15 **Abstract.** Dissimilatory iron reduction is probably one of the earliest metabolisms, which still
16 participates in important biogeochemical cycles such as carbon and sulfur. Traditionally, this process is
17 thought to be limited to the shallow part of the sediment column, as one of the energetically favorable
18 anaerobic microbial respiration cascade, usually coupled to the oxidation of organic matter. However, in
19 the last decade iron reduction has been observed in the methanogenic depth in many aquatic sediments,
20 suggesting a link between the iron and the methane cycles. Yet, the mechanistic nature of this link has
21 yet to be established, and has not been studied in oligotrophic shallow marine sediments. In this study
22 we present first geochemical and molecular evidences for microbial iron reduction in the methanogenic
23 depth of the oligotrophic Southern Eastern (SE) Mediterranean continental shelf. Geochemical pore-
24 water profiles indicate iron reduction in two zones, the traditional zone in the upper part of the sediment
25 cores and a deeper second zone located in the enhanced methane concentration layer. Results from a
26 slurry incubation experiment indicate that the iron reduction is microbial. The Geochemical data,
27 Spearman correlation between microbial abundance and iron concentration, as well as the qPCR analysis
28 of the *mcrA* gene point to several potential microorganisms that could be involved in this iron reduction
29 via three potential pathways: H₂/organic matter oxidation, an active sulfur cycle or iron driven anaerobic
30 oxidation of methane.

31 **1 Introduction**

32 Iron (Fe) is the fourth most abundant element in the Earth's crust. It appears as elemental Fe, Fe(II) and
33 Fe(III), and has an important geobiological role in natural systems (Roden, 2006). Dissimilatory
34 microbial iron reduction is likely one of the first evolutionary metabolisms, and plays a key role in the
35 reductive dissolution of Fe(III) minerals in the natural environment (Weber et al., 2006), in the
36 mineralization of organic matter in freshwater sediments (Roden and Wetzel, 2002), and as a redox wheel
37 that drives the biogeochemical cycles of carbon, nitrogen, sulfur and phosphorous (Li et al., 2012).

38 Dissimilatory iron reduction is part of the anaerobic respiration cascade, in which different organic
39 substrates are used for energy by microorganisms and oxidized to dissolved inorganic carbon (DIC). This
40 is accomplished by reduction of electron acceptors, other than oxygen, according to their availability and

41 energy yield. Denitrification is the first respiratory process in anoxic sediments, followed by manganese
 42 and iron reduction and then sulfate reduction. Methane (CH₄) production (methanogenesis) by archaeal
 43 methanogens is traditionally considered to be the terminal process of microbial organic matter
 44 mineralization in anoxic environments, after the other electron acceptors have been exhausted (Froelich
 45 et al., 1979). When outward diffusing methane meets an electron acceptor it can be consumed by
 46 microbial oxidation (methanotrophy). In anoxic marine sediments anaerobic oxidation of methane
 47 (AOM) is coupled mainly to sulfate reduction (Hoehler et al., 1994). This process was found to consume
 48 up to 90 % of the methane that diffuses upwards to the sulfate methane transition zone (SMTZ)
 49 (Valentine, 2002).

50 The classical process of dissimilatory iron reduction is coupled to the oxidation of organic matter
 51 (organoclastic iron oxidation, Eq. 1) (Lovley, 1991; Lovley et al., 1996). However, iron reduction can be
 52 coupled to other processes as well, such as hydrogen (H₂) oxidation (hydrogenotrophic iron reduction)
 53 (Eq. 1). Besides H₂ oxidation, Fe(III) can be reduced microbially (and also abiotically) by pyrite
 54 oxidation (Eq. 2) (Bottrell et al., 2000), leading to S intermediates, and followed by their
 55 disproportionation to sulfate and sulfide via a "cryptic" sulfur cycle (e.g. Holmkvist et al., 2011).

58 Another, recently discovered, pathway of iron reduction is by AOM (Eq. 3).

60 This process in marine sediments was evident through incubations of marine seeps (Beal et al., 2009;
 61 Sivan et al., 2014). It was suggested through the modeling of geochemical profiles in deep sea sediments
 62 (Sivan et al., 2007; Riedinger et al., 2014) and in brackish coastal sediments (Slomp et al., 2013; Segarra
 63 et al., 2013; Egger et al., 2015; Egger et al., 2016; Rooze et al., 2016). In freshwater, it was suggested to
 64 occur in lakes (Crowe et al. 2011; Norði et al., 2013), and was shown in enriched, denitrifying cultures
 65 from sewage, where it was performed by methanogens (Ettwig et al., 2016). Iron-coupled AOM in natural
 66 lake sediments was indicated using isotope pore-water depth profiles (Sivan et al., 2011), rate modeling
 67 based on these profiles (Adler et al., 2011), microbial profiles (Bar-Or et al., 2015), and directly by a set
 68 of sediment slurry incubation experiments using several methods (Bar-Or et al. 2017). The few microbial
 69 studies about iron-coupled AOM (mainly in cultures) showed the involvement of
 70 methanogenic/methanotrophic archaea (Scheller et al., 2016; Ettwig et al., 2016; Cai et al., 2018; Yan et
 71 al., 2018; Rotaru and Thamdrup, 2016) or cooperation between methanotrophic archaea and iron
 72 reducing bacteria (Bar-Or et al., 2017).

73 Whereas Fe(II) is highly soluble, Fe(III) appears as low solubility minerals, and is the most abundant
 74 species of iron under natural conditions close to neutral pH. This makes iron usage a challenge to
 75 microorganisms, which need to respire low-solubility iron oxide minerals, thus rendering many of iron-
 76 oxide minerals effectively unavailable for reduction and leading to the dominance of sulfate reducing
 77 bacteria beyond a certain depth.

