## Abstract

Nitrous oxide ( $\text{N}_2\text{O}$ ) and methane ( $\text{CH}_4$ ) are atmospheric trace gases which play important roles of the climate and atmospheric chemistry of the Earth. However, little is known about their emissions from rivers and estuaries which seem to contribute significantly to the atmospheric budget of both gases. To this end concentrations of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  were measured in the Rajang, Maludam, Sebuyau and Simunjan Rivers draining peatland in northwestern (NW) Borneo during two campaigns in March and September 2017. The Rajang River was additionally sampled in August 2016 and the Samunsam and Sematan Rivers were additionally sampled in March 2017. The Maludam, Sebuyau, and Simunjan Rivers are typical ‘blackwater’ rivers with very low pH (3.7 – 7.8), very high dissolved organic carbon (DOC) concentrations (235 – 4387  $\text{mmol L}^{-1}$ ) and very low  $\text{O}_2$  concentrations (31 – 246  $\mu\text{mol L}^{-1}$ ; i.e. 13 – 116 %  $\text{O}_2$  saturation). The spatial and temporal variability of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  concentrations (saturation) in the six rivers/estuaries was large and ranged from 2.0  $\text{nmol L}^{-1}$  (28 %) to 41.4  $\text{nmol L}^{-1}$  (570 %) and from 2.5  $\text{nmol L}^{-1}$  (106 %) to 1372  $\text{nmol L}^{-1}$  (57,459 %), respectively. We found no overall trends of  $\text{N}_2\text{O}$  with  $\text{O}_2$  or  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ ,  $\text{NH}_4^+$  and there were no trends of  $\text{CH}_4$  with  $\text{O}_2$  or dissolved nutrients or DOC.  $\text{N}_2\text{O}$  concentrations showed a positive linear correlation with rainfall. We conclude, therefore, that rainfall is the main factor determining the riverine  $\text{N}_2\text{O}$  concentrations since  $\text{N}_2\text{O}$  production/consumption in the ‘blackwater’ rivers themselves seems to be low because of the low pH.  $\text{CH}_4$  concentrations were highest at salinity = 0 and most probably result from methanogenesis as part of the decomposition of organic matter under anoxic conditions.  $\text{CH}_4$  in the concentrations in the ‘blackwater’ rivers showed an inverse relationship with rainfall. We suggest that  $\text{CH}_4$  oxidation in combination with an enhanced river flow after the rainfall events, might be responsible for the decrease of the  $\text{CH}_4$  concentrations. The rivers and estuaries studied here were an overall net source of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  to the atmosphere. The total annual  $\text{N}_2\text{O}$  and  $\text{CH}_4$  emissions were 1.09  $\text{Gg N}_2\text{O yr}^{-1}$  (0.7  $\text{Gg N yr}^{-1}$ ) and 23.8  $\text{Gg CH}_4 \text{ yr}^{-1}$ , respectively. This represents about 0.3 – 0.7 % of the global annual riverine and estuarine  $\text{N}_2\text{O}$  emissions and about 0.1 – 1 % of the global riverine and estuarine  $\text{CH}_4$  emissions. Therefore, we conclude that rivers and estuaries in NW Borneo –despite the fact their water area covers only 0.05 % of the global river/estuarine area– contribute significantly to global riverine and estuarine emissions of  $\text{N}_2\text{O}$  and  $\text{CH}_4$ .

