12 **Abstract**

13 Sedimented hydrothermal vents are likely to be widespread compared to hard substrate hot vents. They host  
14 chemosynthetic microbial communities which fix inorganic C at the seafloor, as well as a wide range of  
15 macroinfauna, including vent-obligate and background non-vent taxa. There are no previous direct observations  
16 of Carbon cycling at a sedimented hydrothermal vent. We conducted <sup>13</sup>C isotope tracing experiments at 3  
17 sedimented sites in the Bransfield Strait, Antarctica, which showed different degrees of hydrothermalism. Two  
18 experimental treatments were applied, with <sup>13</sup>C added as either algal detritus (photosynthetic C), or as  
19 bicarbonate (substrate for benthic C fixation). Algal <sup>13</sup>C was taken up by both bacteria and metazoan  
20 macrofaunal, but its dominant fate was respiration, as observed at deeper and more food limited sites elsewhere.  
21 Rates of <sup>13</sup>C uptake and respiration suggested that the diffuse hydrothermal site was not the hotspot of benthic  
22 C-cycling that we hypothesised it would be. Fixation of inorganic C into bacterial biomass was observed at all  
23 sites, and was measurable at 2 out of 3 sites. At all sites, newly fixed C was transferred to metazoan macrofauna.  
24 Fixation rates were relatively low compared to similar experiments elsewhere, thus C fixed at the seafloor was a  
25 minor C source for the benthic ecosystem. However, as the greatest amount of benthic C fixation occurred at the

26 off vent (non-hydrothermal) site ( $0.077 \pm 0.034$  mg C m<sup>-2</sup> fixed during 60 h), we suggest that benthic fixation of  
27 inorganic C is more widespread than previously thought, and warrants further study.  
28

## 29           1. Introduction

30 Sedimented hydrothermal vent (SHV) sites are those where hydrothermal fluid diffuses through soft sediment  
31 cover on its way to mixing with oceanic bottom water. This creates hot (up to ~100°C) sediments with  
32 porewaters rich in dissolved sulphide and methane. This supports microbes that conduct chemosynthetic C  
33 fixation through a range of pathways (Bernardino et al., 2012). These hydrothermally influenced sediments are  
34 likely to be more spatially extensive than hard substrate vents, although their diffusive nature makes their extent  
35 hard to quantify. Sedimented hydrothermal vents have been shown to influence biological community  
36 composition and nutrition at adjacent sites which were otherwise characterised as ‘inactive’ or ‘off-vent’ (Levin  
37 et al., 2009; Bell et al., 2016a; Bell et al. 2016b; Bell et al., 2017a). However, the ecology of sedimented  
38 hydrothermal sites has received relatively little study. There is only one modelling study that has focused on the  
39 interaction between benthic ecosystems and C-cycling at SHVs (Bell et al., 2017b), and there are no direct  
40 observations of SHV C-cycling by components of the benthic ecosystem.

41 So far, a limited number of studies have used natural stable isotopic analysis to determine carbon sources and  
42 their fixation pathways utilised by infauna at SHVs (Levin et al., 2009; Soto, 2009; Sweetman et al., 2013; Bell  
43 et al. 2016b; Portail et al. 2016). Evidence has shown that C fixed during anaerobic oxidation of methane, oxic  
44 methanotrophy, sulphide oxidation, as well photosynthetic organic matter (OM) sinking from the surface, are all  
45 utilised by macrofauna to varying extents at SHVs (Levin et al., 2009; Bernardino et al., 2012). It is challenging  
46 to quantify the relative contributions of different C sources to macrofaunal diets, both because the natural  
47 isotopic ranges of some C sources overlap, and because often the isotopic compositions of those end members  
48 could not be measured (Levin et al., 2009; Bell et al., 2016b). Unknown variability in trophic discrimination  
49 factors also currently preclude quantitative estimates of the relative contribution of different C sources.

50 Stable isotope tracing experiments offer a way to overcome some of these issues. The experimental addition of  
51 labelled C sources, either photosynthetic OM or dissolved inorganic C (bicarbonate) to SHV sediment allows  
52 production of chemosynthetic OM, and the transfer of different OM types into the macrobenthos and other C  
53 pools in the short term to be directly observed. Such experiments (using only photosynthetic OM) have been  
54 conducted at a wide range of (ostensibly) non-chemosynthetic benthic sites, and have shown a wide variation in  
55 the relative importance of different biological C processing pathways (Woulds et al., 2009; 2016). At food  
56 limited sites in the deep-sea, respiration tends to be the dominant fate of added OM (van Oevelen et al. 2011;  
57 2012). Shallower, more food rich settings such as coastal fjords and estuaries, with greater sedimentary organic  
58 C concentrations and higher macrofaunal biomass, show a pattern of biological C processing in which uptake by

59 fauna is a more important process, and at unusual and particularly food rich sites, such as the lower margin of  
60 the Arabian Sea oxygen minimum zone (~1000 m depth), macrofaunal C uptake can even be the dominant  
61 process (Woulds et al., 2009; 2016).

62 The occurrence of chemosynthesis in a benthic habitat represents an additional source of fresh, labile OM in an  
63 environment that would otherwise be more severely food limited. For this reason, it has been suggested that  
64 hydrothermally influenced sites can be biomass hotspots, where biogeochemical cycling is rapid (Bernardino et  
65 al., 2012). However, due to the environmental toxicity created by hydrothermal fluid, and the fact that the  
66 majority of taxa inhabiting SHVs are background rather than vent-endemic, the difference in faunal biomass  
67 between SHVs and adjacent non-vent sites is highly variable (Levin et al., 2009; Bernardino et al., 2012; Bell et  
68 al., 2016). It therefore seems possible that biological C processing at SHVs will show a distinct complement of  
69 biological C processing patterns unlike those observed elsewhere in the deep sea. The food rich, high biomass  
70 characteristics of some SHVs may lead to biological C processing that is and more similar to shallower, food  
71 rich environments. On the contrary, spatially variable biomass patterns, as well as the metabolic costs associated  
72 with potentially high temperatures and porewater toxicity could counteract the effect of enhanced food  
73 availability. As direct measurements of biological C processing rates and pathways have not previously been  
74 made at SHVs or in the Southern Ocean, there remains a gap in our understanding of sedimentary C and N-  
75 cycling.