78 Therefore, the observation of iron reduction below its traditional depth, in the methanogenic zone, where
79 iron-oxides are assumed to be inactive, is surprising. Moreover, this reduction is occasionally
80 accompanied by a depletion in methane concentrations, suggesting a possible link between the iron and
81 the methane cycles. The coupling can be through a competition between methanogens and iron reducing
82 bacteria, methanogens switching from methanogenesis to iron reduction metabolism, and/or iron coupled
83 AOM, as mentioned above. Previous observations in other environments demonstrated the inhibition of
84 methanogenesis under iron-reducing conditions due to competition between methanogens and iron-
85 reducing bacteria for the common acetate and hydrogen substrates (Conrad, 1999; Lovley and Phillips,
86 1986; Roden and Wetzel, 1996; Roden, 2003). Different methanogens can also utilize iron directly, by
87 reducing Fe(III). This was shown in pure cultures with the amorphous Fe(III) oxyhydroxide (Bond and
88 Lovley., 2002), in pure cultures close to natural sedimentary conditions (Sivan et al., 2016), in natural
89 lake sediments with different iron oxides (i.e. amorphous iron, goethite, hematite and magnetite) (Bar-or
90 et al., 2017), and in iron-rich clays (Liu et al., 2011; Zhang et al., 2012; Zhang et al., 2013).

91 Despite the above studies, the nature of the link between the iron and the methane cycles in marine
92 methanogenic zone, which reactivates iron oxides and making them available for reduction, has not been
93 determined yet. Furthermore, microbial iron reduction in methanogenic zones has not been shown in
94 oligotrophic shallow marine environments. In this study we report observations of microbial iron
95 reduction in the methanogenic depth in marine sediments of the oligotrophic SE Mediterranean
96 continental shelf. We show both geochemical pore-water profiles and microbial investigation at three
97 different stations combined with a basic incubation experiment with slurry from the methanogenic zone.
98 These profiles and the incubation, including the related microorganisms, are discussed in terms of the
99 possible links between iron and methane cycles.

100 2 Methods

101 2.1 Study site

102 The Levantine Basin of the SE Mediterranean Sea is one of the most oligotrophic nutrient-poor marine
103 environment in the world (Kress and Herut, 2001), including the Israeli continental shelf (Herut et al.,
104 2000). The continental shelf narrows from south to north and is built mainly of Pliocene-Quaternary
105 Nile-derived sediments, whose rate of sedimentation decreases with increasing distance from the Nile
106 Delta and from the shoreline (Nir, 1984; Sandler and Herut, 2000). While the highest levels of total
107 organic carbon (TOC) (1 – 2%) in sediments were found in the Western Mediterranean Basin and
108 offshore the Nile River delta, the central and eastern deep water regions of the Levantine Basin have
109 relatively low TOC levels (0 – 0.5%) (Astrahan et al., 2017). Along the Egyptian coast, maximal contents
110 of TOC in surface sediments on the shelf is up to 1.5% (Aly Salem et al., 2013), while in the Israeli shelf
111 sediments (< 100 m depth) the TOC levels vary between < 0.1 – 1% (Almogi-Labin et al., 2009). The
112 discovery of a 'gas front' from seismic profiles within the sediments of the continental shelf of Israel
113 (Schattner et al., 2012), led to the findings of biogenic methane formation at some locations in shallow
114 sediments (Sela-Adler et al., 2015). The bottom seawater across the shelf is well oxygenated therefore
115 sulfate concentration in the water-sediment interface is ~30 mmol L⁻¹ (Sela-Adler et al., 2015).

116 2.2 Sampling

117 Seven sediment cores (~5 – 6 m long) were collected using a Benthos 2175 piston corer, from the
118 undisturbed seafloor sediments of the SE Mediterranean continental shelf of Israel at water depths of 81
119 – 88 m from three stations; SG-1 (32°57.82' N 34°55.30' E), PC-3 (32°55.30' N 34°54.14' E) and PC-5
120 (32°55.47' N 34°55.01' E). The cores were sampled by the R.V. *Shikmona* between 2013 to 2017, and by
121 the R.V. *Bat-Galim* on January 2017. The sediment cores were sliced on board every 25 – 35 cm within
122 minutes upon retrieval from the seafloor. These stations were investigated previously with other focuses,
123 such as the sulfate reduction in the SMTZ (Antler et al., 2015; Wurgaft et al., unpublished), and
124 methanogenesis characteristics (Sela-Adler et al., 2015).

125 From each interval, a 2.5 mL sediment sample was collected and inserted into an anaerobic 10 mL glass
126 bottle filled with 5 mL NaOH 1.5 N for headspace measurements of methane concentration (after
127 Nusslein et al, 2003). In addition, another 2.5 mL sediment sample was taken from each segment of the
128 cores and transferred into a 20 mL glass bottle filled with NaCl saturated solution for H₂ concentrations
129 measurements. Sediment samples from each segment of the cores were centrifuged on board if possible
130 or in the lab within a day by Sorval centrifuge at 9500 RPM under 4 °C and Ar atmosphere in order to
131 extract pore-water for chemical analysis. The supernatant was filtered (0.22 µm) and analyzed for Fe(II),
132 sulfate, sulfide and the isotope composition of the DIC ($\delta^{13}\text{C}_{\text{DIC}}$). After the pore-water extraction, the
133 sediment was analyzed for the content of the different iron oxides. In addition, sediment sub-sample from
134 each segment of the January 2017 core from SG-1 station was kept in -20 °C for molecular analysis. Due
135 to high water content in the upper part of the sediments, the top 20 cm of the piston cores pore-water
136 measurements might be affected by sediment movement and mixing; to avoid this, two ~30 cm cores
137 were collected during the September 2015 and January 2017 cruises via a 0.0625 m² box corer (Ocean
138 Instruments BX 700 AI). The cores were stored at 4 °C and cut in the lab less than 24 hours after their
139 collection. Sediment and pore-water samples were measured for CH₄, Fe(II), sulfate and $\delta^{13}\text{C}_{\text{DIC}}$
140 measurements.