## 1. Introduction

Nitrous oxide ( $\text{N}_2\text{O}$ ) and methane ( $\text{CH}_4$ ) are atmospheric trace gases which influence the climate and atmospheric chemistry of the Earth (IPCC, 2013; WMO, 2014). They act as greenhouse gases in the troposphere and are indirectly involved in stratospheric ozone depletion. Emission estimates indicate that rivers and estuaries contribute significantly to the atmospheric budget of both  $\text{N}_2\text{O}$  and  $\text{CH}_4$ .  $\text{N}_2\text{O}$  emission estimates for rivers and estuaries range from 0.05 to 3.3 Tg  $\text{N}_2\text{O}$   $\text{yr}^{-1}$  and from 0.09 to 5.7 Tg  $\text{N}_2\text{O}$   $\text{yr}^{-1}$ , respectively (see overview in (Maavara et al., 2019)). Thus, the combined riverine and estuarine emissions may contribute up to 32 % of the global natural and anthropogenic emissions of  $\text{N}_2\text{O}$  (28.1 Tg  $\text{N}_2\text{O}$   $\text{yr}^{-1}$ ; IPCC, 2013).  $\text{CH}_4$  emission estimates for rivers and estuaries are in the range of 1.5 – 26.8 Tg  $\text{CH}_4$   $\text{yr}^{-1}$  (Bastviken et al., 2011; Stanley et al., 2016) and 0.8 – 6.6 Tg  $\text{CH}_4$   $\text{yr}^{-1}$  (see overview in (Borges and Abril, 2011)), respectively. The combined emissions from rivers and estuaries can contribute up to 6% of the global natural and anthropogenic atmospheric emissions of  $\text{CH}_4$  (556 Tg  $\text{CH}_4$   $\text{yr}^{-1}$ ; IPCC, 2013). As indicated by the wide range of the estimates cited above, the emission estimates of both gases are associated with a high degree of uncertainty, which is mainly caused by an inadequate coverage of the temporal and spatial distributions of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  in rivers and estuaries and the inherent errors of the model approaches to estimate their exchange across the water/atmosphere interface (see e.g. (Alin et al., 2011; Borges and Abril, 2011)).

$\text{N}_2\text{O}$  is produced by microbial processes such as nitrification (i.e. oxidation of ammonia,  $\text{NH}_3$ , to nitrite,  $\text{NO}_2^-$ ) in estuarine waters (see e.g. (Barnes and Upstill-Goddard, 2011)) and heterotrophic denitrification (i.e. reduction of nitrate,  $\text{NO}_3^-$ , to dinitrogen,  $\text{N}_2$ ) in river sediments (Beaulieu et al., 2011). The yields of  $\text{N}_2\text{O}$  from these processes are enhanced under low oxygen (i.e. suboxic) conditions (see e.g. (Brase et al., 2017; Zhang et al., 2010)), whereas  $\text{N}_2\text{O}$  can be reduced to  $\text{N}_2$  under anoxic conditions via sedimentary denitrification in rivers (see e.g. (Upstill-Goddard et al., 2017)). Apart from ambient oxygen ( $\text{O}_2$ ) concentrations, riverine and estuarine  $\text{N}_2\text{O}$  production is also dependent on the concentrations of dissolved inorganic nitrogen, DIN ( $= \text{NH}_4^+ + \text{NO}_2^- + \text{NO}_3^-$ ) and organic carbon (Quick et al., 2019). There seems to be a general trend towards high estuarine/riverine  $\text{N}_2\text{O}$  concentrations when DIN concentrations are high as well (Barnes and Upstill-Goddard, 2011; Quick et al., 2019; Zhang et al., 2010). However, this trend masks the fact that in many cases the spatial and temporal variability of riverine and estuarine  $\text{N}_2\text{O}$  is often not related to DIN (see e.g. (Borges et al., 2015; Brase et al., 2017; Müller et al., 2016a; Quick et al., 2019)).

$\text{CH}_4$  is produced during microbial respiration of organic matter by anaerobic methanogenesis in riverine and estuarine sediments (see e.g. (Borges and Abril, 2011; Romeijn et al., 2019; Stanley et al., 2016)). A significant fraction of the  $\text{CH}_4$  produced in sediments can be oxidized to carbon dioxide ( $\text{CO}_2$ ) via anaerobic  $\text{CH}_4$  oxidation in sulphate-reducing zones of estuarine sediments (see e.g. (Maltby

et al., 2018)) and aerobic CH<sub>4</sub> oxidation in riverine sediments (see e.g. (Shelley et al., 2017)). When released to the overlying riverine/estuarine water CH<sub>4</sub> can be oxidized by aerobic CH<sub>4</sub> oxidation before reaching the atmosphere (see e.g. (Borges and Abril, 2011; Sawakuchi et al., 2016; Steinle et al., 2017)).

In general, the temporal and spatial distributions of N<sub>2</sub>O and CH<sub>4</sub> in rivers and estuaries are driven by the complex interplay of microbial production and consumption pathways (see above) as well as physical processes such as input via shallow groundwater, river discharge, tidal pumping, release to the atmosphere and export to coastal waters (Barnes and Upstill-Goddard, 2011; Borges and Abril, 2011; Quick et al., 2019; Stanley et al., 2016).

