O}_{\text{source-water}}$  reconstructions.

605 (vi) reconstructed (biomarker-based)  $\text{RH}_{\text{MDV}}$  values tend to underestimate climate  
606 station-derived  $\text{RH}_{\text{MDV}}$  values ( $\Delta\text{RH}_{\text{MDV}} = \sim -17\% \pm 12$ ). For coniferous sites the  
607 underestimations are strongest, which can be explained with understory grasses  
608 being the main source of *n*-alkanes for the investigated soils under coniferous  
609 forests.

610 Overall, our study highlights the great potential of brGDGTs and the coupled  $\delta^2\text{H}_{n\text{-alkane}}$ -  
611  $\delta^{18}\text{O}_{\text{sugar}}$  approach for more quantitative paleoclimate reconstructions. Taking into account  
612 effects of different vegetation types improves correlations and reconstructions. This holds  
613 particularly true for the coupled  $\delta^2\text{H}_{n\text{-alkane}}\text{-}\delta^{18}\text{O}_{\text{sugar}}$  approach, which is affected by “signal  
614 damping” of the grass vegetation or variable  $\varepsilon_{\text{bio}}$  (regarding  $^2\text{H}$  between *n*-alkanes and leaf  
615 water) along with vegetation types. By contrast, vegetation-related effects do not strongly  
616 influence the brGDGT-derived reconstructions. Assuming constant  $\varepsilon_{\text{bio}}$  is likely a considerable  
617 source of uncertainty and should be further addressed in future field and/or modelling studies.  
618 Climate chamber experiments are most promising to further evaluate and refine the coupled  
619  $\delta^2\text{H}_{n\text{-alkane}}\text{-}\delta^{18}\text{O}_{\text{sugar}}$  approach, because uncertainties related to microclimate variability can be  
620 reduced. Field experiments like ours suffer from the fact that biomarker pools in the sampled  
621 topsoils may have been affected by past vegetation and climate changes and by the rather small  
622 range covered by the sampled transect. Both makes the comparison between reconstructions  
623 and observations more difficult compared to large datasets und well defined conditions.

## 625 Acknowledgements

626 We thank L. Wüthrich, H. Veit, T. Sprafke, A. Groos (all University of Bern), A. Kühnel  
627 (Technical University of Munich) for constructive discussions and statistical advices, and M.  
628 Schaarschmidt (University of Bayreuth), C. Heinrich and M. Benesch (Martin-Luther-  
629 University Halle-Wittenberg) for laboratory assistance during  $\delta^{18}\text{O}_{\text{sugar}}$  analysis and pH  
630 measurements, respectively. The Swiss National Science Foundation (PP00P2 150590) funded  
631 this research. J. Hepp greatly acknowledges the support by the German Federal Environmental  
632 Foundation (DBU) in form of his PhD-fellowship. This publication was funded by the German  
633 Research Foundation (DFG) and the University of Bayreuth in the funding programme Open  
634 Access Publishing.