141 2.3 Slurry incubation experiment

142 The experimental set-up consisted of 11 bottles with sediment from the methanogenic zone, 260 cm
143 below sea floor level from SG-1 station, where iron reduction was apparent in the pore-water profiles.
144 The sediment from the designated depth was homogenized in an anaerobic bag under N₂ atmosphere. It
145 was then transferred under anaerobic conditions to a 250 mL glass bottle with the addition of synthetic
146 sea water without sulfate to reach 1:1 sediment – water slurry ratio for 3 months incubation period. Then
147 the slurry was sub-divided anaerobically to the 60 mL experiment bottles, and synthetic sea water was
148 added for final sediment – water ratio of 1:3. The bottles were sealed with a crimp cap and were flushed
149 with N₂ for 5 minutes, shaken vigorously and flushed again, (repeated 3 times). The experiment bottles
150 were amended with iron oxides (hematite (Fe₂O₃) or magnetite (Fe₃O₄) with final concentration of 10
151 mmol L⁻¹) with/without hydrogen (H₂) (to the final concentration of ~4% of the Head space volume).
152 The experiment bottles were sampled several times for dissolved Fe(II) concentrations during the 14 day
153 experiment period.

154 2.4 Analytical methods

155 2.4.1 Pore-water analyses

156 Methane concentrations were analyzed by Focus Gas – Chromatograph (GC; Thermo) equipped with
157 FID detector with detection limit of 50 $\mu\text{mol L}^{-1}$. H_2 concentrations were analyzed in a Reducing
158 Compound Photometer Gas-Chromatograph (RCP-GC; Peak Laboratories). Dissolved Fe(II)
159 concentrations were measured using the ferrozine method (Stookey, 1970) by a spectrophotometer at 562
160 nm wavelength with detection limit of 1 $\mu\text{mol L}^{-1}$. Sulfide was measured using the Cline (1969) method
161 by a spectrophotometer at 665 nm wavelength with detection limit of 1 $\mu\text{mol L}^{-1}$. Sulfate concentrations
162 were measured in an inductive coupled plasma atomic emission spectrometer (ICP-AES), Perkin Almer
163 Optima 3300, with an analytical error of $\pm 1\%$ (average deviations from repeated measurements of a
164 seawater standard). The $\delta^{13}\text{C}_{\text{DIC}}$ values were measured on a DeltaV Advantage Thermo© isotope-ratio
165 mass-spectrometer (IRMS) at a precision of $\pm 0.1\%$. Results are reported versus VPDB standard. Several
166 pore-water profiles were performed during the study, and all of them are presented (and not their
167 average). For each profile, the error bar is that of the average deviation of the mean of the duplicates, in
168 cases where they were taken, otherwise it is that of the analytical error (if larger than the symbol).

169 2.4.2 Sediment analysis

170 Reactive Fe(III) in the sediments was measured according to Poulton and Canfield (2005) definition and
171 sequential extraction procedure. The different reactive iron oxides were separated to (1) carbonate-
172 associated Fe; (2) easily reducible oxides; (3) reducible oxides and (4) magnetite. At the end of each
173 extraction stage, the extractant was transferred to a 15 mL falcon tube with 0.1 mL ascorbic acid and 0.1
174 mL ferrozine solution to reduce all the Fe(III) to Fe(II) and fix it, then it was measured
175 spectrophotometrically. The results are presented as "reactive Fe(III)", which was the sum of the easily
176 reducible oxides, reducible oxides and magnetite.

177 2.4.3 Quantitative PCR and 16S rRNA gene V4 amplicon pyrosequencing

178 DNA was extracted from the sediment core of station SG-1 from January 2017 using PowerSoil DNA
179 Kit (MoBio Laboratories, Inc., Carlsbad, CA, USA) following manufacturer's instructions. Copy
180 numbers of selected genes were estimated with quantitative PCR (qPCR) as described previously (Niu
181 et al., 2017) using specific primers: Uni519f/Arc908R and bac341f/519r for archaeal and bacterial 16S
182 rRNA genes, respectively, and mlas/mcrA-rev for the *mcrA* gene, which encodes the α -subunit of methyl-
183 coenzyme M reductase. The amplification efficiency was 94.5%, 106.3% and 92.4% for the archaeal 16S
184 rRNA, bacterial 16S rRNA and the *mcrA* gene, respectively (the respective R^2 of the standard curve was
185 0.998, 0.998 and 0.995).