Peatlands, which are found in the tropics and at high latitudes, constitute one of the largest reservoirs of organic-bound carbon worldwide (Minasny et al., 2019; Page et al., 2011; Treat et al., 2019; Yu et al., 2010). Rivers and streams draining peatlands have exceptionally high concentrations of dissolved organic carbon (DOC) and low pH and, thus, belong to the ‘blackwater’ river type which is also found in southeast (SE) Asia (see e.g. (Alkhatib et al., 2007; Martin et al., 2018; Moore et al., 2011)).

Despite the fact that a number of studies about N<sub>2</sub>O and CH<sub>4</sub> emissions from peatlands in southeast (SE) Asia have been published (see e.g. (Couwenberg et al., 2010; Hatano et al., 2016; Jauhiainen et al., 2012)), only a few studies about their emissions from peatland draining rivers in SE Asia have been published so far (Jauhiainen and Silvennoinen, 2012; Müller et al., 2016a). Therefore, our knowledge about the biogeochemistry and emissions of N<sub>2</sub>O and CH<sub>4</sub> from peatland draining rivers is still rudimentary at best.

Here we present measurements of dissolved N<sub>2</sub>O and CH<sub>4</sub> in six rivers and estuaries in northwestern (NW) Borneo during August 2016, March 2017 and September 2017. The objectives of our study were (i) to measure the distributions of dissolved N<sub>2</sub>O and CH<sub>4</sub>, (ii) to identify the major factors influencing their distributions and (iii) to estimate the N<sub>2</sub>O and CH<sub>4</sub> emissions to the atmosphere.

## 2. Study site description

Discrete samples of surface water were taken at several stations along the salinity gradients of the Rajang, Maludam, Sebuyau and Simunjan Rivers in NW Borneo during two campaigns in March and September 2017 (Figure 1, Table 1). The Rajang River was additionally sampled in August 2016 and the Samunsam and Sematan Rivers were additionally sampled in March 2017. The environmental settings of the river basins are summarized in Table 2. Based on the areas affected by oil palm plantations and logging in combination with our own observations during several samplings

campaigns, we classified the Rajang and Simunjan river basins as ‘disturbed’, the Maludam, Sebuyau, Sematan and Samunsam river basins as ‘undisturbed’ (Table 2).

### 3. Methods

#### 3.1 Measurements of N<sub>2</sub>O and CH<sub>4</sub>

Water was collected from 1 m depth by using a Niskin sampler. Subsamples for N<sub>2</sub>O and CH<sub>4</sub> were taken as duplicates or triplicates in 20 or 37 mL glass vials. The vials were first rinsed with sample water, then filled to the maximum (without air bubbles), and finally sealed on the spot using a crimper. The samples were kept on ice for a maximum of 3 hours. When returned to the field station, 50 µL of saturated aqueous mercuric chloride (HgCl<sub>2</sub>) solution was immediately added to stop any biological activity and samples were stored at 4 °C until shipment. The samples were shipped to GEOMAR Helmholtz Centre for Ocean Research Kiel, Germany, for further analysis within a few weeks after sampling. For the determination of the N<sub>2</sub>O and CH<sub>4</sub> concentrations we applied the static-headspace equilibration method followed by gas chromatographic separation and detection with an electron capture detector (ECD, for N<sub>2</sub>O) and a flame ionization detector (FID, for CH<sub>4</sub>) as described in (Bastian, 2017) and (Kallert, 2017). Calibration of the ECD and FID were performed with standard gas mixtures of 348.4 – 1476.1 ppb N<sub>2</sub>O and 1806.10 – 3003.79 ppb CH<sub>4</sub> in synthetic air which have been calibrated against NOAA-certified primary gas standards in the laboratory of the Max Planck Institute for Biogeochemistry in Jena, Germany.

Dissolved N<sub>2</sub>O/CH<sub>4</sub> concentrations ( $C_{obs}$  in nmol L<sup>-1</sup>) were calculated with

$$C_{obs} = x'PV_{hs} / (RTV_{wp}) + x'\beta P \quad (1),$$

where  $x'$  is the dry mole fraction of N<sub>2</sub>O or CH<sub>4</sub> in the headspace of the sample,  $P$  is the ambient pressure (set to 1013.25 hPa),  $V_{hs}$  and  $V_{wp}$  are the volumes of the headspace and the water phase, respectively.  $R$  stands for the gas constant (8.31451 m<sup>3</sup> Pa K<sup>-1</sup> mol<sup>-1</sup>),  $T$  is the temperature during equilibration and  $\beta$  is the solubility of N<sub>2</sub>O or CH<sub>4</sub> (Weiss and Price, 1980; Wiesenburg and Guinasso Jr., 1979). The estimated mean relative errors of the measurements were +/- 9 % and +/- 13 % for N<sub>2</sub>O and CH<sub>4</sub>, respectively. These comparably high relative errors most probably resulted from the long storage time (six – seven months after sampling) for some of the samples. The higher mean measurement error of the CH<sub>4</sub> samples (compared to the N<sub>2</sub>O measurements) was attributed to the fact that CH<sub>4</sub> samples are more sensitive to storage time than N<sub>2</sub>O samples (Wilson et al., 2018).

