Abstract. We use observations of dissolved inorganic carbon (DIC) and total alkalinity (TA) to assess the impact of ecosystem metabolic processes on coastal waters of the eastern Red Sea. A simple, single-end-member mixing model is used to account for the influence of mixing with offshore waters and evaporation/precipitation, and to model ecosystem-driven perturbations on the carbonate system chemistry of coral reefs, seagrass meadows and mangrove forests. We find that 1) along-shelf changes in TA and DIC exhibit strong linear trends that are consistent with basin-scale net calcium carbonate precipitation; 2) ecosystem-driven changes in TA and DIC are larger than offshore variations in >85% of sampled seagrass meadows and mangrove forests, changes which are influenced by a combination of longer water residence times and community metabolic rates; and 3) the sampled mangrove forests show strong and consistent contributions from both organic respiration and other sedimentary processes (carbonate dissolution and secondary redox processes), while seagrass meadows display more variability in the relative contributions of photosynthesis and other sedimentary processes (carbonate precipitation and oxidative processes).

1. Introduction

25 Coral reefs, seagrass meadows and mangrove forests are sites of intense metabolic processes. These habitats are distributed heterogeneously in the coastal zone, at shallow depths where perturbations in the carbonate system by metabolic processes can have the greatest influence on water chemistry and air-sea carbon dioxide (CO₂) exchange (Bauer et al., 2013; Camp et al., 2016; Cyronak et al., 2018; Gattuso et al., 1998; Guannel et al., 2016; Unsworth et al., 2012).

30 The cumulative impact of coastal habitats on the carbonate system, along with their overall importance in the global carbon cycle, is difficult to quantify and is poorly represented when compared to knowledge of open ocean processes (IPCC, 2014). The open ocean is geographically separated from the benthos and land so their influences on the carbonate system often can be ignored over short time-scales. In addition to the influence of metabolism in coastal habitats, the carbonate system of the coastal zone is also influenced by both the benthos and the land over short time-scales. Thus, terrestrial and freshwater inputs (dissolved and particulate), sediment exchanges, biological processes, and changes in circulation and water residence time must all be considered when studying

perturbations in the carbonate system of the coastal zone (Doney, 2010;Duarte et al., 2013;Giraud et al., 2008;Jiang et al., 2014;IPCC, 2014).

5 Changes in carbonate system concentrations in the coastal zone can be conservative or non-conservative (Jiang et al., 2014). Conservative changes arise from the mixing of water masses and from evaporation. The salinity of a water mass is a conservative property and can be used to estimate the conservative component of changes in carbonate system concentrations. The conservative mixing of coastal water masses is often conceptualized as a two-end-member problem; with changes in carbonate system concentrations linearly related to salinity between a freshwater end-member (e.g. rivers, land run-off) and an offshore oceanic end-member (Jiang et al., 10 2014;Robbins, 2001). Non-conservative changes in the coastal zone are driven by metabolic processes, sediment exchanges and land inputs (Duarte et al., 2013;Jiang et al., 2014). As such, these non-conservative changes can be measured as departures, or anomalies, from a “norm” defined by the expected carbonate system resulting from conservative mixing.

15 The lack of significant freshwater inputs, via rivers and rainfall, in the arid Red Sea means that offshore waters are the only source of mixing exchange to the coastal zone, allowing for the implementation of a single end-member mixing model (Sofianos and Johns, 2003). A constant oceanic salinity for the offshore region cannot be used to model conservative behaviour, due to basin-scale evaporation which causes a south-to-north increase in salinity along the central axis of the Red Sea. The observed south-to-north increase in alkalinity is smaller than 20 would be predicted for conservative behaviour as a result of chemo-genetic and biogenic calcium carbonate (CaCO₃) precipitation throughout the Red Sea (Jiang et al., 2014; Steiner et al., 2014; Steiner et al., 2018;Wurgaft et al., 2016). The linear trend in offshore carbonate system concentrations, combined with the additional variability of coastal evaporation, defines the “norm” or expected conservative behaviour for the entire coastal zone of the Red Sea.

25 Here we explore the carbonate system in the eastern (Saudi-EEZ) coastal zone of the Red Sea. We examine concentrations of total alkalinity (TA) and dissolved inorganic carbon (DIC) over and around coral reefs, seagrass meadows and mangrove forests, and compare these to the same properties measured in offshore Red Sea surface waters. By using a simple single-end member mixing model, that accounts for conservative changes in the carbonate system of the coastal zone, we detect large ecosystem-driven anomalies in coastal habitats. Smaller 30 non-conservative changes, particularly characteristic of coral reefs, were not able to be detected with high confidence using the over-simplified circulation model but could be resolved with more knowledge of offshore circulation and variability of the carbonate system in the Red Sea.

2. Methods

2.1 KAUST Observations

Between February 2016 and August 2017, seawater samples were collected in the Red Sea during daylight hours from six oceanographic cruises (January/February 2016, January/February 2017, March 2017, April 2017, May 5 2017, July/August 2017) and at coastal time series stations (Figure 1, Table S1). The six oceanographic cruises visited the three shallow coastal habitats, spanning the full length of the Saudi-EEZ coast. Open-water samples were also collected on cruises at a distance from (ie. not directly above, or beside) the three shallow coastal habitats. The coastal time series sampling of surface waters was conducted every two weeks at four stations near the King Abdullah University of Science and Technology (KAUST): a transition water station (22.3093°N 10 38.9974°E, n = 31), a coral reef station (22.25285°N 38.96122°E, n = 32), a mangrove forest station (22.3394°N 39.0885 °E, n = 23) and a seagrass meadow station (22.3898°N 39.1355 °E, n = 32) (Figure S1).

Transition and offshore water samples were collected using a Niskin bottle deployed off the side of the vessel, together with temperature (T) and salinity (S) recorded with an Ocean Seven 305Plus multi-parameter 15 conductivity-temperature-depth (CTD) instrument. Seawater samples collected over coastal habitats were collected in close proximity to the habitat with a 10 cm diameter by 30 cm long polyvinyl-chloride cylinder, to avoid disturbing the benthic organisms and the associated re-suspension of sediments or epiphytes. The cylinder was carefully moved over the ecosystem and sealed with rubber caps. Measurements of S and T were made at the sampling point using a hand-lowered Ocean Seven 305Plus multi-parameter CTD instrument. The cylinders were 20 then transported to the vessel where water was carefully siphoned using a silicone tube.

Water samples were collected into 12 ml glass vials (DIC) and 50 ml plastic falcon tubes (TA), for all cruises except one (Cruise ID = CSM16) during which TA samples were collected in 12ml glass vials. To halt biological 25 activity, DIC and TA samples were poisoned to a concentration 0.02 % mercury chloride solution. TA and DIC were measured at KAUST according to the standard operating procedures as set out by Dickson et al. (2007). DIC was measured by an infrared technique with an Appolo SciTech AS-C3 DIC analyser, and TA was measured by open-cell titration with 0.1 M hydrochloric acid using a Mettler Toledo T50 Autotitrator equipped with a InMotion Pro Autosampler. Both measurements were standardized using certified reference materials (CRM) obtained from Dr. A. Dickson. Observations were flagged based on the standard error between replicates, and those that had 30 only single replicates or high standard error ($SE > 20 \mu\text{mol/kg}$) were excluded from further analysis (n = 17).