76 In this study we conducted stable isotope tracing experiments at three sites of variable hydrothermal activity in  
77 the Bransfield Strait, Antarctica. To the best of our knowledge this is the first isotope tracing experiment in this  
78 type of system. The following hypotheses were tested:

- 79 • Hydrothermally influenced sites exhibiting chemosynthesis will show elevated rates of biological C  
80 processing.
- 81 • At hydrothermally influenced sites bicarbonate will be fixed by chemoautotrophs and transferred to the  
82 macrofauna.
- 83 • Preference for feeding on photosynthetic versus chemosynthetic OM will be taxon dependent.

## 84 2. Methods

### 85 2.1 2.1 Study sites

86 In this study we focus on a SHV in the Bransfield Strait, close to the tip of the Antarctic peninsula. The  
87 discovery of hydrothermal venting in the Bransfield Strait was reported by Klinkhammer et al. (2001), who  
88 detected hydrothermal plumes in the water column, and recovered hot ‘soupy’ sediment from Hook Ridge. In  
89 addition, a species of *Sclerolinum* (Sahling et al., 2005; Georgieva et al., 2015) there has been described, and  
90 porewater geochemistry and hydrothermal flux rates have been published (Sahling et al., 2005; Aquilina et al.,  
91 2013).

92 Experiments were conducted at three sites in the Bransfield Strait, Antarctica (Fig. 1). Two of the sites lay on  
93 raised edifices, known as Hook Ridge and Middle Sister, along the axis of the basin, and were selected as being  
94 likely to exhibit diffuse hydrothermal venting, and the former was the location where diffuse venting had been  
95 identified. A third site, at a similar depth but along the north side of the basin, was chosen as an off-vent control  
96 (hereafter known as ‘Off-Vent’).

97 Porewater geochemistry at Middle Sister and Off-Vent were consistent with microbial processes without  
98 influence of hydrothermal activity. Porewater  $\text{NO}_3^-$  and  $\text{NH}_4^+$  profiles were indicative of nitrate reduction, but  
99 downcore declines in  $\text{SO}_4^{2-}$  and  $\text{Cl}^-$  were lacking over the ~40 cm depth sampled. In contrast, at Hook Ridge  
100  $\text{SO}_4^{2-}$  was depleted by up to 11% compared to seawater, and  $\text{Cl}^-$  by up to 7%, allowing calculation of  
101 hydrothermal advection of 9-33  $\text{cm y}^{-1}$  (Aquilina et al., 2013).

102 Sediment organic carbon (Corg) concentrations were lower at Hook Ridge (0.97 wt% Corg) than at the Off-Vent  
103 and Middle Sister sites, which showed similar values (1.35 and 1.4 wt% Corg respectively, Table 1). The sites  
104 differed in biomass of different groups, with Hook Ridge and Middle Sister showing higher bacterial biomass  
105 and lower macrofaunal biomass than the Off-Vent site (Table 1). Hook Ridge was the only site classified as  
106 hydrothermally active by Aquilina et al. (2013). Porewaters were enriched in sulphide, methane and dissolved  
107 metals and depleted in chloride, and the calculated hydrothermal advection rate was 9-33  $\text{cm y}^{-1}$ . Macrofauna  
108 tended to be representative of the background taxa of the region. Polychaetes were numerically dominant (41-  
109 56%), except at Hook Ridge, which was dominated by peracarids. Oligochaetes were the next most dominant at  
110 all sites. Vent endemic fauna were represented by two species of siboglinid polychaete; *S. contortum* at Hook  
111 Ridge, and *Siboglimun sp.* elsewhere (Bell et al., 2016a). Each site also supported one species of siboglinid

112 polychaete. In the case of Hook Ridge this was *S. contortum*, and at Middle Sister and the Off-Vent site it was  
113 *Siboglinum sp.*, and they were always a minority constituent of the community (Bell et al., 2016 a).

## 114 **2.2 Isotope tracing experiments**

115 Sediment cores (10 cm i.d.) were recovered using a multiple corer, and kept in the dark at seafloor temperatures  
116 (Table 1) using cooled incubators. Experiments were initiated by addition of isotopically enriched substrates.

117 Cores were then sealed and incubated for ~60 h, during which core-top water was continuously stirred.

118 Duplicate cores were subjected to each of two treatments. In the ‘algae’ treatment, lyophilized algal cells  
119 (*Chlorella*, Cambridge Isotope Laboratories, CNLM-455-1) enriched in  $^{13}\text{C}$  and  $^{15}\text{N}$  (both ~100 at %) were  
120 allowed to settle on the sediment surface, giving a final dose of  $436 \pm 30 \text{ mg C m}^{-2}$ . This was equivalent to ~1.6%  
121 of total OC in the surface 1 cm of sediment, or ~9% of annual OC input (Bell et al., 2017b). It is recognised that  
122 such organic detritus is less degraded than the sinking photosynthetic material which normally reaches the  
123 depths of our study sites. This is a limitation of the method common to all such experiments in the literature, and  
124 means that rates for processing of added C in ‘algae’ experiments should be considered maximal. Further,  
125 diatom detritus would have been more representative of local photosynthetic material, but was unfortunately not  
126 available.