186 The V4 regions of bacterial and archaeal 16S rRNA genes were amplified using barcoded 515FB/806RB
187 primers (Walters et al., 2015) and Arch519/Arch806 primers (Song et al., 2013), respectively. PCR
188 mixture contained 6 – 10 ng total DNA, 5 μL 10 \times Ex Taq buffer, 4 μL 2.5 mmol L^{-1} dNTP mix, 1 μL of
189 each primer, 0.25 μL Ex Taq polymerase (Ex-Taq; TaKaRa, Dalian, China) and 5 μL bovine serum
190 albumin (25 mg mL^{-1}) in a total volume of 50 μL . DNA was sequenced as 2 \times 150 bp reads using Illumina
191 MiSeq platform (Illumina, USA). Sequence quality assessments, chimera detection and down-stream

192 phylogenetic analyses were conducted in QIIME (Caporaso et al., 2010). Taxonomical assignments for
193 each OTU were performed in QIIME using the BLAST method and the SILVA128 reference database.
194 24056 to 132042 high quality sequences were obtained per sample, with the proportion of high-quality
195 sequence versus total sequence between 81.97 – 99.89%. Spearman correlation was performed using the
196 online calculator (<http://www.sthda.com/english/rsthd/correlation.php>) to test the relevance of
197 microbial abundance and communities with Fe(II) concentration along the depth of the sediment core
198 from 185 cm to the bottom 575 cm, which is the methanogenic zone of the sediment core according to
199 the geochemical profile (see the results below).

200 3 Results

201 3.1 Geochemical profiles

202 Geochemical pore-water profiles of several sediment cores from the three stations (SG-1, PC-3 and PC-
203 5) were performed in order to test the possibility of the iron reduction process in the methanogenic zone
204 of the SE Mediterranean continental shelf and its potential sources. Pore-water analyses of sulfate
205 concentrations show complete depletion at approximately 150 cm depth in all cores at station SG-1 (Fig.
206 1). Sulfide concentrations were below the detection limit in all cores and therefore are not presented.
207 Methane profiles show an increase in concentration immediately after the consumption of sulfate. The
208 maximal methane concentration was the saturation level (Sela-Adler et al., 2015) of about 10 mmol L⁻¹
209 at ~140 cm depth in June 2015 (station SG-1), probably due to intensive methane production at the exact
210 location of the core collected at that time. The other methane depth-profiles show high concentrations of
211 methane of approximately 2 mmol L⁻¹ all the way to the bottom of the cores (~600 cm). Detected
212 dissolved Fe(II) concentrations were found in the traditional iron reduction zone in the upper part of the
213 cores (between 30 – 90 cm depth). However, a second peak was found in the deeper part of the sediment,
214 at the methanogenic zone (below 180 cm depth). Maximum dissolved Fe(II) concentrations reached 84
215 μmol L⁻¹ in the traditional iron reduction zone of the sediment cores, and 65 μmol L⁻¹ in the methanogenic
216 zone (Fig. 1). It should be noted that iron species are highly sensitive to environmental changes such as
217 shifts in local pH, the different types of electron shuttles, and organic compounds that are present in the
218 surroundings. These changes affect the net dissolved Fe(II) observed; consequently the dissolved Fe(II)
219 results show variability between the cores that were extracted and analyzed from the same station. The
220 δ¹³C_{DIC} values were the lowest (-35 ‰) at the SMTZ depth, as expected from the intensive sulfate-
221 coupled AOM process there, which uses the isotopically light carbon of the methane as a carbon source
222 with only small fractionation. The δ¹³C_{DIC} values were the highest in the methanogenic zone, as expected
223 (the carbon source for the methane comes from the CO₂, leaving the residual DIC heavier by about 60
224 ‰ (Whiticar, 1999)). Fitting the intensive methane profile from June 2015, the δ¹³C_{DIC} showed the most
225 dramatic decrease and increase that date as well. The SMTZ was also the shallowest in this core because
226 of the intensive methane oxidation, thus the traditional iron reduction is missing in the sampled pore-
227 water. H₂ concentrations decreased to a minimum peak of 17 nmol L⁻¹ at 155 cm depth, and then
228 increased to a maximum of 147 nmol L⁻¹ at 485 cm depth.

229 Pore-water analyses from station PC-3 on all three sampling dates show similar patterns to SG-1 with
230 less methane activity (Fig 1). Sulfate was completely depleted within the upper 300 cm depth. Sulfide
231 concentrations were below the detection limit at this station as well. The methane profiles show an
232 increase in methane concentration immediately after the consumption of sulfate. The maximum methane
233 concentration reached 0.8 mmol L^{-1} at 450 cm depth in the Aug-13 core. Fe(II) profiles show two peaks,
234 one in the upper part of the cores with maximum of $32 \text{ } \mu\text{mol L}^{-1}$ at 177 cm depth, and another one with
235 maximum of $64 \text{ } \mu\text{mol L}^{-1}$ at 390 cm depth at the methanogenic depth. The $\delta^{13}\text{C}_{\text{DIC}}$ decreased from
236 approximately -10 ‰ at the water-sediment interface to -20 ‰ at the SMTZ. Below that zone there was
237 an increase in $\delta^{13}\text{C}_{\text{DIC}}$ values to about -5 ‰ due to methanogenesis. H_2 concentrations remained around
238 $2 \text{ } \mu\text{mol L}^{-1}$ along the core. The few deviating points do not fit a clear pattern and therefore not discussed.
239 The H_2 concentrations at the PC-3 station are higher by one order of magnitude than the concentrations
240 at the SG-1 station. This is probably due to the more intensive methanogenesis process at SG-1 station,
241 as shown by the higher methane concentrations than those at PC-3 station.

242 Pore-water analyses from the core collected at station PC-5 resembles the profiles of PC-3 station. Sulfate
243 was depleted at approximately 300 cm, and methane concentrations increased below that depth to 0.3
244 mmol L^{-1} . The Fe(II) profile shows two peaks in this core as well, one in the upper part of $20 \text{ } \mu\text{M}$ at 150
245 cm depth and the second of $30 \text{ } \mu\text{mol L}^{-1}$ in the methanogenic zone. The $\delta^{13}\text{C}_{\text{DIC}}$ value decreased from -5
246 ‰ at the water-sediment interface to -25 ‰ at the SMTZ, and below that depth $\delta^{13}\text{C}$ values increased to
247 -17 ‰ .