2.2 WHOI Observations

Two oceanographic cruises led by the Woods Hole Oceanographic Institution (WHOI) were conducted in March 35 2010 and September/October 2011. Targeting open waters of the Red Sea, the cruises traversed the length of the Saudi-EEZ coast. T and S observations were acquired using the ship's CTD, and water samples were collected using Niskin bottles on the CTD rosette. On deck, water samples were transferred into 250-ml glass bottles, taking care to minimize exchange with the atmosphere, and were poisoned with 50 μL of a saturated mercuric chloride solution immediately after acquisition. The samples were analysed at WHOI for TA and DIC using a Marianda

VINDTA-3C analysis system. TA was determined by non-linear curve fitting of data obtained by open-cell titrations, and DIC concentrations were determined by coulometric analysis, according to the standard operating procedures as set out by Dickson et al. (2007). Both measurements were standardized using CRM obtained from Dr. A. Dickson. The difference between replicate samples averaged 0.6 and 1.5 $\mu\text{mol kg}^{-1}$ for alkalinity and 3.0 and 2.7 $\mu\text{mol kg}^{-1}$ for DIC, for the 2010 and 2011 cruises, respectively.

2.3 Published Data-Sets

Open-water surface observations (<50m) collected over 2007-2010 were sourced from published data-sets (Table S1). Data was constrained to a comparable area of the Red Sea in which new observations collected by KAUST and WHOI were obtained (17-28 °N, 30-44°E). We elected to only use data collected within a decade of coastal observations (2007-2010), as long-term changes were observed in carbonate variables in the Red Sea. This observation has been recently confirmed by Steiner et al. (2018).

2.4 Implementing a single-end-member mixing model

A single-end-member mixing model was used to model conservative TA (cTA) and conservative DIC (cDIC) for coastal observations. This was achieved by 1) describing the linear variations of S, TA and DIC along the south-north central axis of the Red Sea (D), so that predictions of offshore S (S_0), offshore TA (TA_0) and offshore DIC (DIC_0) can be made from D, and then 2) calculating cTA and cDIC for coastal observations according to Equations 1-2, which predict the simple dilution and concentration (SDC) effects of coastal evaporation (Figure 2).

$$\text{Equation 1: } cTA = (S/S_0) * TA_0$$

$$\text{Equation 2: } cDIC = (S/S_0) * DIC_0$$

Where S is the observed salinity at a coastal observation point and S_0 , TA_0 and DIC_0 are calculated for a distance D corresponding to the coastal observation point from linear trends found in step 1.

Offshore observations used to describe the offshore end-member were those (from KAUST, WHOI and published sources) with bathymetry > 200 m below sea-level according to the General Bathymetry Chart of the Oceans (GEBCO) gridded bathymetry with a 30s resolution (BODC, <https://www.bodc.ac.uk/>). All other open-water observations were labelled as transition waters. The distance along the central axis of the Red Sea in km (D) was calculated for each observation using the “alongTrackDistance” function (default settings) in the R package “geosphere” (Hijmans, 2017) with the reference point 12.7737°N 43.2618°E to represent D = 0 and the reference point 28.2827°N 34.0694°E to define position of the central south-north axis.

Other carbon parameters (OCP's), the partial pressure of CO_2 ($p\text{CO}_2$), pH, the saturation state of aragonite (Ω_{Ar}), were calculated with the R package “seacarb” (Gattuso et al. 2018) assuming silicate and phosphate concentrations

of zero, employing the total scale for pH and using the carbonate constants from Millero et al. (2010). Both conservative estimates and observed estimates were calculated for OCP's at coastal locations, from cTA and cDIC, and observed TA and DIC, respectively.

- 5 Residual TA (rTA) and residual DIC (rDIC) were then calculated by subtracting cTA and cDIC from observed TA and observed DIC, respectively. Residual OCP's (r_{pCO_2} , r_{pH} , $r_{\Omega_{Ar}}$) were calculated by subtracting conservative estimates of OCP's (calculated from cTA and cDIC) from observed estimates of OCP's (calculated from TA and DIC observations).

10

2.5 Model Assumptions and Limitations

The single-end-member mixing model assumes simple two-dimensional circulation in a region that exhibits more complex flow. The modelled flow follows a south to north trajectory along the central axis of the Red Sea, with perpendicular coastal flushing from offshore waters located at similar distances along the central axis (Figure 2).

- 15 It is well known that this is not the case and the Red Sea has a complex surface flow displaying multiple dynamic eddies along its length (Sofianos and Johns, 2003; Zhan et al., 2014). Depending on the direction of flow, these eddies promote coastal flushing from offshore waters originating further north or further south along the central axis of the Red Sea, mixing in a way the simple two-end-member mixing model cannot capture.

- 20 Other limitations of the simple two-end-member model include its inability to account for coastal upwelling along the continental shelf, variable mixing of Gulf of Aden waters with Red Sea offshore waters and changes in basin scale evaporation and calcification which have been documented in previous studies (Anderson and Dyrssen, 1994; Churchill et al., 2014; Krumgalz et al., 1990; Papaud and Poisson, 1986; Steiner et al., 2018). These limitations cannot be addressed within the present study and require a sustained observational effort to address
25 knowledge gaps in the carbon chemistry of the Red Sea, combined with more complex circulation models.

2.6 Statistical tests

All statistical tests were performed using R software (R core team, 2017) with a 95% confidence level. Least squares regression analysis was used to calculate linear trends with D for S, temperature and carbonate variables.

- 30 Least squares analysis of variance (LS-ANOVA) was also used to investigate interaction effects between D and habitat groups to test for significant differences between slopes with D across S, temperature and carbon variables. Seagrass meadows and mangrove forests displayed greater variances compared to other groups (maximum variance/minimum variance > 2) between carbon variables, violating the assumption of homoscedasticity between groups required for parametric analysis of variance. For this reason, a Wilcoxon's robust ANOVA (WR-ANOVA)
35 was chosen to account for heteroscedasticity across habitat groups. WR-ANOVA's for differences in medians were conducted between observations from offshore waters, transition waters and coastal habitats. Tests between medians were chosen, rather than between means, as mangrove habitats displayed skewed TA and DIC observations. Wilcoxon's robust statistical methods were implemented using the R package "WRS2" (Mair and

Wilcox 2018), with the functions “med1way” for testing differences in medians and a bootstrapped t-test employed (Supplementary R Code) for post-hoc analysis.

5 To assess the strength of seasonal cycles at time series stations and to test differences in habitats, a seasonal proxy (SP) was constructed from temperature observations at the transition and coral reef time series stations. A cubic smoothing spline, with a smoothing parameter of 0.55, was fit to three iterations of the temperature seasonal cycle at the coral reef station. The fit was then scaled such that a value of 1 indicates peak summer period, and a value of -1 indicates peak winter period. Parametric tests were chosen to detect correlations with season, as variances across season were roughly homoscedastic. LS-ANOVA was used to assess the significance of seasonal cycle as a predictor in time-series observations, to infer the presence of interaction effects between habitats and season in 10 time-series observations, and to infer differences in $r_{TA}:r_{DIC}$ slopes between time series observations and spatial observations. WR-ANOVA was also performed on time series observations to assess median differences between the four time series stations.

3. Results

3.1 The Red Sea offshore end-member

The carbonate system of the Red Sea offshore end-member was characterized along the south-north central axis. Offshore waters exhibited strong (high r^2), significant linear increases in S, TA and DIC along the central south-north axis of the Red Sea as indicated by respective regression analysis with D (Figure 3). TA and DIC were normalized to a salinity of 35 (nTA and nDIC), and both exhibited weak, significant linear decreases along the central south-north axis of the Red Sea (Figure 4). However, winter nDIC values appear to deviate from this trend. The nTA and nDIC co-varied along this axis in an average ratio of 0.63 (SE= 0.06, $r^2 = 0.52$, $F = 95.8$, $p < 0.001$) nTA to 1 nDIC (Figure 4c). A weak (low r^2), significant linear decrease was found for T against D, that displayed clear seasonal dependencies between summer and winter/spring temperatures. A weak, significant increase in pH, a weak, significant decrease in $p\text{CO}_2$, and no significant trend in Ω_A , against D were also observed.