127 In the ‘Bicarbonate’ treatment a solution of 100 %  $^{13}\text{C}$  labelled sodium bicarbonate and 100 %  $^{15}\text{N}$  labelled  
128 ammonium chloride was injected in the surface 5 cm of sediment porewater, to give a dose of  $306 \text{ mg C m}^{-2}$  and  
129  $2.52 \text{ mg N m}^{-2}$ , and an estimated porewater bicarbonate concentration of 1 mM.

130 At intervals (T0 and every ~12 h thereafter) during the incubation, core top water samples were withdrawn from  
131 Algae treatment cores, and stored in crimp-cap vials poisoned with  $\text{HgCl}_2$  for dissolved inorganic carbon (DIC)  
132 analysis. At the end of the experiment cores were extruded and sectioned at intervals of 0-1, 1-2, 2-3, 3-5 and 5-  
133 10 cm. Half of each section was frozen at  $-20^\circ\text{C}$ , and the other half was preserved in buffered 10% formalin.

## 134 **2.3 Sample processing and analysis**

135 Overlying water samples were analysed for concentration and isotopic composition of DIC in triplicate on a  
136 Thermalox TOC analyser coupled to a Thermo Delta V Advantage IRMS via a Conflo IV interface, using a  
137 Thermo TriPlus autosampler. The reaction column was filled with  $\text{H}_3\text{PO}_4$ -coated beads.

138 Frozen sediment samples were freeze dried, and surface 0-1 cm horizons were analysed for phospholipid fatty  
139 acids (PLFAs) following Main et al. (2015). Briefly, samples were extracted in a modified Bligh and Dyer

140 extraction solution of chloroform:methanol:citrate buffer, 1:2:0.8. The polar fraction was obtained by loading  
141 samples onto ISOLUTE SPE columns, washing with chloroform and acetone, and eluting with methanol. After  
142 addition of nonadecanoic acid (C19:0) as an internal standard, extracts were derivatised in the presence of KOH  
143 in methanol. Derivatization was quenched with water and acetic acid, and the organic fraction was extracted by  
144 washing with 4:1 isohexane:chloroform. Samples were dried and then taken up in isohexane for analysis on a  
145 Trace Ultra GC, connected via a GC Combustion III to a Delta V Advantage IRMS (Thermo Finnigan,  
146 Bremen). The isotopic signature of each PLFA was measured against a CO<sub>2</sub> reference gas which is traceable to  
147 IAEA reference material NBS 19 TS-Limestone, with a precision of  $\pm 0.31$  ‰, and corrected for the C atom  
148 added during derivatization.

149 Sediment horizons between 0 and 10 cm preserved in formalin were sieved over a 300 $\mu$ m mesh. Macrofauna  
150 were extracted under a binocular microscope, identified to broad taxonomic level, air dried in pre-weighed tin  
151 capsules, and weighed. In some cases multiple individuals were pooled to create samples large enough for  
152 analysis. Fauna were de-carbonated by dropwise addition of 0.1M HCl, followed by air drying at 50°C.  
153 Calcareous foraminifera and bivalves which were too small for manual removal of shells were de-carbonated  
154 with 6N HCl. Fauna were analysed for their C contents and isotopic signature using a Flash EA 1112 Series  
155 Elemental Analyser connected via a ConFlo III to a Delta<sup>Plus</sup> XP isotope ratio mass spectrometer (all Thermo  
156 Finnigan, Bremen). Carbon contents was quantified using the area under the mass spectrometer response curve,  
157 against National Institute of Standards and Technology reference material 1547 peach leaves (repeat analysis  
158 gave precision  $\pm 0.35$  ‰). Isotopic data were traceable to IAEA reference materials USGS40 and USGS41 (both  
159 L-glutamic acid), with a precision  $\pm 0.13$  ‰.

## 160 **2.4 Data treatment**

161 Respiration of added algal C was calculated for cores subjected to the algae treatment. The amount of excess  
162  $\text{DI}^{13}\text{C}$  in each sample was calculated by first subtracting the natural abundance of  $^{13}\text{C}$  in DIC. This was scaled  
163 up to give the total amount of DIC from the added algae at each sample timepoint, and corrected for water  
164 removed and added during sampling. Respiration rate was calculated for each core by placing a line of best fit  
165 through the amount of added  $^{13}\text{C}$  over time, and normalised to surface area.

166 Bacterial incorporation of  $^{13}\text{C}$  was calculated by first subtracting the natural abundance of  $^{13}\text{C}$  from the isotopic  
167 signature of each PLFA (data published in Bell et al., 2017), where the difference exceeded the precision of the  
168 analytical technique, to give the amount of added C in each compound. Bacterial incorporation was then

169 calculated using the 4 bacteria-specific PLFAs isoC14:0, isoC15:0, antisoC15:0, and isoC16:0, following  
170 Boschker and Middelburg (2002). Uptake of  $^{13}\text{C}$  into these bacteria-specific PLFAs was summed, and scaled up  
171 on the basis that they together account for 14% of total bacterial PLFA, and that PLFAs account for 5.6% of  
172 total bacterial biomass. For samples in the bicarbonate treatment further scaling up was applied, to account for  
173 the fact that the addition of  $^{13}\text{C}$  bicarbonate was calculated to result in a porewater DIC pool that was 22 atom %  
174  $^{13}\text{C}$ .