248 The reactive Fe(III) oxide profile from SG-1 (Fig. S1) shows a general decrease from 3 dry wt % at 13
249 cm depth to 2.3 dry wt % at 507 cm depth, with two minimum peaks of 2.4 dry wt % at 103 cm and of
250 1.9 dry wt % at 312 cm. PC-3 profile shows no significant trends in the reactive Fe(III) concentrations.
251 The values vary between 2.1 dry wt %, which is the maximum point at 167 cm, and 1.8 dry wt %, which
252 is the minimum point at 137 cm depth.

253 3.2 Abundance and diversity of bacteria and archaea

254 The qPCR of bacterial and archaeal 16S rRNA genes from the SG-1 core revealed that the abundance of
255 bacterial genes was between $1.46 - 9.45 \times 10^6$ copies per g wet sediment, while that of archaea was
256 between $8.15 \times 10^5 - 2.25 \times 10^7$ copies per g wet sediment (Fig. 2). These abundances are typical to
257 oligotrophic marine sediments (e.g. South China Sea that contain $\sim 0.5 - 1 \text{ ‰}$ TOC (Yu et al., 2018a)).
258 The abundance of bacteria and archaea decreased gradually in the top 95 cm, increased sharply at 125
259 cm within the SMTZ, remained relatively stable with high abundance at 185 – 245 cm (the top layer of
260 the methanogenic zone), and then decreased. Notably, the abundance of both bacteria and archaea peaked
261 within the methanogenic zone at 245 cm in correspondence with a Fe(II) concentration peak. However,
262 it is not feasible to compare the abundance of archaea and bacteria by this method due to bias caused by
263 the PCR primers used (Buongiorno et al., 2017). The abundance of the *mcrA* gene increased sharply from
264 the surface layer to the SMTZ, peaked at 155 cm and remained stable at 155 – 245 cm, indicative of
265 active anaerobic methane metabolism in the SMTZ and active methanogenic zone (Fig. 2). Spearman
266 correlation test shows that the abundance of the bacteria and archaea 16S rRNA genes and *mcrA* genes

267 correlated with Fe(II) concentration in the methanogenic zone, where *mcrA* gene correlated the most
268 significantly ($r = 0.5429$, p value = 0.04789).

269 Illumina-sequencing of the 16S rRNA gene revealed diverse bacterial and archaeal communities
270 throughout the SG-1 core. Although no clear plateau was observed on species rarefaction curve for the
271 current sequencing depth (Fig. S2), Shannon diversity indices reached stable values, indicating that those
272 sequences well covered the diversity of bacterial and archaeal populations in the samples (Fig. S3).
273 Shannon index, based on 16S rRNA gene sequences, showed higher diversity in the top layers of the
274 sediment along with similar values through the core using the bacterial primers, while for sequences
275 using archaeal primers, the values varied in different layers (Table S1). The bacterial sequences were
276 affiliated with the following phyla: Planctomycetes (25.7%), Chloroflexi (23.2 %), Proteobacteria
277 (12.9%), Deinococcus-Thermus (9.9 %), Acidobacteria (3.5%), Aminicenantes (3.3 %), Spirochaetes
278 (2.3%), Deferribacteres (1.7%), Elusimicrobia (1.6%), Aerophobetes (1.6%), Nitrospirae (1.4%),
279 Firmicutes (1.4 %), Actinobacteria (1.4 %), TM6 (Dependentiae) (1.2%), Marinimicrobia (SAR406 clade)
280 (1.0%), and other taxa with less than 1% of the bacterial communities (Fig. 3a). Bathyarchaeota were the
281 predominant archaea in all the sediment layers, based on the high relative abundance of their 16S rRNA
282 gene sequences (91.0%). The remaining archaeal phyla comprised Euryarchaeota (3.2%),
283 Thaumarchaeota (2.4%), Lokiarchaeota (1.0%), and other phyla with less than 1% of the archaeal
284 communities (Fig. 3b). Spearman correlation analysis revealed that uncultured SBR1093 ($r = 0.6176$, p
285 value = 0.01859) from bacterial Candidate Phylum SBR1093, subgroup 26 of Acidobacteria ($r = 0.5841$,
286 p value = 0.02828), the uncultured bacterium from TK10 Class of Chloroflexi phylum ($r = 0.5297$, p
287 value = 0.0544) and *uncultured Bathyarchaeota sp.* (archaea) ($r = 0.5516$, p value = 0.04388) correlated
288 significantly with Fe(II) iron concentration.

289 3.3 Incubation experiment

290 Sediment from the observed deep iron reduction zone of SG-1 station from January 2017 core was taken
291 for a basic short-term (few weeks) slurry incubation experiment in order to characterize the iron reduction
292 process in the methanogenic zone. The results of the experiment are shown in figure 4. Dissolved Fe(II)
293 concentrations show significant increase from $11 \mu\text{mol L}^{-1}$ to approximately $90 \mu\text{mol L}^{-1}$ during the first
294 three days in all the experimental bottles, except for the killed bottles, implying that the reduction is
295 microbially mediated. Another observation was that the microorganisms were able to reduce both
296 hematite and magnetite to the same extent. In addition, no difference in the Fe(II) concentrations between
297 bottles with and without the addition of H_2 was observed.