#### 3.2 Ancillary measurements

Water temperature, dissolved oxygen, and salinity were recorded with an Aquaread® 2000. Nutrient measurements are described in detail in (Sia et al., 2019). In short, all samples were collected within the upper 1 m (surface) using pre-washed bottles via a pole-sampler to reduce contamination from the surface of the boat and engine coolant waters (Zhang et al., 2015). Samples were filtered through a 0.4 µm pore-size polycarbonate membrane filters (Whatman) into pre-rinsed bottles, conserved with concentrated HgCl<sub>2</sub> solution and kept in a cool, dark room. Nutrients were determined utilizing a Skalar SANplus auto analyser with an analytical precision <5%. pH was measured using a YSI Aquaread® multiple parameters probe (AP-2000). The measurements of dissolved organic carbon (DOC) are described in detail in (Martin et al., 2018). The performance of the DOC measurements was monitored by using deep-sea water samples with certified a DOC concentration of 42 – 45 µmol L<sup>-1</sup> provided by the Hansell Laboratory, University of Miami. Our analyses consistently yielded slightly higher concentration for the reference water, with a long-term mean (± 1 sd) of 47 ± 2.0 µmol L<sup>-1</sup> (n = 51). The DOC data are available from the supplementary material in (Martin et al., 2018).

### 3.3 Computations of saturations and flux densities

The saturations (*Sat*, %) for N<sub>2</sub>O, CH<sub>4</sub> and O<sub>2</sub> were calculated as

$$Sat = 100 C_{obs} / C_{eq} \quad (2)$$

where  $C_{eq}$  is the equilibrium concentration of N<sub>2</sub>O/CH<sub>4</sub>/O<sub>2</sub> calculated according to (Weiss and Price, 1980), (Wiesenburg and Guinasso Jr., 1979) or (Weiss, 1970), respectively, with the *in-situ* temperature and salinity as well as the mean dry mole fractions of N<sub>2</sub>O/CH<sub>4</sub> at the time of the sampling. Mean monthly N<sub>2</sub>O/CH<sub>4</sub> dry mole fractions of 329/1841 10<sup>-9</sup> (ppb), 331/1880 ppb and 330/1852 ppb for August 2016, March 2017 and September 2017, respectively, were measured at the atmospheric monitoring station Bukit Kototabang, located on the west coast of Sumatra (Indonesia). This station is operated by the NOAA/ESRL Global Monitoring Division program and data are available from <http://www.esrl.noaa.gov/gmd>. A saturation < 100 % indicates a concentration lower than the theoretical equilibrium concentration (i.e. undersaturation) and a saturation > 100 % indicates supersaturation.

Flux densities ( $F$ , nmol·m<sup>-2</sup>·s<sup>-1</sup>) were calculated as

$$F = k_w (C_{obs} - C_{eq}) \quad (3)$$

$$k_w = k_{600} (Sc/600)^{-0.5} \quad (4)$$

$k_w$  is the gas transfer velocity and  $Sc$  is the Schmidt number, which was calculated with the equations for the kinematic viscosity of water (Siedler and Peters, 1986) and the diffusion of N<sub>2</sub>O or CH<sub>4</sub> in