175 Faunal uptake of added  $^{13}\text{C}$  was calculated by subtracting  $^{13}\text{C}$  attributable to its natural abundance in the  
176 appropriate taxon (data published in Bell et al., 2017 a) from faunal isotopic signatures, where the difference  
177 exceeded the precision of the analytical technique, and multiplying by the quantity of organic C in each  
178 specimen. Specimens were summed for each core, and the value multiplied by 2, to account for only half of  
179 each horizon being used for faunal extraction.

### 180 **3. Results**

181 Data files can be accessed at DOIxxxx.

#### 182 **3.1 3.1 Respiration**

183 Respiration rates measured in algae addition experiments varied from  $0.03 \text{ mg C m}^{-2} \text{ h}^{-1}$  at the off vent site to  
184  $0.15 \text{ mg C m}^{-2} \text{ h}^{-1}$  at Middle Sister (Fig. 2).

#### 185 **3.2 3.2 Bacterial uptake and PLFA suite**

186 In the algae addition experiments, total bacterial uptake of C throughout the experiment was maximal at Middle  
187 Sister and Hook Ridge ( $1.30\text{-}1.91$  and  $1.25 \text{ mg C m}^{-2}$ , respectively), and minimal at the off vent site ( $0.25\text{-}0.77$   
188  $\text{mg C m}^{-2}$ , Fig. 3). In bicarbonate addition experiments, in which incorporation of  $^{13}\text{C}$  into bacterial PLFAs  
189 represents chemosynthesis, bacterial incorporation of bicarbonate was maximal at the off vent site ( $0.05\text{-}0.10$   
190  $\text{mg C m}^{-2}$ ), and was also detectable in one of the replicates at Middle Sister ( $0.003 \text{ mg C m}^{-2}$ , close to detection  
191 limits, so this value is treated with caution), however it was not detectable at Hook Ridge.

192 The PLFA suites at all sites were qualitatively similar. They were dominated by C16:0, C16:1 $\omega$ 7c, and  
193 C18:1 $\omega$ 7, which together constituted  $42 \pm 2\%$  of total PLFAs (Fig. 4). This is at the high end of contributions  
194 from these compounds elsewhere, such as 34-45% in the Arabian Sea, and 41% on the Galicia Bank (Kunihiro  
195 et al., 2014). The relatively high proportions of C16:1 $\omega$ 7 and C18:1 $\omega$ 7 are indicative of the presence of  
196 chemosynthetic and specifically sulphide oxidising bacteria (Colaco et al., 2007). In addition C18:1 $\omega$ 9, which is

197 linked to endosymbionts in vent mussels, and C18:1 $\omega$ 13, which is associated with methylotrophic bacteria were  
198 also present (Colaco et al., 2007).

199 In both algae and bicarbonate addition experiments,  $^{13}\text{C}$  incorporation into PLFAs was dominated by C16:0,  
200 followed by C18:1 $\omega$ 9 and the sulphide oxidiser indicators C16:1 $\omega$ 7 and C18:1 $\omega$ 7 (Fig 4).

### 201 **3.3 Faunal uptake**

202 Faunal uptake of added C differed between A and B replicate cores in all experiments except the algae addition  
203 at the off vent site, and bicarbonate addition at Middle Sister (Fig. 5).

204 In algae addition experiments faunal uptake was similar between the off vent site and one of the Hook Ridge  
205 cores ( $\sim 0.03 \text{ mg C m}^{-2}$ ), while the other Hook Ridge core showed very low faunal C uptake. Considerably  
206 greater faunal uptake ( $0.12 \text{ mg C m}^{-2}$ ) was observed in one of the replicate cores from Middle Sister (Fig. 5).

207 In bicarbonate addition experiments, measurable uptake of  $^{13}\text{C}$  by fauna was observed at all sites. It was  
208 maximal at Hook Ridge ( $0.02 \text{ mg C m}^{-2}$  in one replicate), and the off vent and Middle Sister sites showed  
209 similar values (Table 2, Fig. 5).

210 Small size of individuals meant that organisms had to be pooled for isotopic analysis, limiting the taxonomic  
211 resolution of the faunal uptake data. Although limited in this way, the data show that faunal uptake of  $^{13}\text{C}$  in  
212 both algae and bicarbonate addition experiments was mostly carried out by either polychaetes, or 'mixed  
213 macrofauna' (Fig. 6). This latter category contained variously bivalves, crustaceans, echinoderms, nematodes  
214 and foraminifera, in cases where those groups were not present in sufficient numbers for separate reporting of  
215 their C uptake. When a group was present in sufficient quantity it was analysed separately. As with total  
216 macrofaunal  $^{13}\text{C}$  uptake, there was considerable variability between replicate cores in the most abundant  
217 taxonomic groups. In addition, meiofaunal organisms took up  $^{13}\text{C}$  at Middle Sister, and the bicarbonate  $^{13}\text{C}$  that  
218 was transferred to macrofauna at Hook Ridge was mostly observed in amphipod crustaceans.

## 219 **4. Discussion**

### 220 **4.1 Occurrence of inorganic C fixation**

221 The results of bicarbonate addition experiments show evidence for occurrence of benthic C-fixation at all sites,  
222 and transfer of that C to the macrofauna, in the form of isotopic enrichment of bacterial PLFAs at the off-vent  
223 and Middle Sister sites (Fig. 3), and of macrofauna at the Hook Ridge and Middle Sister sites (Fig. 5). The

224 quantities of bicarbonate  $^{13}\text{C}$  detected in bacterial and faunal biomass were low, and tended to be 1 to 2 orders of  
225 magnitude smaller than equivalent values for algae addition experiments (Table 2). We have confidence that the  
226 values reported are above detection limits, in that data were only used where the enrichment of organisms or  
227 PLFAs above their natural background signatures was greater than the analytical precision of the method. The  
228 greatest quantities of bacterial uptake were measured at the off-vent site (Fig. 3), and the greatest quantity  
229 transferred to the fauna was measured at Hook Ridge (Fig. 5), however, due to the low values measured and the  
230 evident patchiness of faunal communities we do not feel these differences are suitable for further discussion.