In defining the offshore end-member for implementation in the single-end-member mixing model, offshore observations not representative of the expected trends in the surface offshore Red Sea were removed. These were identified as nine outlying offshore observations exhibiting a Cook's distance greater than five times the mean in at least one of the three linear models of D, against S, TA and DIC (Figure 1; (Cook and Weisberg, 1997)). Linear models were then re-fit with the remaining offshore observations ($n = 92$) to yield Equations 3-5, to be substituted into Equations 1-2 to complete the single-end-member mixing model (Figure 3).

Equation 3: $S_O = 0.00147 * D + 37.62$
Equation 4: $TA_O = 0.0497 * D + 2408$
Equation 5: $DIC_O = 0.0437 * D + 2027$

To approximate the error of the single-end-member mixing model, 99% prediction intervals (99% P.I. = mean \pm 2.576*sd) were calculated by applying the single-end-member mixing model to offshore observations to yield rTA , $rDIC$, $r\text{pCO}_2$, $r\text{pH}$ and $r\Omega_{Ar}$ (Table S2). These 99% P.I represent a cumulative error due to the natural variations of S_O , TA_O and DIC_O , along with the error propagation associated with the calculations of OCPs. Two offshore observations used in defining the norm fell outside the 99% P.I., both exhibiting high TA, and one exhibiting high DIC.

3.2 The Red Sea Coastal Zone

Coastal observations also displayed significant spatial trends in S along the south-north central axis of the Red Sea (Figure 3-5). At the transition and coral reef sites, increases in S with D were significant and of comparable strength (indicated by r^2 values) to those observed offshore, while a weaker (lower r^2) increase in S with D was observed at seagrass meadows (Table S3). No significant increase in S with D was observed at mangrove forests. No interaction effects between habitat type and D were observed for S, meaning that rates of increases in S with D did not differ significantly between habitats or the offshore end-member ($F = 0.94$, $p = 0.395$). Consequently, it can be concluded that compared to offshore waters, irrespective to D, significantly higher median S were

observed at mangrove forests and seagrass meadows (Figure 6). Similarly, it can be concluded that irrespective to D median S for coral reef and transition waters were comparable to the median S observed offshore.

5 Within coral reefs, seagrass meadows and mangrove forests, decreases in T with D were significant and stronger (higher r^2), compared to the decreases observed in offshore waters (Figure 3, Table S3). Tests for interaction effects indicated that rates of change of T with D differed significantly among habitats ($F = 6.25$, $p < 0.001$), but these differences were small and did not deviate largely away from those observed in the offshore end-member (Figure 3). Transition waters displayed similar T to offshore waters along the entire length of the Red Sea. Differently, the three coastal habitats displayed on average slightly higher average T in the southern Red Sea, compared to the 10 offshore end-member (Figure 3). There was a high sampling bias towards winter/spring in coastal observations and corresponding measurements of in-situ T were not successfully made for all summer observations, so the seasonal trends cannot be confidently compared or described here.

15 Compared to the offshore end-member, TA and DIC across transition, coral reef and seagrass meadow sites displayed similar rates of increases with D but differing median values and distribution (Figure 3, Figure 6a). Increases in TA with D for each coastal habitat were much weaker (lower r^2) compared to those observed in offshore waters. There were no interaction effects between D and habitat groups ($F = 0.10$, $p = 0.903$), meaning that coastal TA displayed increased variability and similar rates of increase with D compared to the offshore end-member. Increases in DIC with D were also weaker (lower r^2) for coastal observations compared to the offshore 20 end-member and exhibited no interaction effects with D across habitats ($F = 1.99$, $p = 0.162$). This means that coastal DIC displayed increased variability and similar rates of increase with D compared to the offshore end-member.

25 Although rates of increase of TA and DIC with D were similar between habitats and the offshore end-member, median TA and DIC were not. Compared to the offshore end-member, lower median TA was observed at transition, seagrass meadow and coral reef sites across the Red Sea (Figure 3, Figure 6a). Compared to the offshore end-member, lower median DIC was observed at seagrass meadows and coral reefs across the whole Red Sea, whilst transition waters displayed similar median DIC. Compared to the offshore end-member, observations of DIC at mangrove forests displayed similar median DIC but displayed much higher variability.

30 Observations of pH and $p\text{CO}_2$ showed statistically significant, but relatively weak (low r^2), trends with D for only seagrass meadow and coral reef sites (Figure 3, Figure 6a). No interaction effects were observed between these habitats and offshore waters meaning that rates of change with D were statistically similar ($F = 0.18$, 0.45 , $p = 0.670$, 0.503 for pH and $p\text{CO}_2$ respectively). Compared with the offshore end-member, pH and $p\text{CO}_2$ at coral reefs showed statistically similar medians and greater variability. Compared to the offshore end-member, mangrove forest and seagrass habitats displayed lower median pH and higher median $p\text{CO}_2$, and greater variability. Compared to the offshore end-member, transition observations displayed slightly lower median pH and higher median $p\text{CO}_2$, and greater variability. As seen in the offshore end-member no significant trends with D were observed for Ω_{Ar} at coastal habitats or transition waters, however coastal observations of Ω_{Ar} displayed lower

medians and higher variability, compared to the offshore end-member. Mangrove forests displayed the most variability in observed values across all carbon variables.

5 One outlying mangrove forest observation showed high TA values, and low DIC, leading to unrealistic estimations of OCP's (Figure 5). This outlying observation was taken near KAUST in April 2016 and was most likely caused by sample handling error (degassing or the inclusion of sediments in sample). Further, an isolated mangrove stand was sampled from an inland lake that was tidally flushed (Figure S2a). The two observations taken from this mangrove stand contained much higher TA and DIC compared to observations from coastally residing mangrove stands.

10

3.3 Coastal Ecosystem Anomalies

Using a simple single-end-member mixing model, large non-conservative carbonate system residuals were detected in the coastal Red Sea. Slopes from least-squares linear regressions with D indicate that non-conservative carbonate system residuals display no significant trends along the south-north central axis of the Red Sea (Table S3, Figure S4). Compared to the norm, coral reefs and mangrove forests exhibited similar median rDIC and lower median rTA, whilst transition waters exhibited similar median rTA and higher median rDIC, and seagrass meadows exhibited lower median rTA and lower median rDIC (Figure 6b). Variability in rTA and rDIC was much larger for seagrass meadows and mangrove forests, compared to the variability of the norm, coral reefs and transition waters.

20

Non-conservative carbonate system residuals that fall outside of 99% P.I. deviate significantly away from the norm or expected behaviour of the coastal zone and are concluded to be ecosystem-driven anomalies in the carbonate system (Figure 6b). Transition waters displayed the lowest occurrences of ecosystem-driven anomalies, that were equally distributed towards higher TA and lower TA compared to the norm, and mostly towards higher DIC compared to the norm. Coral reefs also displayed a relatively low range of TA and DIC ecosystem-driven anomalies, equally distributed to higher and lower values when compared to the norms for both TA and DIC. There was a similar occurrence of DIC ecosystem-driven anomalies in coral reefs that were equally distributed towards higher DIC and lower DIC compared to the norm. Seagrass meadows and mangrove forests displayed markedly higher occurrences of ecosystem-driven anomalies compared to transition waters and coral reefs. Seagrass meadows displayed ecosystem-driven anomalies distributed mostly towards lower TA compared to the norm, and DIC ecosystem-driven anomalies distributed mostly towards lower DIC values compared to the norm. Mangrove forests displayed ecosystem-driven anomalies distributed mostly towards lower TA compared to the norm, and DIC ecosystem-driven anomalies distributed equally above and below the norm.