298 4 Discussion

299 This study was performed in the SE Mediterranean in the area of the recently discovered 'gas front'
300 (Schattner et al., 2012), where biogenic methane was found at some locations in shallow sediments with
301 low TOC content (Sela-Adler et al., 2015). SG station is located at the center of this area, while PC-3
302 and PC-5 at the edges, and indeed methane involved processes seem more intensive at this station (SG-
303 1) (Fig. 1). At this station methane reaches higher concentrations, and the intensive methanogenesis also
304 leads to intensive methane oxidation by sulfate at the SMTZ, causing it to occur at shallower depth with

305 lower $\delta^{13}\text{C}_{\text{DIC}}$ values, as observed in previous studies (e.g. Sivan et al., 2007). The shallower SMTZ
306 values also interfered with the ability to observe the traditional iron reduction zone in our SG-1 sampling
307 resolution.

308 Despite the pore-water profiles variability between the stations, they show a resemblance in their trends.
309 All geochemical pore-water and reactive Fe(III) profiles suggest that the sediments in this area of the SE
310 Mediterranean shelf can be classified into three general depth-zones (Fig. 1): **zone 1** is the upper part of
311 the sediment, where the traditional classical iron reduction occurs, probably coupled to organic matter
312 oxidation, with sulfate reduction below it; **zone 2** is the SMTZ, where methane starts to increase with
313 depth, sulfate is completely depleted, sulfide is absent and Fe(II) is either present in low concentrations
314 or absent as well (probably due to the precipitation of iron-sulfide minerals); **zone 3** is the methanogenic
315 zone, where methane concentrations increased to the highest values in all stations. At this zone, local
316 maxima of Fe(II) concentrations in the pore-water were found in all cores, indicating iron oxides
317 reactivation and reduction. The results of the slurry experiment show only a slight increase in Fe(II)
318 concentrations in the killed bottles compared to the non-killed bottles, indicating that most of the iron
319 reduction in zone 3 is microbial (Fig. 4).

320 The observed intensive iron reduction in the methanogenic sediments is the first in the Southeastern
321 Mediterranean shelf. The phenomenon of iron reduction in the methanogenic depth has been observed
322 before in other marine provinces (Egger et al., 2016; Jorgensen et al., 2004; März et al., 2008; Riedinger
323 et al., 2014; Slomp et al., 2013; Treude et al., 2014), however, the type of link to the methane cycle is
324 complex. Usually, iron reduction is coupled to oxidation of organic matter (Lovley and Phillips, 1988)
325 and is performed by iron reducing bacteria, which is probably the case in zone 1. It is however
326 questionable if this also stands for zone 3 and if not, what process is responsible for the reactivation of
327 iron oxides at this depth and its relation to methane.

328 The oligotrophic nature of the studied area would suggest that intensive bacterial iron reduction coupled
329 to the oxidation of organic matter in zone 3 is less likely. The present low nutrient and low chlorophyll
330 concentrations in the water results in low amount of TOC in the sediments, reaching up to ~1% (Sela-
331 Adler et al., 2015). However, we observe in situ biogenic methane formation in the shallow shelf
332 sediments based on the geochemical ($\delta^{13}\text{C}_{\text{DIC}}$) and microbial profiles (population and functional *mcrA*
333 gene). This indicates that regardless the area's present oligotrophic nature, the TOC substrate is enough
334 to sustain all the microbial activity up to methanogenesis. These environmental conditions are
335 hypothetically attributed to the Last Glacial Maximum or Mid-Pleistocene sources (Schattner et al.,
336 2012). At the methanogenic zone and below, it might be that the microbial communities present at these
337 depths are used as a food source.

338 Another potential process that can be coupled to iron reduction in the methanogenic zone is H_2 oxidation.
339 H_2 is an important intermediate in anaerobic aquatic sediments. In this type of environment, it is produced
340 mainly by fermentation of organic matter (Chen et al., 2006), and can be involved in different microbial
341 processes; where each process would need a certain amount of H_2 in order to occur (Lovley and Goodwin,
342 1988). The H_2 levels at stations SG-1 and PC-3 (Fig. 1) are relatively high (Lilley et al., 1982; Novelli et

343 al., 1987), suggesting that there is enough H₂ to sustain the iron reduction process. The increase in H₂
344 concentration at the methanogenic zone in SG-1 station could be explained by the occurrence of
345 fermentation processes, which enables H₂ to accumulate (Chen et al., 2006).

346 H₂ involvement was tested by injecting 1 mL of this gas to the experimental bottles in the methanogenic
347 iron reduction process (Fig. 4). We observed that the increase of Fe(II) concentration was similar in the
348 bottles with H₂ addition compared to the bottles without H₂. This could mean that either there is enough
349 H₂ in the sediments as it is, as implied by the H₂ pore-water profiles, or that at the methanogenic depth
350 H₂ is not involved in the iron reduction process.

351 A different way to reactivate the iron reduction process in zone 3 is to have an active sulfur cycle at this
352 depth. In this scenario, Fe(III) is reduced by pyrite oxidation (Eq. 3) (Bottrell et al., 2000), which triggers
353 the sulfur "cryptic" cycle (Holmkvist et al., 2011). In this cycle elemental sulfur and eventually, by
354 disproportionation, sulfide and sulfate are produced, the sulfide reacts with iron-oxide and precipitates
355 as FeS. The sulfate can inhibit methanogenesis (Mountfort et al., 1980; Mountfort and Asher, 1981),
356 which can result in the enhancement of the iron reduction process due to competition for substrate with
357 the methanogenesis process.