231 The most striking result of the bicarbonate addition experiments was that evidence for benthic C fixation was  
232 found at all sites, not only at the hydrothermally influenced Hook Ridge. Further, the site showing the largest  
233 amount of incorporation of bicarbonate  $^{13}\text{C}$  into bacterial PLFAs was the off-vent ‘control’ site (Table 2, Fig. 3).  
234 This is consistent with the occurrence of siboglinids at all sites. These host chemosynthetic endosymbionts most  
235 of which conduct sulphide oxidation (Thornhill et al., 2008; Georgieva et al., 2015). It should be noted that the  
236 evidence for inorganic C fixation comes from PLFAs in the bulk sediment, while isotopic signatures of  
237 siboglinids did not show enrichment above background values. Therefore the occurrence of benthic C fixation is  
238 not only associated with siboglinids.

239 Experiments were designed to replicate natural conditions as far as practically possible, while being limited to  
240 shipboard rather than in situ methods. One result of this is that the sediment contained in cores was detached  
241 from the upward flux of hydrothermal fluid, and the electron donors it supplied. This could have limited  
242 inorganic C fixation, which would have impacted the rates measured at Hook Ridge. We suggest however that  
243 this is not a serious limitation, as Hook Ridge was rather mildly hydrothermal. Vent endemic fauna were almost  
244 absent (Bell et al., 2016), there was no increase in faunal biomass close to venting, downcore profiles of  
245 alkalinity, nitrate and ammonium were consistent with normal microbial processes, and hydrothermal advection  
246 rates were  $9\text{-}33\text{ cm y}^{-1}$  (Aquilina et al., 2013). At these low advection rates we suggest that there would not have  
247 been sufficient time during our  $\sim 60$  h experiments for a noticeable depletion in availability of electron donors  
248 supplied by hydrothermal fluid.

249 The evidence suggests that while the amount of benthic C-fixation was always low, it was not restricted to  
250 environments typically thought of as chemosynthetic (sedimented or hard substrate hydrothermal vents, methane  
251 seeps, or organic falls (Bernardino et al., 2012)). Thus, benthic C-fixation appears to play a role in benthic C-  
252 cycling at a much wider range of sites and over a much larger area of the seafloor than previously thought. This  
253 is supported by linear inverse modelling of C-cycling at the sites in this study, which led Bell et al. (2017b) to

254 suggest that chemosynthetic support for ecosystems may have a far greater spatial extent than previously  
255 thought, extending beyond those which are directly hydrothermally influenced. Similar results have also been  
256 reported in non-hydrothermal, but methane rich sediments on the South Georgia margin, where assimilation of  
257  $^{13}\text{C}$  labelled bicarbonate into bacterial biomass, and transfer into macrofauna was also observed (Would et al.,  
258 2019). In addition, in situ observations of benthic C fixation have also been made at mesotrophic, abyssal sites  
259 in the eastern equatorial Pacific, which were not associated with hydrothermal or methane seep activity  
260 (Sweetman et al. 2018). In that study incorporation of  $^{13}\text{C}$  labelled bicarbonate into bacterial PLFAs was  
261 observed at 2 sites separated by 100's of kilometres, at rates similar to bacterial assimilation of phytodetritus C  
262 at the same sites. Together with global scale modelling completed by Middelburg (2011), these studies suggest  
263 that chemoautotrophic C fixation may be considerably more widespread than previously thought. It is therefore  
264 deserving of further study so that it can be quantitatively incorporated into our understanding of the marine C-  
265 cycle.

266 In their study using linear inverse modelling of the benthic food web and C cycle, based on natural isotopic and  
267 biomass data, Bell et al. (2017b) modelled a rate for chemosynthesis of  $5.76\text{-}8.4\text{ mg C m}^{-2}\text{ d}^{-1}$  at Hook Ridge,  
268 and  $<0.006\text{ mg C m}^{-2}\text{ d}^{-1}$  at the off-vent site. These modelled rates at Hook Ridge are considerably higher than  
269 Hook Ridge benthic C-fixation measured in this study, for which there was evidence (labelled PLFAs), but a  
270 rate could not be calculated. The higher modelled rates by Bell et al. (2017 b) may be explained by the fact that  
271 a temperature of  $50^{\circ}\text{C}$  was used for the Hook Ridge site, based on previously published conditions of the site  
272 (Klinkhammer et al., 2001). Unfortunately, equipment was not available while at sea for measurement of  
273 sediment temperature at the study sites, therefore all experiments, including that at Hook Ridge, were conducted  
274 at measured bottom water temperatures of  $0\text{-}1^{\circ}\text{C}$ . It is likely that the rates measured here for chemosynthetic  
275 incorporation of labelled bicarbonate are lower than those that would have been measured in situ. It is also  
276 probable that measurable rates could have been detected at Hook Ridge had more samples been available for  
277 replicate analyses.