35 Coastal observations of OCP's displayed lower median rpH, higher median rpCO₂ and lower rΩ_{Af} compared to the norm. Differences in OCPs compared to the norm were most pronounced and displayed a large variability in mangrove forests. A significant proportion of ecosystem-driven anomalies in OCP's was detected at all coastal habitat types. In transition waters, mangrove forests and seagrass meadows, these ecosystem-driven anomalies were mostly observed to have lower pH, higher pCO₂ and lower Ω_{Af} compared to the norm. Compared to the

norm, coral reef observations exhibited a relatively equal distribution of both high and low ecosystem-driven anomalies in pH, pCO₂ and Ω_A.

5

3.4 Coastal Time Series

Despite their proximity, there were significant differences in temperatures and S between the three coastal time series sites (Figure 7, Table S6). The coral reef and transition stations displayed similar S of comparable variability, exhibiting no variation with season. Observations of S at the seagrass meadow station were higher, and more variable than those observed at coral reef and transition stations. A seasonal trend in S was indicated by correlation with the seasonal proxy at this station, however, the correlation is weak and the cycle exhibits a small amplitude. The mangrove forest displayed the highest S, exhibiting no relationship with season and higher variability compared to the coral reef and transition stations.

10
15 Strong seasonal trends in T were observed at all four time series stations. The seasonal cycles exhibited slower rates of decreases in T towards winter and larger rates of increase in T towards summer. The interaction effect between habitat and the seasonal proxy was significant, indicating that seasonal cycles of T changed between habitat (F = 3.99, p = 0.01). Compared to the transition and coral reef stations, the T observed at the seagrass stations was often higher in winter, and lower in summer, whilst T observed at the mangrove forest station was only higher in summer (Figure 7, Figure S3).

20
25 The coral reef and transition stations displayed a similar series of observations of TA, DIC and their respective residuals. The seagrass meadow station was the only station at which strong, statistically significant seasonal cycles, were observed in both TA and DIC. During summer, the TA and DIC were lower at the seagrass meadow station compared transition and coral reef stations; whereas similar TA and DIC were seen at all stations during winter. Similarly, during summer rDIC was lower at the seagrass meadow station compared to that observed at the transitions and coral reef stations, but in winter rTA and rDIC did not completely return to values observed at the transitions and coral reef stations. Weak (low r²), statistically significant seasonal cycles were observed at the seagrass station in pH and pCO₂, and at the transition station in DIC, although no clear deviations from other stations exist in these carbon variables. Compared to the other three stations, the mangrove forest station displayed no correlations with the seasonal proxy for all carbon variables, and exhibited much larger variability. TA and DIC at the mangrove forest station were similar to TA and DIC at transition and coral reef stations, indicated by differences in medians. However, rTA and rDIC at the mangrove forest station more closely resembled rTA and rDIC observed at the seagrass station than at the other two stations, as indicated by differences in medians. No large differences in medians were observed across OCP's and their respective residuals.

3.5 Relationship between rTA and rDIC

- Slopes, intercepts and appropriate statistics are presented in Table 1 for linear regression analysis of transition waters, coral reefs, seagrass meadows and mangrove forests. The slope of the relationship between rTA and rDIC was similar between the time series observations and the spatial observations in transition waters, coral reefs and mangrove forests ($F = 1.10, 1.13$ and 0.07 respectively, $p = 0.297, 0.291$ and 0.790 respectively) but different in seagrass meadows ($F = 6.41, p = 0.014$), as indicated by the significance of interaction effects between rDIC across observation subset for each habitat.
- 5
- 10 Transition water and coral reef observations displayed a weak (low r^2) relationship between rTA and rDIC with an intercept close to zero. Seagrass meadow observations displayed significant relationships between rTA and rDIC over both subsets of data, with significant differences in slope of 0.36 and 0.73 for spatial and time series observations respectively, with both regressions displaying similar negative rTA intercepts. The two observations from the inland mangrove stand deviated largely from the extrapolated linear relationships calculated using coastal mangrove stands, and as such were excluded from following regression analysis'. Mangrove forest observations displayed a strong, positive relationship between rTA and rDIC over both subsets of data, with a negative rTA intercept and a slope of 0.62 and 0.60 for spatial and time series observations respectively.
- 15

4. Discussion

The relatively simple oceanography of the offshore Red Sea, with only one oceanic end-member influencing a narrow basin, yields simple linear trends in salinity (S), temperature (T), total alkalinity (TA), dissolved inorganic carbon (DIC), pH and pCO₂ along the south-north central axis (Figure 3). The observed increases in TA along the central axis of the Red Sea were smaller than would be predicted from the central axis salinity data, consistent with previous studies which found that basin-scale calcification produces non-conservative deficits of TA that accumulate along the south-north central axis (Figure 3; (Jiang et al., 2014;Steiner et al., 2014;Steiner et al., 2018;Wurgaft et al., 2016). The observed increases in DIC were also consistent with basin-scale calcification in summer/spring, but winter results showed more variance around this trend. These offshore trends are reflected in the water chemistry of the coastal zone and are removed with the use of a single-end-member conservative mixing model (Figure 2; Figure S4). Doing so enables us to study non-conservative perturbations of carbonate system in shallow benthic habitats at a basin-scale.

To distinguish ecosystem-driven deviations in the carbonate system from conservative variability, conservative TA and DIC in the off-shore end-member is estimated and 99% P.I. are constructed for rTA and rDIC, from offshore observations (Table S2). This error bound captures offshore variability in in S, TA and DIC due to the effects of inter-annual differences, eddies and variable circulation patterns, which act along similar spatial scales in both the offshore and coastal zones. We expected to observe only evaporation-driven increases of S in the coastal zone, as freshening by land inputs and precipitation is thought to be not significant. Yet, roughly 25% of observations of S in coral reefs and transition waters were lower than those observed in the offshore end-member, highlighting the simplifications inherent in the one-end-member model (Figure 3, Figure 6a). In winter, this observed freshening could be due to winter precipitation which is accounted for in the model. Alternatively, it could be due to effects that are not captured in the model, including seasonal rivers (wadis) caused by flash floods that occur mainly during October-May (de Vries et al., 2013;Robbins, 2001). These flooding events have not been explored in the context of TA and DIC inputs. In summer, the observed freshening may be due to the influx of Gulf of Aden waters. This circulation pattern causes cross-shelf variations in surface S along the coast, with salinities in coastal waters observed to be up to 2 units lower than corresponding offshore waters (Churchill et al., 2014;Sofianos and Johns, 2003;Wafar et al., 2016). The implications on the carbonate system of this circulation pattern have not been characterized. This possibly obscures ecosystem-driven perturbations of rTA and rDIC at coral reefs but has only a small effect on the large ecosystem-driven perturbations observed at mangrove forests and seagrass meadows.

By comparing relative changes in rTA and rDIC in each habitat, inferences can be made regarding the balance of ecosystem processes within Red Sea coastal habitats (Figure 8, (Albright et al., 2013;Challener et al., 2016;Cyronak et al., 2018;Gattuso et al., 1998;Zeebe and Wolf-Gladrow, 2001). If a habitat conforms closely to a linear trend, it can be inferred that the balance of ecosystem processes is relatively uniform across sites. The slope of the trend indicates the balance of ecosystem processes, with a value determined by the relative proportions

of dominant ecosystem processes represented as directional vectors in Figure 8a. Additionally, the intercepts of the linear trend are inherited from the signals of upstream ecosystems, and the amplitude of an observation along this trend is an indication of a combination of metabolic rate and residence time. It also follows that if a habitat doesn't conform closely to a linear trend, then the balance of ecosystem processes is variable across sites. These inferences can be made from changes in DIC and TA as they are affected by only mixing and metabolic processes and are invariant with temperature or pressure. In contrast, OCP's are all affected strongly by temperature variations and they respond non-linearly to mixing and variations in TA and DIC. Particularly, large but linked changes in TA and DIC in the ratio of roughly 1:1 causes OCP's to change very little (Zeebe and Wolf-Gladrow, 2001). This effect can be observed at the seagrass meadow time series station, with the loss of seasonal cycle in OCP's (Figure 6).