water (Jähne et al., 1987; Rhee et al., 2009).  $k_{600}$  was determined in a study for the Lupar and Saribas Rivers which are located in close vicinity to the Maludam River (Müller et al., 2016a; Müller et al., 2016b). Both rivers have similar environmental and morphological settings in comparison to the rivers studied here. Therefore, we assume that the  $k_{600}$  values measured by (Müller et al., 2016a) are representative for the rivers in NW Borneo studied here. Mean  $k_{600}$  range from 13.2 +/- 11 cm h<sup>-1</sup> to 23.9 +/- 14.8 cm h<sup>-1</sup>. On the basis of the data in (Müller et al., 2016a) we computed a mean  $k_{600}$  of 19.2 cm h<sup>-1</sup> (5.33 10<sup>-5</sup> m s<sup>-1</sup>) which we used to estimate the flux densities of N<sub>2</sub>O and CH<sub>4</sub>. This  $k_{600}$  is in good agreement with the mean  $k_{600}$  for rivers < 100 m wide (22.4 +/- 14.3 cm h<sup>-1</sup>) and estuaries/rivers > 100 m wide (10.3 +/- 7.7 cm h<sup>-1</sup>) listed in (Alin et al., 2011) which range from 6.0 to 35.3 and 4.8 to 30.6 cm h<sup>-1</sup>, respectively.  $k_w$  in rivers depends on the turbulence at the river water/atmosphere interface, which in turn is mainly affected by water current velocity, water depth and river bed roughness and to a lesser extent by the wind speed (Alin et al., 2011; Borges and Abril, 2011). Since the  $k_{600}$  reported by (Müller et al., 2016a) were determined only during the wet season (March 2014), our mean  $k_{600}$  is biased because it does not account for a lower  $k_{600}$  which is to be expected during the dry season (resulting from a lower water current velocity (Alin et al., 2011)). This results in an overestimation of the flux densities.

### 3.4 Rainfall data

In order to account for the regional variability of the rainfall in NW Borneo, we used rainfall data with a 3 h resolution recorded at the weather stations in Kuching, Bandar Sri Aman and Sibu (all in NW Borneo). The rainfall data were provided by World Weather Online (Dubai, UAE, and Manchester, UK) and are available via <https://www.worldweatheronline.com/>. Representative weather stations were chosen for each river basin studied here and allocated as follows: The rainfall data for the Simunjan, Sematan and Samunsam River basins are represented by the data from Kuching, the Maludam/Sebuyau, and the Rajang River basins are represented by the data from the Bandar Sri Aman and Sibu weather stations, respectively. We also included the N<sub>2</sub>O and CH<sub>4</sub> concentrations data from two measurement campaigns to the Lupar and Saribas Rivers in June 2013 and March 2014 (Müller et al., 2016a). The Lupar and Saribas data were associated with the rainfall data from the weather station in Bandar Sri Aman. Accumulated rainfall amount was computed by summing up the 3 h rainfall data for the periods of one to four weeks prior to the sampling dates.

## 4 Results and Discussion

All rivers showed low concentrations of DIN in the range from 1.1 to 29 µmol L<sup>-1</sup> (Table 1). NO<sub>3</sub><sup>-</sup> concentrations ranged from below the detection limit of 0.14 µmol L<sup>-1</sup> up to 19 µmol L<sup>-1</sup> and NH<sub>4</sub><sup>+</sup> concentrations were in the range of 0.3 to 17 µmol L<sup>-1</sup>. The Maludam, Sebuyau, and Simunjan Rivers can be classified as ‘blackwater’ rivers with low pH (3.7 – 4.8), high DOC concentrations (1960 –

4387  $\mu\text{mol L}^{-1}$ ) and low  $\text{O}_2$  concentrations (31 – 95  $\mu\text{mol L}^{-1}$ ; 13 – 39 % saturation) at salinity = 0 (Table 1). Comparable settings have been reported from other tropical ‘blackwater’ rivers in SE Asia as well (Alkhatib et al., 2007; Baum et al., 2007; Moore et al., 2011; Rixen et al., 2008; Wit et al., 2015).