278 The maximal rate of benthic C-fixation measured in this study was  $0.050\text{ mg C m}^{-2}\text{ d}^{-1}$ , which occurred in one  
279 core at the off-vent site. This remains considerably lower than the  $0.24\text{-}1.02\text{ mg C m}^{-2}\text{ d}^{-1}$  measured by Molari et  
280 al. (2013, rates calculated in Sweetman et al., 2018) at depths ranging between 1207-4381 m on the Iberian  
281 margin and in the Mediterranean, and the  $1.29\text{ mg C m}^{-2}\text{ d}^{-1}$  measured by Sweetman et al. (2018) at  $\sim 4100$  m  
282 depth in the Clarion Clipperton Zone. The Bransfield Strait sites in this study were shallower, had higher  
283 concentrations of sedimentary organic C, and slightly lower bottom water temperatures than either of the

284 previous studies cited. The very low temperatures at which experiments were conducted (1°C at Hook Ridge  
285 and 0°C at the off vent site) is likely to have contributed to the slow measured rates of benthic C-fixation.  
286 Another factor which may influence benthic C-fixation is the annual flux of photosynthetic C from the surface  
287 (Molari et al., 2013; Bell et al., 2017a). The annual flux of POC to the sediments in the Bransfield Strait is  
288 greater than in the Clarion Clipperton Zone, and probably than in the Mediterranean as well (Masque et al.,  
289 2002; Sweetman et al., 2017), and this may be an additional driver behind the low benthic C-fixation rates  
290 observed. Archaeal abundance has been shown to correlate with dark C-fixation, and addition of labile organic  
291 material has been shown to increase inorganic C fixation rates, perhaps through a combination of heterotrophy  
292 and mixotrophy (Molari et al., 2013). Overall, the factors governing benthic C-fixation rates require  
293 investigation. In addition, the pathways (i.e. autotrophic C fixation versus anapleurotic C fixation by  
294 heterotrophs, Wegener et al., 2012), energy sources (e.g. sulphide, methane) and organisms responsible for  
295 benthic inorganic C fixation have not been identified, and warrant further study.

#### 296 4.2 Carbon uptake by macrofauna

297 Uptake of added C by fauna in isotope tracer experiments usually shows a degree of spatial patchiness (e.g.  
298 Woulds et al., 2007), but this seems to have been particularly marked in the Bransfield Strait, mainly at those  
299 sites with hydrothermal influence. This is consistent with the patchiness of *Sclerolinum contortum* in replicate  
300 cores at Hook Ridge (Bell et al. 2016a). At both Hook Ridge and Middle Sister there was a very marked  
301 difference in faunal uptake of algal C between the A and B replicate cores in algae addition experiments (Fig.  
302 5), and this was considerably greater than that observed, for example, in experiments on the Pakistan margin  
303 Woulds et al. (2007). This is likely to be due to difference in the biomass of fauna present in each core, and such  
304 marked small scale patchiness in faunal communities has been noted previously as a particular feature of SHVs  
305 (Levin et al., 2009; Bernardino et al., 2012). Fine scale distribution of fauna is related to variations in  
306 concentrations of substrates such as sulphide and methane (Levin et al., 2003), therefore the patchiness observed  
307 especially at Hook Ridge is likely related to spatial and temporal fluctuation in hydrothermal advection.  
308 Faunal uptake of added C appeared to be greatest at Middle Sister in algae addition experiments, and at Hook  
309 Ridge in bicarbonate addition experiments, however the variation between replicate cores limits conclusions that  
310 can be drawn. Previous isotope tracing experiments have noted correlations between biomass of taxa and the  
311 amount of C they take up (e.g. Woulds et al., 2007). Further, there was no systematic variation in biomass-  
312 specific C uptake (0.026-0.13 ug C uptake / mg C biomass) between sites, therefore the patterns observed here  
313 in faunal C uptake are likely to result from variation in biomass present in each experimental core.

314 Similarly, the identities of fauna responsible for  $^{13}\text{C}$  uptake was variable between replicate cores (Fig. 6), and  
315 this is also likely to have been driven by variation in the macrofaunal community present in each core. The  
316 prevalence and variable importance of the 'mixed macrofauna' category indicates that in some cases a fairly  
317 diverse assemblage was engaged in C uptake and processing.

318 Previous studies have suggested that SHVs tend to exhibit relatively high biomass macrofaunal communities,  
319 sustained by the additional food source provided by chemosynthesis (Bernadino et al., 2012), and this leads to  
320 an expectation that the macrofauna may be particularly active in processing of organic C in the sediment, in line  
321 with other food rich environments such as estuaries and fjords (Moodley et al., 2000; 2005; Witte et al., 2003a).  
322 This was not the case in the algae addition experiments, with faunal uptake accounting for only 0.05-2.2 % of  
323 total biological  $^{13}\text{C}$  processing (Fig. 7). This is similar to the role of faunal C uptake in overall C processing seen  
324 at deep, organic carbon poor sites such as at 2170 m depth off NW Spain (2.2 %, Moodley et al., 2002), or at  
325 1552 m depth in the Eastern Mediterranean (0.2 %, Moodley et al., 2005), and is lower than that at 4800 m  
326 depth on the Porcupine Abyssal Plain (1.5-26 %, Witte et al., 2003b). Such sites tend to have lower OC  
327 concentrations and lower macrofaunal biomass (Woulds et al., 2016) than was observed in the Bransfield Strait,  
328 therefore the unusually small role of macrofaunal in C uptake in the Bransfield Strait may be due to low  
329 temperatures. Both low temperature and food scarcity have previously been observed to limit metabolic rates in  
330 polar environments (Brockington and Peck, 2001; Sommer and Portner, 2002). Another possible explanation for  
331 the rather small amount of macrofaunal C uptake at the Hook Ridge site may be that the macrofaunal  
332 community, which was composed almost entirely of non vent-obligate, ambient Southern Ocean taxa (Bell et  
333 al., 2016a), had reduced levels of function due to the stress imposed by living at a site influenced by  
334 hydrothermal fluid. The toxicity and relatively high temperature of their environment (compared to non-  
335 hydrothermal Southern Ocean benthic settings) may have resulted in reduced C uptake activity. Therefore,  
336 macrofaunal biomass and C processing activity were limited by a hydrothermal flux that was sufficient to limit  
337 functioning and preclude occurrence of some some locally common taxa, but insufficient to sustain a high  
338 biomass, vent endemic macrofaunal community as seen in other SHVs (Bell et al., 2016 a).