All mangrove forests in the Red Sea are comprised of a single species, *Avicennia marina* (Chaidez et al., 2017), and display a relatively uniform balance of ecosystem processes across the Red Sea (Figure 8). Both the time-series data and the spatial data show statistically similar trends (Figure 8, Table 1). It follows from this that differences in residence times and metabolic rates are the strongest driver of variability between sites, whilst underlying ecosystem processes remain relatively stable. The positive changes in rTA and rDIC are indicative of high respiration rates, mainly due to high rates of organic matter remineralization, from sediments rich in organic carbon. This lowers pH inducing calcium carbonate dissolution, a mechanism which has been found to be important in previous process-based studies (Burdige & Zimmerman, 2002; Krumins et al., 2013; Meister, 2013; Middelburg et al., 1996). Changes in the negative direction, with deficits in rTA and rDIC, are less expected in mangrove forests, as sediments are rarely net autotrophic (Bouillon et al., 2008; Krumins et al., 2013; Zablocki et al., 2011), but could be inherited from upstream seagrass meadows and coral reefs (Guannel et al., 2016). More support for the latter can be found in time-series observations, with TA and DIC at the mangrove forest station conforming closely to those at the seagrass meadow station, but also displaying erratic deviations towards high rTA and rDIC that varies similarly to other mangrove forest sites (Figure 7; Figure 8). A negative TA intercept is observed in the mangrove forest rTA:rDIC trend (Figure 8), which is consistent with a basin-wide cumulative cross-shelf calcification signal, inherited from upstream coral reefs and potentially even seagrass meadows.

These results suggest that the carbonate system and contributions to air-sea CO₂ exchanges of overlying waters in Red Sea mangrove forests is likely significantly mediated by water residence time and mixing, not only by metabolic rates. The inland mangrove forest sampled contained drastically higher TA and DIC in surrounding waters, and further resulted in higher pCO₂ and a large CO₂ source to the atmosphere, compared to coastally-residing mangrove forests (Figure S2, Figure 5). De-gassing of CO₂, an increase in calcium carbonate dissolution due to decrease in pH, or an increase in redox processes due to oxygen depletion is most-likely the cause for the ratio of rTA:rDIC deviating at this site to an almost perfect 1:1 ratio, from the 0.61 observed elsewhere. This implies that the carbonate system in stagnant water columns over mangrove forests could be different to what is observed in those with variable water exchanges, and the flushing of mangrove forests from surrounding waters can vastly reduce their contribution to air-sea CO₂ exchanges. As such, the control of surrounding water exchanges and water residence times should be considered further in these ecosystems, as studies often quantify the influence

of mangrove forests on air-sea CO₂ exchange using stagnant water columns (Bouillon et al., 2007; Bouillon et al., 2008; Macklin et al., 2019; Sea et al., 2018).

5 Red Sea seagrass meadows have a high species diversity (Qurban et al., 2019; Kenworthy et al., 2007) and show
large ecosystem-driven anomalies in rTA and rDIC, but vary in the balance of ecosystem processes between sites
(Figure 8). At the time-series station a slope of 0.73 is observed, whilst across other sites no significant trend is
found. This slope is consistent with the coupling of photosynthesis and sedimentary calcification, promoted by
increased pH due to net autotrophy in seagrass meadows, which has been shown to result in a ratio of 1:1 change in
rTA:rDIC (Barrón et al., 2006; Burdige and Zimmerman, 2002; Krumins et al., 2013; Lyons et al., 2004; Macreadie
10 et al., 2017; Unsworth et al., 2012). Sedimentary sulphur and iron oxidation which, occur alongside sedimentary
calcification in oxygenated environments and higher pH, potentially contributes to the lowering of the rTA:rDIC
slope below 1 (Burdige and Zimmerman, 2002; Krumins et al., 2013), however, Red Sea seagrass sediments have
been observed to contain low levels of iron (Saderne et al. in review; Anton et al. 2018). At the time-series station,
lower TA and DIC in summer months is due to a combination of increased metabolic rates and/or residence times.
15 The variability between rTA and rDIC between sites, and the lack of a significant trend indicates that the balance
between ecosystem processes is important in driving the carbonate system of Red Sea seagrass meadows, in
combination with metabolic rates and residence times. This is a finding that has been confirmed in separate studies,
with the balance of ecosystem processes often effected by variable seagrass meadow density and site oxygenation
(Burdige and Zimmerman, 2002; Krumins et al., 2013; Unsworth et al., 2012). Indeed, a separate study of some
20 seagrass meadow sites visited in the present study found that metabolic rates were observed to be highly variable
and species dependent (Anton et al. in prep).

Due to small perturbations in the carbonate system exhibited by transition waters and coral reefs and the
uncertainty limits of our model, little can be concluded about the large-scale variability in ecosystem processes in
25 this habitat. Transition waters show few occurrences of ecosystem anomalies inherited from surrounding coastal
habitats. Small temporal variations in rTA and rDIC at the coral reef time series station show no trend or seasonal
cycle, consistent with variability driven by exchanges through the complex reef system rather than inherent
ecosystem processes and metabolic rate. Spatial variability shows similar characteristics, which can be attributed
to a combination of spatial changes in ecosystem processes, residence times, metabolic rates and connectivity
30 (Cyronak et al., 2018; Gattuso et al., 1999; Kleypas et al., 2011; Takeshita et al., 2018). What can be concluded is
that coral reef and transition waters have little consequence to air-sea carbon fluxes on a local scale, offering little
change in the carbonate system compared to offshore conditions (Figure 3, Figure 6).

5. Conclusion

35 We observed strong evidence of ecosystem-driven perturbations in the carbonate system over Red Sea coastal
habitats. We employed a simple single-end-member mixing model to estimate the expected conservative
behaviour over the coastal zone of the Red Sea. We find that 1) along-shelf changes in TA and DIC exhibit strong
linear trends that are consistent with net basin-scale calcium carbonate precipitation; 2) ecosystem-driven changes

in TA and DIC are larger than offshore variations in >85% of sampled seagrass meadows and mangrove forests, changes which are influenced by a combination of longer water residence times and community metabolic rates; and 3) the sampled mangrove forests show strong and consistent contributions from both organic respiration and other sedimentary processes (carbonate dissolution and secondary redox processes), while seagrass meadows display more variability in the relative contributions of photosynthesis and other sedimentary processes (carbonate precipitation and oxidative processes). With the available data we cannot conclude if differences in magnitude of rTA and rDIC within habitats reflect differences in residence times or metabolic rates. The results of this study highlight the importance of resolving the influences of water residence times, mixing and upstream habitats on mediating the carbonate system and coastal air-sea CO₂ fluxes over coastal habitats in the Red Sea.

Code Availability

Code for the calculation of the Wilcoxon Robust ANOVA post-hoc test can be found in the supplementary material. All other code relating to figures and analysis was constructed in R (version 3.4.3) and is available upon request to the corresponding author.