#### 4.1 Nitrous oxide

The measured ranges of  $\text{N}_2\text{O}$  concentrations and saturations are listed in Table 3 and the distributions of  $\text{N}_2\text{O}$  saturations along the salinity gradients are shown in Figure 2.  $\text{N}_2\text{O}$  concentrations (saturations) were highly variable and ranged from 2.0  $\text{nmol L}^{-1}$  (28 %) in the Rajang River (at salinity = 0 in August 2016) to 41.4  $\text{nmol L}^{-1}$  (570 %) in the Simunjan River (at salinity = 0 in March 2017).  $\text{N}_2\text{O}$  concentrations in the Rajang, Maludam and Sebuyau Rivers were generally higher in September 2017 compared to March 2017 (Figure 2a-c). A decreasing linear trend of the  $\text{N}_2\text{O}$  saturations with salinity was only observed for the Rajang River in March 2017 (Figure 2a) indicating a conservative mixing and no  $\text{N}_2\text{O}$  sources or sinks along the salinity gradient. Our results are in general agreement with the  $\text{N}_2\text{O}$  measurements in the Lupar and Saribas Rivers (which are located in close vicinity of the Maludam River) in June 2013 and March 2014: (Müller et al., 2016a) measured  $\text{N}_2\text{O}$  concentrations (saturations) from 6.6 to 117  $\text{nmol L}^{-1}$  (102 to 1679 %) in the Lupar and Saribas Rivers. Salinity and  $\text{N}_2\text{O}$  concentrations in the Lupar and Saribas Rivers were negatively correlated in June 2013 but were not correlated in March 2014 (Müller et al., 2016a). In contrast to our study, no  $\text{N}_2\text{O}$  undersaturations have been observed by (Müller et al., 2016a). Our results are at the lower end of  $\text{N}_2\text{O}$  concentrations reported from rivers around the globe which can range from extreme undersaturation (down to about 3 %, i.e. almost devoid of  $\text{N}_2\text{O}$ ) as measured in a tropical river in Africa (Borges et al., 2015) to extreme supersaturation (of up to 12,500 %) as measured in an agriculture dominated river in Europe (Borges et al., 2018).

Maximum  $\text{N}_2\text{O}$  saturations measured in March 2017 were in the range from 106 % to 142 % for the rivers classified as undisturbed (Maludam, Sebuyau, Sematan and Samunsam) whereas the maximum saturation for the rivers classified as disturbed (Rajang and Simunjan) were in the range from 329 % to 570 % (Tables 2 and 3) indicating higher emissions from the disturbed rivers. The maximum  $\text{N}_2\text{O}$  saturations in September 2017 ranged from 329 % to 390 % and no differences were observed between undisturbed and disturbed rivers (Table 3).

We found no overall trends of  $\text{N}_2\text{O}$  with  $\text{O}_2$  or  $\text{NO}_3^-$ ,  $\text{NO}_2^-$ ,  $\text{NH}_4^+$  and DIN. Therefore, it is difficult to decipher the major consumption or production processes of  $\text{N}_2\text{O}$  or to locate the influence of (local) anthropogenic input of nitrogen compounds on riverine  $\text{N}_2\text{O}$  cycling. This is in line with results from studies of other tropical rivers (Borges et al., 2015; Müller et al., 2016a). There are, however, occasional observations of  $\text{N}_2\text{O}$  correlations with  $\text{O}_2$ /nutrients in tropical rivers which were attributed

to river types such as swamp and savannah rivers (Upstill-Goddard et al., 2017). Figure 3 shows the  $\text{N}_2\text{O}$  concentrations along the pH gradients. Obviously there are no trends except for an enhancement of the  $\text{N}_2\text{O}$  concentrations in September 2017.  $\text{N}_2\text{O}$  production via nitrification depends on the prevailing pH because nitrifiers prefer to take up ammonia ( $\text{NH}_3$ ). The concentration of dissolved  $\text{NH}_3$  is dropping significantly at  $\text{pH} < 8 - 9$  (Bange, 2008) because of its easy protonation to ammonium ( $\text{NH}_4^+$ ). A low pH of about 5 – 6 can reduce nitrification ( $\text{NH}_4^+$  oxidation) significantly as it was recently shown for the Tay Ninh River in Vietnam (Le et al., 2019). Moreover, the optimum for a net  $\text{N}_2\text{O}$  production by nitrification, nitrifier-denitrification and denitrification lies between a pH of 7 – 7.5 (Blum et al., 2018). Therefore, a net  $\text{N}_2\text{O}$  production may be low in the ‘blackwater’ rivers studied here because of their low pH (see Table 1). The observed  $\text{N}_2\text{O}$  supersaturations, therefore, might have been mainly the result of external inputs of  $\text{N}_2\text{O}$ -enriched waters or groundwater. The observed  $\text{N}_2\text{O}$  undersaturations were most probably resulting from heterotrophic denitrification which could have taken place either in organic matter-enriched anoxic river sediments or in anoxic environments of the surrounding soils. However, the main factor for riverine  $\text{N}_2\text{O}$  under- or supersaturation might be rainfall, because rainfall events determine the height of the water table in the surrounding soils which, in turn, determines the amount of suboxic/anoxic conditions favourable for  $\text{N}_2\text{O}$  production or consumption (Jauhiainen et al., 2016). See also discussion in Section 4.3.