339 Siboglinid polychaetes, known to host chemosynthetic endosymbionts, were present at all study sites (Bell et al.,  
340 2016 a), but were not found to make a substantial contribution to uptake of added  $^{13}\text{C}$ . This is to be expected in  
341 the algae addition experiments, as siboglinids would have direct access to algal C (except possibly via DOC).  
342 Most specimens recovered from biocarbonate addition experiments also showed  $\delta^{13}\text{C}$  values indistinguishable

343 from their natural signature, with one exception at the Middle Sister site which was enriched compared to the  
344 natural signature by 3.2 ‰. The fact that siboglinids did not have a major role in C fixation and cycling in our  
345 experiments may have been partly due to their low abundances in experiment cores compared to patches where  
346 they were maximally abundant (Bell et al., 2016a), or because experiments were not long enough for uptake by  
347 endosymbionts. Nonetheless, our findings show a much reduced role for siboglinids compared to suggestions  
348 made in previous publications. Aquilina et al. (2014) suggested that *Siboglinum sp.* at Hook Ridge may be  
349 sufficiently abundant to be conduits for a quantitatively meaningful flux of dissolved iron out of the sediment,  
350 and Bell et al. (2017 b) found that they may be a key taxon facilitating input of chemosynthetic C into the food  
351 web. In agreement with the point made by Bell et al. (2016a), the spatial distribution of siboglinids is extremely  
352 patchy, and thus their role in benthic biogeochemical processes is spatially heterogeneous (Bell et al., 2017a, b).

#### 353 4.3 Carbon processing and SHVs as biogeochemical hotspots

354 Respiration rates measured in the algae addition experiments were maximal at Middle Sister, and minimal at the  
355 off-vent site (Fig. 2). Temperature is often recognised as a dominant control on benthic respiration rates (e.g.  
356 Moodley et al., 2005; Woulds et al., 2009), however these experiments were all conducted within 1°C of each  
357 other, so temperature is unlikely to have driven differences in respiration rates. Instead, the differences between  
358 sites may have been driven by differences in bacterial biomass (Table 1), which was maximal at Middle Sister  
359 and minimal at the off-vent site. The bacteria are often found to account for a large majority of benthic  
360 community biomass, and are thus usually assumed to be responsible for the majority of benthic community  
361 respiration (e.g. Heip et al., 2001). The measured respiration rates were similar to those measured at 2170 m on  
362 the NW margin of Spain (Moodley et al., 2002), and on the Porcupine Abyssal Plain (Witte et al., 2003b), both  
363 of which were considerably deeper, and had lower sediment organic C concentrations, but higher bacteria  
364 biomass (Woulds et al., 2016). They were also lower than respiration rates measured at similar depths in the  
365 Eastern Mediterranean (Moodley et al., 2005), and Arabian Sea (Woulds et al., 2009). These sites showed  
366 similar bacteria biomass to the Bransfield Strait, but were all considerably warmer (7-14°C, Woulds et al.,  
367 2016), therefore the low ambient temperatures of the Southern Ocean appeared to reduce respiration rates.

368 It has been suggested that reducing benthic environments are often hotspots of faunal biomass and  
369 biogeochemical cycling due to the increased availability of labile food sources supplied by chemosynthesis  
370 (Bernardino et al., 2012). In this study, the hydrothermally active site Hook Ridge showed rates of respiration  
371 and bacterial uptake of algal C that were intermediate between the two non-hydrothermally active sites (Figs. 2,  
372 3). Whilst comparison between sites is limited by very marked faunal patchiness, the amount of faunal uptake of

373 algal  $^{13}\text{C}$  at Hook Ridge was similar to that at the off-vent control site, while that at Middle Sister was, in one  
374 replicate, considerably greater (Fig. 5). This suggests that SHVs are not necessarily biogeochemical cycling  
375 hotspots, as in algae addition experiments the overall amount of added C processed by the benthic community  
376 was not greater than that observed at non-hydrothermal sites (Fig. 8). In line with this, biological processing of  
377 added C in the algae addition experiments did not show a major role for faunal C uptake as we hypothesised, but  
378 was instead dominated by respiration, as is typically observed at relatively deep, cold sites (Woulds et al., 2009).  
379 The Middle Sister site showed the greatest amount of biological processing of added algal C, which was  
380 probably attributable to it having the greatest bacterial biomass and organic carbon concentrations, and the fact  
381 that the macrofaunal community, composed mostly of ambient Southern Ocean taxa, will have been functioning  
382 without the stress imposed by hydrothermal fluid.

### 383 **5. Conclusions**

384 The main fate of photosynthetic C was respiration in common with other deeper and more food limited sites.  
385 The rates of respiration and C uptake by both macrofaunal and bacteria that we measured were comparatively  
386 low, and this is attributable to the low temperature of the experiments, and the toxicity and thermal stress caused  
387 by hydrothermal fluid. The hydrothermal site (Hook Ridge) in this study did not show more rapid C-cycling  
388 than other similar experiments, as we hypothesised it would.

389 Benthic fixation of inorganic was observed at all sites, and quantified at 2 out of 3 sites. While the rates were  
390 low compared to other similar experiments, the fact that the greatest amount of benthic C fixation occurred at  
391 the off vent site suggests that benthic C fixation may not be restricted to hydrothermal and other reducing  
392 settings. We suggest that it could be an important aspect of the marine C-cycle, and warrants further study.