5 Data Availability

The full data set used in this study can be obtained from PANGAEA (doi: [10.1594/PANGAEA.899850](https://doi.org/10.1594/PANGAEA.899850)).

Author Contribution

K.B. collected a portion of the KAUST samples, performed most of the sample analysis on KAUST samples, performed data analysis, developed conceptual ideas and wrote the manuscript. V.S. collected a portion of the KAUST samples, performed some sample analysis on KAUST samples and contributed to manuscript preparation. D.C.M. and J.H.C. collected and analysed WHOI samples and contributed to concept development and manuscript preparation. S.A. facilitated the collection of samples at three time series stations. C.M.D. contributed to the concept development and aided in manuscript preparation.

Competing Interests

15 The authors of this manuscript declare no competing interests.

Acknowledgments

This research was funded by King Abdullah University of Science and Technology (KAUST) through baseline funding and competitive center funding to Carlos M. Duarte, and Susana Agusti (BAS/1/1072-01-01). The sample collection and laboratory analysis of KAUST observations was carried out by K. Baldry and V. Saderne. The sample collection and laboratory analysis of Woods Hole Oceanographic Institution (WHOI) observations was supported by Award Nos. USA-00002, KSA-00011 and KSA-00011/02 made by KAUST to WHOI. We thank all of the contributors who were responsible for collecting and managing Red Sea data that was openly sourced. The full data set used in this study can be obtained from PANGAEA (doi: [10.1594/PANGAEA.899850](https://doi.org/10.1594/PANGAEA.899850)). Supplementary tables and figures can be found in the supporting information accompanying this manuscript. We thank A. K. Gusti, A. Anton, M.L. Berumen, P. Carrillo-de-Albornoz, D.J. Cocker, N. Garcias-Bonet, C.K. Martin, J. Martinez-Ayala and S. Overmans for their help and support in sample collection and CTD deployments towards this study.

Figures

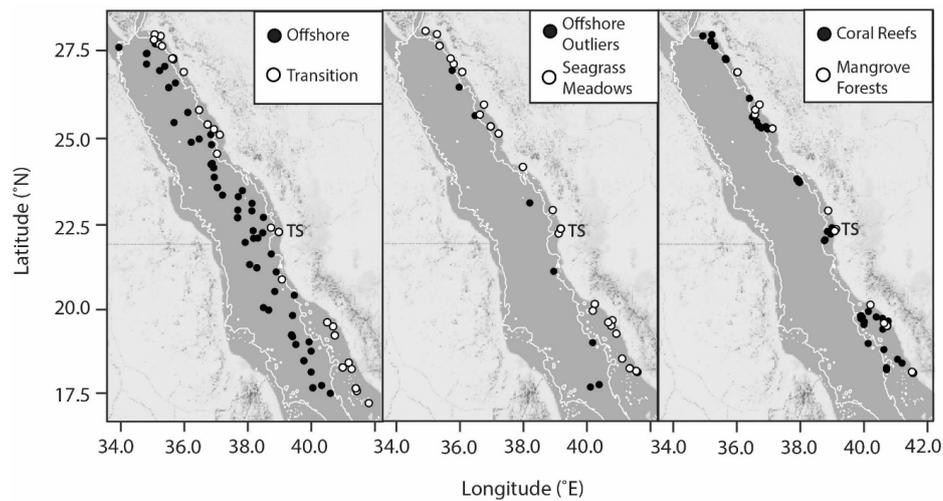

Figure 1. The spatial distribution of combined observations from the Red Sea data sets used in the present study, shown against a 200m bathymetry boundary (thin white line). Observations are classified as offshore, transition, 5 seagrass meadows, coral reefs or mangrove forests. The latitude at which time series stations are at is indicated by the text “TS”. Outliers identified in offshore observations are also shown.

10

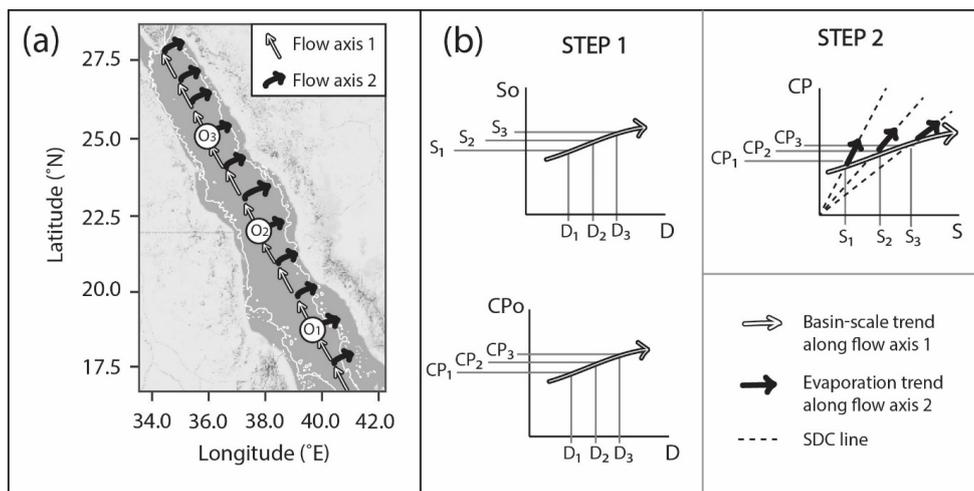

Figure 2. Schematic of the single-end-member mixing model used in the present study. Panel (a) displays the assumed circulation pattern which has two flow axes. Flow axis 1 is along the south-north central axis where waters experience cumulative changes due to basin-scale evaporation and calcification. Flow axis 2 is perpendicular to this axis, where it is assumed that evaporative effects prevail as waters transition from offshore to coastal regions. The thin white line indicates the 200m bathymetry and the transition from offshore to coastal waters. Panel (b) explains the single-end-member mixing model in two steps, to estimate conservative estimates of a carbon parameter (CP: TA or DIC) for the coastal zone. O_i represents a location in the offshore end-member lying along the central axis at distance D_i , and corresponding salinity S_i , and carbon parameter measurement of CP_i , as derived from basin scale-trends. CP_i is then scaled along the simple dilution and concentration (SDC) line to obtain coastal estimates for carbon parameters.