358 The recently discovered iron coupled AOM process (Eq. 3) is another potential process that involves iron
359 oxides reduction in the methanogenic zone. Fe(III) as an electron acceptor for AOM provides a greater
360 free energy yield than sulfate (Zehnder and Brock, 1980), and its global importance was emphasized
361 (Sivan et al., 2011; Lovley, 1991a; Kappler and Straub, 2005; Roden, 2003). In our profiles AOM could
362 be a valid option, as can be inferred from figure 5, where inverse association was observed between the
363 dissolved Fe(II) concentrations in zone 3 and the methane concentrations. In most cores presented in the
364 figure it is apparent that at high concentrations of Fe(II), methane concentrations are low (relatively to
365 the specific core), and at high methane concentrations, Fe(II) concentrations are low (relatively to the
366 specific core). This could be a result of iron-coupled AOM that uses methane to reduce Fe(III)-oxides,
367 releasing dissolved Fe(II) to the pore-water. This can also suggest a type of competitive relationship
368 between methanogenesis and microbial iron reduction; perhaps over substrate, or microbial population
369 switching from methanogenesis to iron reduction metabolism (e.g. Sivan et al., 2016). It should be noted
370 that our experiment was not designed to test AOM due to its short time scale of a few weeks, hence
371 another long experiment with the addition of the ¹³C-labeled methane will enable us to shed more light
372 on this association.

373 Our data profiles and incubation indicate that iron reduction is performed and stimulated by microbial
374 activity. This is despite the fact that the known potential bacterial iron reducers, such as *Alicyclobacillus*,
375 *Sulfobacillus*, *Desulfotomaculum* genera (Firmicutes), *Acidiphilium* (Alphaproteobacteria);
376 *Desulfobulbus*, *Desulfuromonas*, *Geobacter*, *Geothermobacter*, *Anaeromyxobacter* (Deltaproteobacteria);
377 and *Shewanella* (Gammaproteobacteria) (Weber et al., 2006) comprise less than 0.1% of bacteria
378 detected in the methanogenic zone (from 185 cm and below). This is because it appears that both the
379 microbial abundance and the Fe(II) concentration peaked at the methanogenic zone. Cultivation efforts
380 indicated that archaeal methanogens may also play a role in iron reduction within sediments (Sivan et al.,

381 2016). Moreover, the relative abundance of methane-metabolizing archaea was shown to correlate with
382 Fe(II) concentrations in Helgoland muds from the North Sea, where microbial abundance and the Fe(II)
383 concentrations peaked at the methanogenic zone, similarly to the Mediterranean sediments (Oni et al.,
384 2015). It is possible that methane-metabolizing archaea were involved in the iron reduction in the
385 Mediterranean sediments, as the highest *mcrA* gene copies per gram wet sediment were detected in the
386 SMTZ and in the top of the methanogenic zone where the Fe(II) concentrations are high. Methanotrophs,
387 such as ANMEs, were found to be involved in iron coupled AOM in marine and freshwater cultures
388 (Scheller et al., 2016; McGlynn et al., 2015; Ettwig et al., 2016; Cai et al., 2018). ANMEs were found
389 with relatively low frequencies (ANME1, below 1% in most samples, circa 5% in the 185 cm layer), and
390 their role in iron reduction within the Mediterranean sediments remains to be tested. It should be noted
391 that even though, the microbial population was tested only on the sediment core that was extracted on
392 January 2017 at SG-1 station, we believe that it represents the general microbial population abundance
393 in the SE Mediterranean continental shelf.

394 In our study, Spearman correlation analysis revealed that bacterial phyla SBR1093 (candidate Phylum),
395 Acidobacteria and Chloroflexi, as well as archaeal Phylum Bathyarchaeota showed significant
396 correlation with a Fe(II) concentration in the methanogenic zone. The Candidate Phylum SBR1093 was
397 firstly identified in phosphate-removing activated sludge from a sequencing batch reactor (Bond et al.,
398 1995), and continuously detected in a short-chain fatty acid rich environment such as wastewater
399 treatment, and marine sediments (Wang et al., 2014). It was thought to be capable of growing
400 autotrophically, but the metabolic capabilities related to iron reduction remain unclear. Strains of
401 Acidobacteria and Chloroflexi phylum were found to be capable of iron reduction (Kawaiichi et al., 2013;
402 Kulichevskaya et al., 2014). In addition, members of Acidobacteria were found in iron-coupled AOM
403 enrichment (Beal et al., 2009). The metabolic properties of Subgroup 26 from Acidobacteria and TK10
404 Class of Chloroflexi are still not known. Bathyarchaeota are globally distributed and account for a
405 considerable fraction of the archaeal communities in the marine sediments, particularly, in the
406 Mediterranean Pleistocene sapropels (Coolen et al., 2002; Zhou et al., 2018). While Bathyarchaeota have
407 diverse metabolic capabilities (Lloyd et al., 2013; Meng et al., 2014; Evans et al., 2015; He et al., 2016;
408 Yu et al., 2018b; Feng et al., 2019), their role in iron reduction warrants further studies, as suggested
409 from their high abundance here. Therefore, iron reduction and methane cycling within the deep
410 methanogenic zone may be facilitated by an interplay among bacterial and archaeal groups, whose
411 physiology and functions needs further investigation.

412 The geochemical and microbial data from the profiles and the slurry incubation experiment suggest that
413 deep iron reduction is occurring in the methanogenesis depth, and that both Bacteria and archaea can be
414 involved in the process. The geochemical profiles show Fe(II) peaks in the deep part of the sediments,
415 indicating iron reduction. The iron reduction was shown also in the incubation experiment, where
416 microbial involvement was evident. The Spearman correlation pointed out several potential microbial
417 players (bacterial and archaeal) that correlate to the dissolved Fe(II) profiles (e.g. Bathyarchaeota,
418 Acidobacteria and Chloroflexi). The geochemical conditions lead to three possible microbial iron
419 reduction pathways: a) H₂ or organic carbon oxidation, b) an active sulfur cycle, or c) iron driven AOM.