### 393 **Data Availability**

394 Data sets can be found at DOIxxxx

### 395 **Author Contributions**

396 Experiments were conducted by C. Woulds and A. Glover. All authors contributed to analysis of samples, and  
397 commented on the manuscript.

398 **Acknowledgements**

399 This work was funded by Antarctic Science Ltd., and NERC (grant NE/J013307/1). The authors would like to  
400 thank Prof. Paul Tyler, as well as the officers and crew of RRS James Cook, and the on-board scientific party on  
401 cruise JC 55. We would also like to thank Elisa Neame for assistance with extracting macrofauna.

511

Site	Lat.	Long.	Depth (m)	Temperature	Sediment wt%Corg in 0-1 cm horizon	Macrofaunal Biomass (mg C m <sup>-2</sup> )	Bacterial Biomass (mg C m <sup>-2</sup> )
Off-Vent	62.3842 S	57.2440 W	1150	0	1.35	1091	314±145
Hook Ridge	62.1924 S	57.2783 W	1054	1	0.97	318	451±21
Middle Sister	62.6552 S	59.0502 W	1311	0	1.40	374	575±394

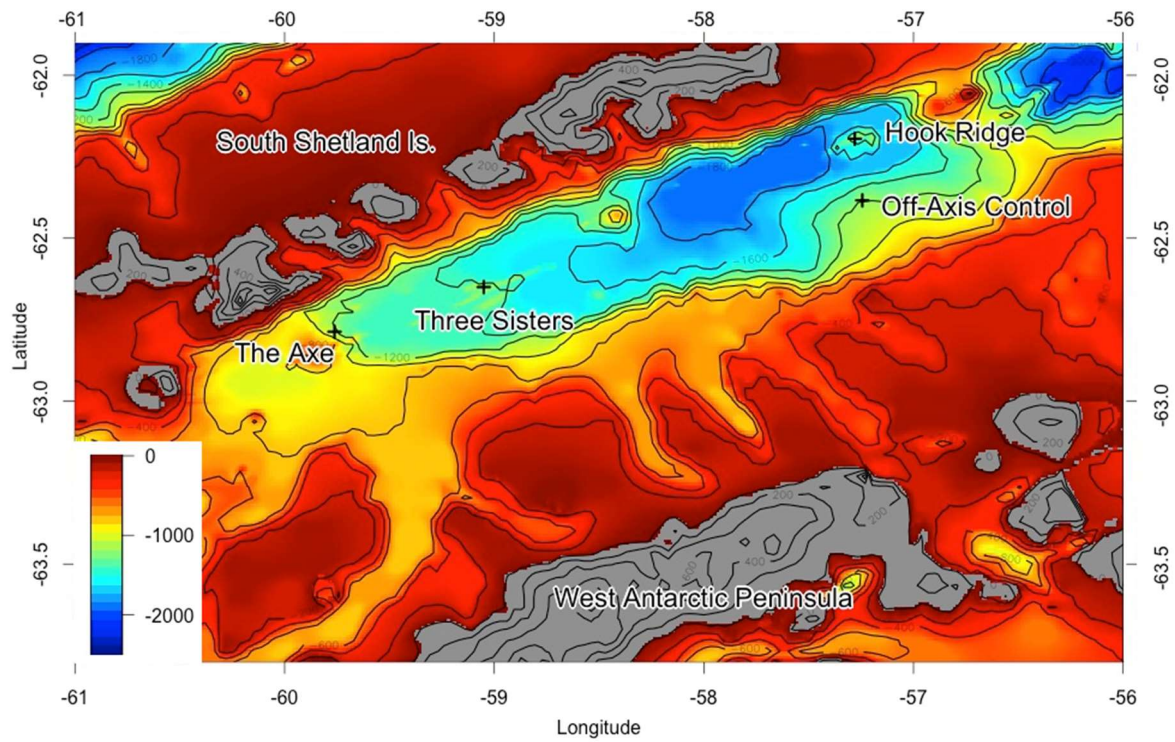

512 **Table 1. Site characteristics, all except bacterial biomass are from Bell et al. (2016).**

513

Site	Treatment and Replicate	Amount Respired (mg C m <sup>-2</sup> )	Respiration Rate (mg C m <sup>-2</sup> h <sup>-1</sup> )	Bacterial Uptake (mg C m <sup>-2</sup> )	Macrofaunal Uptake (mg C m <sup>-2</sup> )
Off-Vent	Algae A	1.23	0.025	0.25	0.027
Off-Vent	Algae B	0.75	0.015	0.77	0.034
Off-Vent	Bicarbonate A	N/A	N/A	0.053	0.0009
Off-Vent	Bicarbonate B	N/A	N/A	0.102	low
Hook Ridge	Algae A	4.97	0.087	n.d.	0.033
Hook Ridge	Algae B	4.06	0.071	1.25	0.003
Hook Ridge	Bicarbonate A	N/A	N/A	n.d.	0.021
Hook Ridge	Bicarbonate B	N/A	N/A	low	low
Middle Sister	Algae A	7.16	0.13	1.91	0.004
Middle Sister	Algae B	8.37	0.15	1.30	0.12
Middle Sister	Bicarbonate A	N/A	N/A	0.00	0.003
Middle Sister	Bicarbonate B	N/A	N/A	0.003*	0.003

514 **Table 2. Amount of C in pools at experiment end, and respiration rates (algae addition experiments only). N/A indicates**  
515 **that it was not appropriate to measure respiration in bicarbonate addition experiments, n.d. indicates no data due to**  
516 **missing sample, and ‘low’ indicates unmeasurably low value. The value marked \* indicates detectable bacterial <sup>13</sup>C**  
517 **uptake, but very close to detection limits, so value to be treated with caution.**