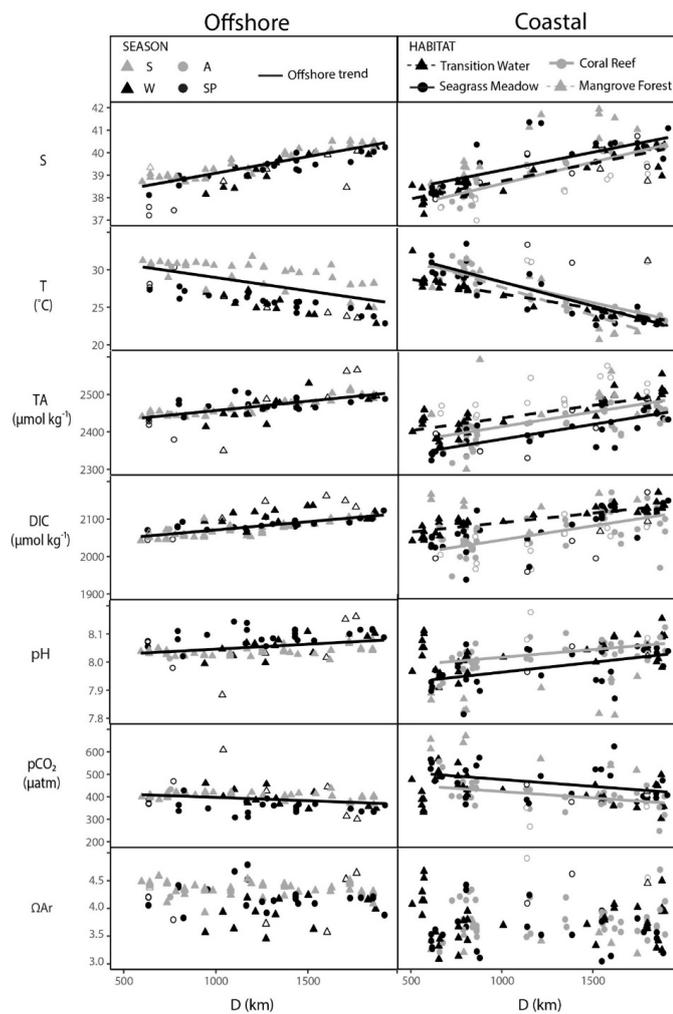

Figure 3. Observations of S, T and carbon variables in the offshore end-member (left) and four coastal habitats (right) are presented against distance along the south-north central axis (D), on the same scales. Significant linear regressions for all combinations of variables are drawn as lines, with associated statistics reported in Table S3. Offshore outliers were not included in determining offshore regressions against D. Note that not all coastal observations are displayed, an expanded scale is shown in Figure 5. Hollow symbols indicate offshore outliers (right panel) and coastal summer observations (left panel). S = summer, A = autumn, W = winter and SP = spring.

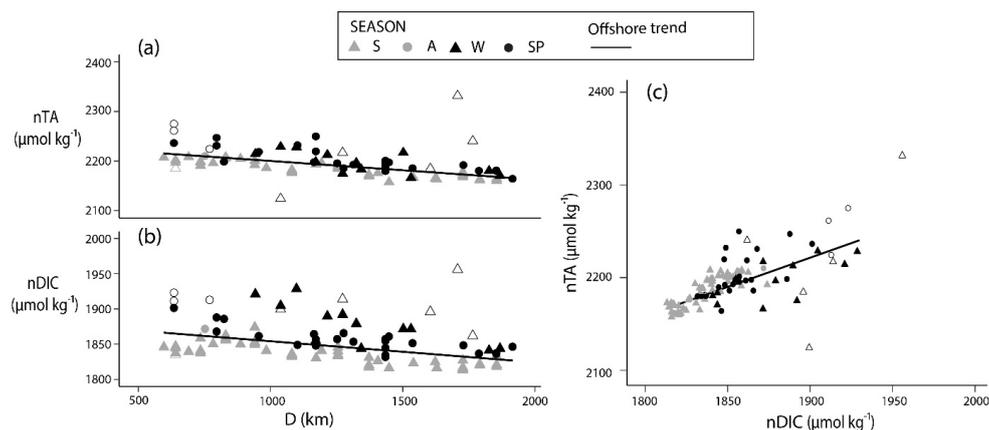

Figure 4. Trends in nTA and nDIC along the south-north central axis of the Red Sea (a-b), and between nTA and nDIC (c) in the offshore end-member. Symbols indicate the season samples were collected in; summer (S), autumn (A), winter (W) or spring (SP). All trends were statistically significant and offshore outliers were not included regressions (hollow symbols).

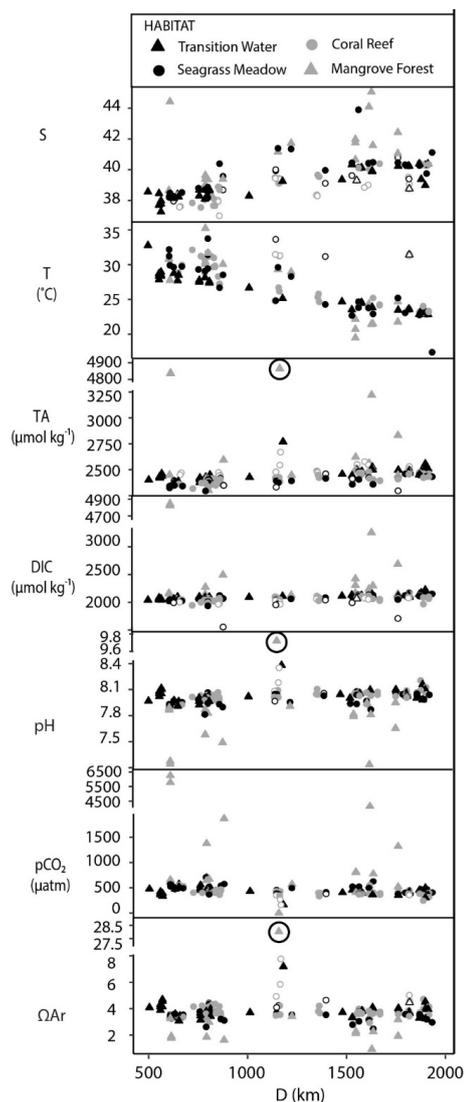

Figure 5. Observations of S, T and carbon variables at four coastal habitats are presented against distance along the south-north central axis (D) on an expanded scale. The circle indicates the location of one outlying observation, of TA and DIC that produce un-realistic values of OCP's. Hollow symbols indicate coastal summer observations.

5

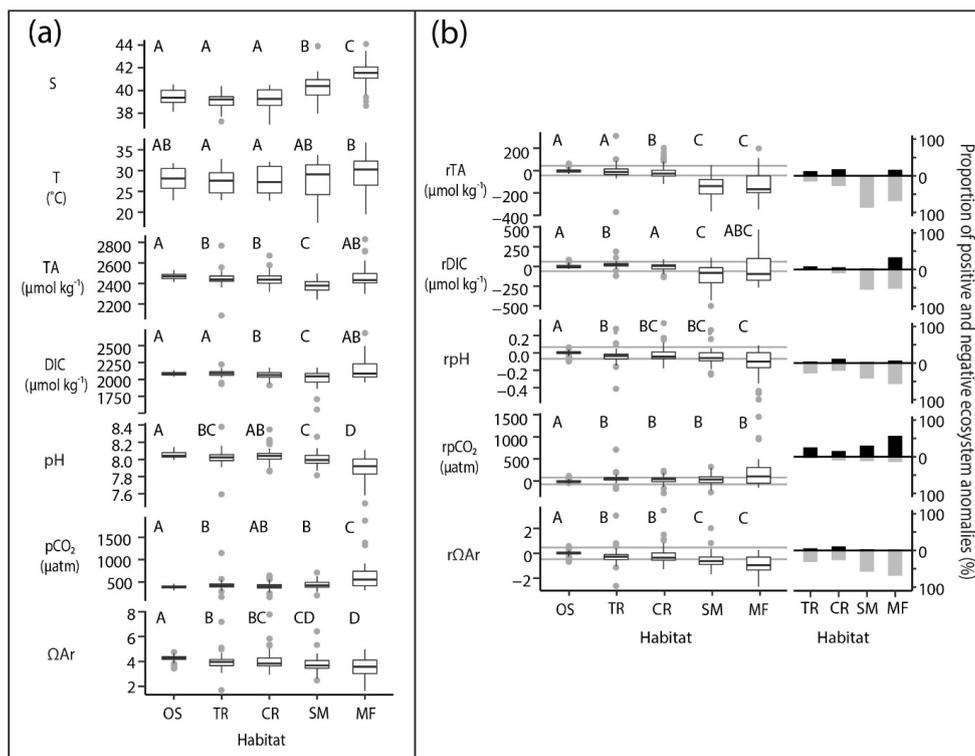

Figure 6. Box-plot distributions of (a) observed S, T, carbon variables and (b) non-conservative carbonate system residuals are presented by habitat group: offshore (OS), transition waters (TR), coral reef (CR), seagrass meadow (SM) and mangrove forest (MF). Each box-plot displays the median, the first and third quartiles, and whiskers that extend to the mean \pm 1.5 times the inter-quartile range. Grey dots represent observations that extend outside the whiskers of the boxplot. Grey lines in panel (b) indicate the upper and lower bounds of the 99% P.I. defined by offshore observations. The proportion of ecosystem anomalies (%) observed in both the positive and negative directions are presented alongside, and to the right of boxplots in panel (b) (Table S4). Grouping letters assigned indicate the results of post-hoc bootstrapped t-tests, summarized from statistics presented in Table S5. If tests showed significant similarities at the 0.05 significance level with another habitat across a variable they were assigned the same letter.