420 To verify the main iron reduction process at the methanogenic depth of the Mediterranean shelf sediments
421 further incubations and microbial work are needed.

422 **5 Author contribution**

423 H.V and O.S designed research; B.H was the PI of the cruises and M.RB was part of the scientific crew
424 on the ship; H.V, E.W and L.L performed research and analyzed the data; H.V, O.S, B.H, F.W, M.RB
425 and L.L synthesized the data and wrote the paper.

426 The authors declare that they have no conflict of interest.

427 **6 Acknowledgments**

428 The authors thank the captain and crew of the R/V Shikmona and R/V Bat Galim from the Israel
429 Oceanographic and Limnological Research for all their help during field sampling. Many thanks to E.
430 Eliani-Russak for her technical assistance in the lab and to V. Boyko for her help with the reactive iron
431 speciation procedure. We also thank all of Orit's lab member for their help. This study was supported by
432 the joint grant of Israel Science Foundation and the National Natural Science Foundation of China (ISF-
433 NSFC) [grant number 31661143022 (FW) and 2561/16 (OS)]. Funding was provided to H. Vigderovich
434 by the Mediterranean Sea Research Center of Israel.

690 **Figures captions:**

Figure 1: Geochemical pore-water profiles of sediment cores collected from the three stations SG-1 (top), PC-3 (middle) and PC-5 (bottom) in the Eastern Mediterranean. The profiles are divided roughly to three zones according to the dominant processes: upper microbial iron and sulfate reduction, sulfate-methane transition zone (SMTZ), and the methanogenic zone at the deep part. The dashed line in the CH₄ graph at SG-1 station represents the CH₄ saturation value in the pore-water. The error bars for CH₄ are presented where duplicate sediment samples were collected. The error bars for Fe(II), $\delta^{13}\text{C}_{\text{DIC}}$ and H₂ are presented where measurement repetition of each sample was taken (at least twice). The analytical errors were smaller than the symbols.

Figure 2: Sedimentary depth profiles of bacterial and archaeal 16S rRNA and mcrA functional genes of Station SG-1 from January 2017. Triplicates were made for each sample with error bars smaller than the symbols.

Figure 3: Phyla level classification of bacterial (a) and archaeal (b) diversity in the sediments of Station SG-1 from January 2017.

Figure 4: Dissolved Fe(II) results of the sediment slurry incubation experiment from SG-1 core. The sediment was collected on January 2017 from sediment depth of 260 cm. The error bars were smaller than the symbol.

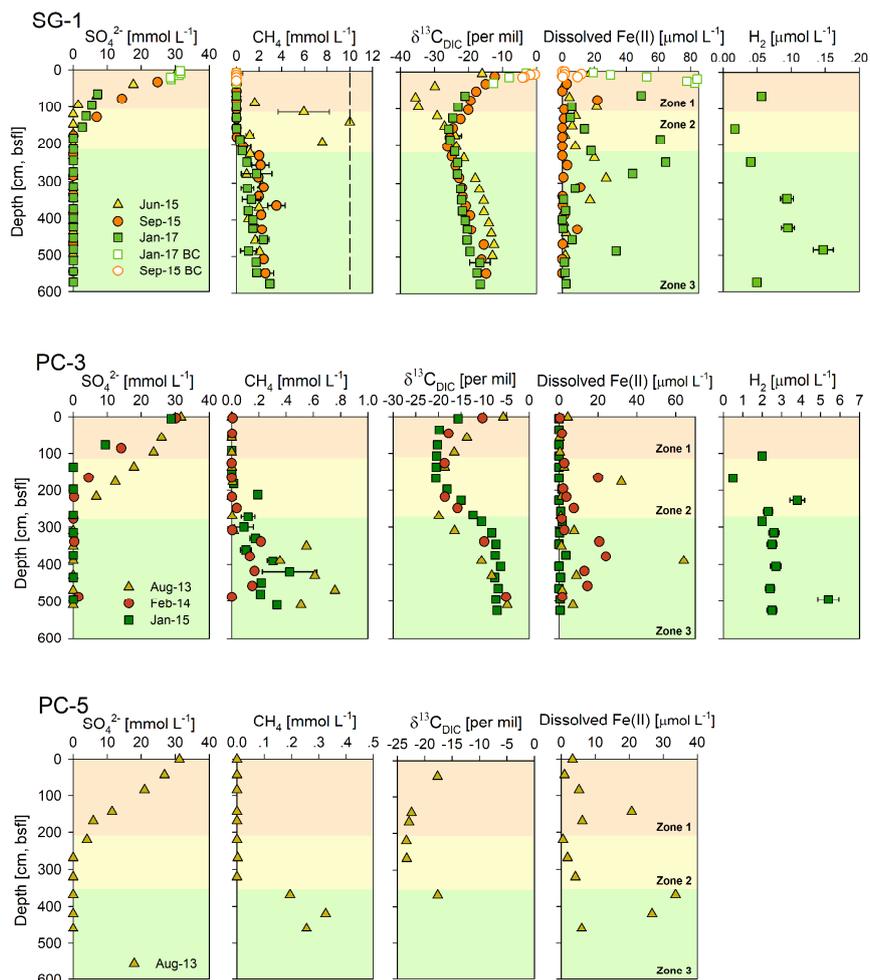

Figure 5: The relationship between dissolved Fe(II) concentrations and methane concentrations in zone 3 sediments at (a) Station SG-1 and (b) Station PC-3. An inverse association is observed between the two species, suggesting a relationship of competition or Fe(III)-coupled anaerobic methane oxidation.