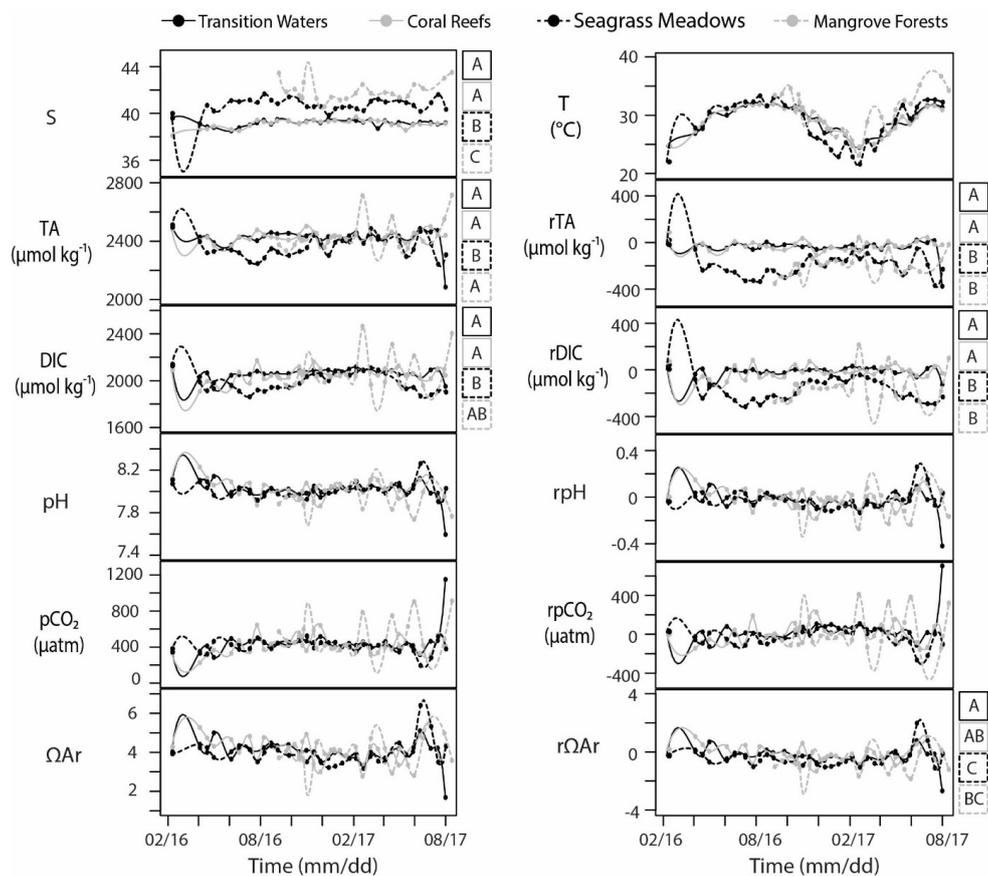

Figure 7. Time series observations of S, T, carbon variables and non-conservative carbonate system residuals collected from the four time series stations. Observations are shown fitted with a spline function of order 100 by the method of Forsythe, Malcolm and Moler (1977). For variables which displayed a significant result for WR-ANOVA tests for differences in medians across habitat groups, results from post-hoc bootstrapped t-tests are shown as letters to the right of the plot.

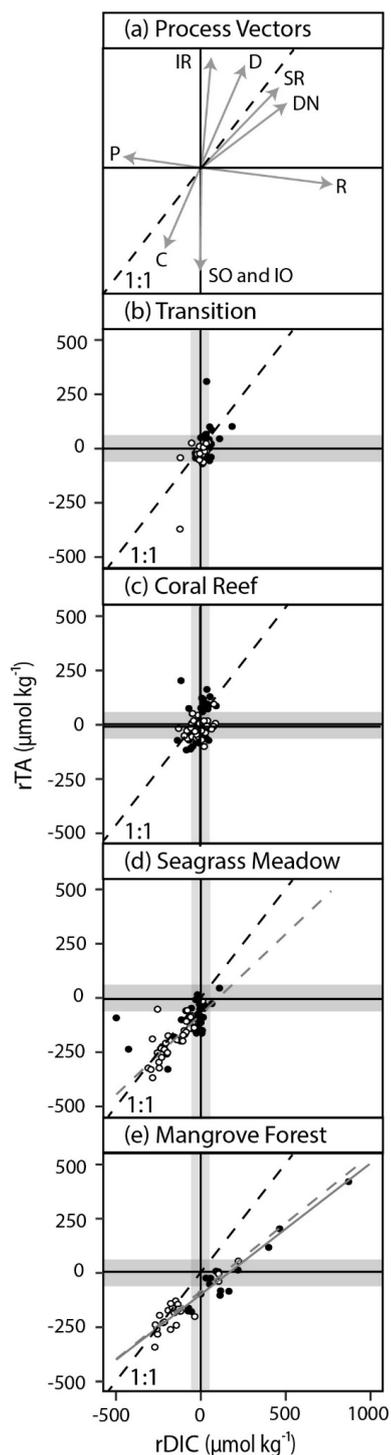

Figure 8. A reference plot (a) showing unitless directional vectors of change in the rTA vs. rDIC space for multiple ecosystem processes. Below, observations of rTA vs. rDIC from transition water and the three coastal habitats is presented (b-e). Time series observations are indicated with open circles, and all other spatial data is indicated with closed circles. A 1:1 reference line is shown in all plots (black dashed line) as well as regression lines ($r^2 > 0.6$) for the time series subset (grey dashed line) and the spatial subset (grey solid line). The reference plot includes directional vectors for calcium carbonate precipitation (C), calcium carbonate dissolution (D), primary production (P), respiration (R), iron reduction (IR), sulphate reduction (SR), denitrification (DN), sulphur oxidation (SO) and iron oxidation (IO). The shaded envelope represents the calculated 99% P.I. for rTA and rDIC. An expanded figure of panel (e) showing inland mangrove stands is presented in Figure S2b.

Tables

Table 1: Intercept (\pm SE), slope (\pm SE), correlation coefficient (r^2), F statistics (F) and p-values (p) of linear regressions of rTA versus rDIC for different subsets of coastal observations.

Data subset	Intercept	Slope	r^2	F	p
Transition Water	-24.7 (\pm 7.8)	0.90 (\pm 0.17)	0.28	27.2	<0.001
Coral Reef	-9.8 (\pm 6.1)	0.39 (\pm 0.13)	0.08	8.47	0.004
Seagrass Meadow: Times-series	-70.9 (\pm 20.5)	0.73 (\pm 0.11)	0.60	45.21	<0.001
Seagrass Meadow: Spatial	-80.2 (\pm 12.2)	0.36 (\pm 0.09)	0.32	15.7	<0.001
Mangrove Forest: Time series	-97.7 (\pm 13.0)	0.62 (\pm 0.07)	0.79	77.29	<0.001
Mangrove Forest: Spatial	-112.2 (\pm 13.58)	0.60 (\pm 0.05) (0.86 with inland stands)	0.92	159.8	<0.001