## 4.2 Methane

The measured ranges of  $\text{CH}_4$  concentrations and saturations are listed in Table 3 and the distributions of  $\text{CH}_4$  saturations along the salinity gradients are shown in Figure 4.  $\text{CH}_4$  concentrations (saturations) were highly variable and ranged from 2.5  $\text{nmol L}^{-1}$  (106 %) in the Simunjan River (at salinity = 0 in September 2017) to 1372  $\text{nmol L}^{-1}$  (57,459 %) in the Simunjan River (at salinity = 0 in March 2017). (Please note that we also measured a  $\text{CH}_4$  concentration of 14,999  $\text{nmol L}^{-1}$  (624,070 %) at one station in the Simunjan River at salinity = 0 in March 2017 which, however, was not included in Figure 4 and which was excluded in the emission estimates because of statistical reasons.)  $\text{CH}_4$  saturations in the Rajang, Maludam, Sebuyau and Simunjan Rivers were higher in March 2017 compared to September 2017. Maximum  $\text{CH}_4$  concentrations were measured at salinity = 0 and there was a general decrease of  $\text{CH}_4$  concentrations with increasing salinity. Exceptions from this trend occurred at individual stations in the Maludam, Sebuyau and Samunsam Rivers which point to local sources of  $\text{CH}_4$  (Figure 3). The range of  $\text{CH}_4$  concentrations (saturations) from our study is larger compared to the concentration range measured in the Lupar and Saribas Rivers (3.7 – 113.9  $\text{nmol L}^{-1}$ ; 168 – 5058 %) (Müller et al., 2016a). (Borges et al., 2015) reported a maximum  $\text{CH}_4$  concentration (saturation) of 62,966  $\text{nmol L}^{-1}$  (appr. 954,000 %) in their study of tropical rivers in Africa which is much higher than the maximum concentration measured in our study. We found no differences in the  $\text{CH}_4$  saturations between the rivers classified as undisturbed and those classified as disturbed in both March and September 2017.

We found no overall trends of CH<sub>4</sub> with O<sub>2</sub> or dissolved nutrients or DOC along the salinity gradients. There are, however, occasional observations in tropical rivers of CH<sub>4</sub> relationships with O<sub>2</sub> which were attributed to different river types such as swamp and savannah rivers (Upstill-Goddard et al., 2017). High CH<sub>4</sub> concentrations, which were often associated with high DOC and low O<sub>2</sub> concentrations at salinity = 0 and pH < 7 (see Figure 3b), might have been produced by methanogenesis in anoxic riverine sediments rich in organic material or in anoxic parts of the surrounding soils drained by the rivers. The decrease of CH<sub>4</sub> with increasing salinity can be attributed to the gas exchange across the river water/atmosphere interface in combination with CH<sub>4</sub> oxidation (Borges and Abril, 2011; Sawakuchi et al., 2016).

#### 4.3 N<sub>2</sub>O/CH<sub>4</sub> concentrations and rainfall

Mean N<sub>2</sub>O concentrations showed linear correlations with accumulated rainfall during different periods from one to four weeks before the dates of sampling (Figure 5, Table 6). Enhanced N<sub>2</sub>O emissions from (peat) soils are usually associated with rainfall when the water table approaches the soil surface (Couwenberg et al., 2010; Jauhiainen et al., 2016). A high water table, in turn, allows decomposition of previously deposited fresh organic material (Jauhiainen et al., 2016) and, thus, will result in favourable conditions for microbial N<sub>2</sub>O production mainly via denitrification in a suboxic/anoxic soil environment (Espenberg et al., 2018; Pihlatie et al., 2004). N<sub>2</sub>O production via nitrification may be less important at high water table (Pihlatie et al., 2004; Regina et al., 1996). Therefore, the positive linear relationship of the riverine N<sub>2</sub>O concentrations with rainfall might result from enhanced N<sub>2</sub>O production in the adjacent soils drained by the rivers. A decreasing trend of N<sub>2</sub>O concentrations which would be expected to be caused by enhanced river discharge after the rain events—which in turn can lead to dilution of the concentrations and enhanced fluxes across the river/atmosphere interface (Alin et al., 2011)—is obviously outcompeted by an enhanced input of N<sub>2</sub>O.

In contrast to N<sub>2</sub>O, the response of riverine/estuarine CH<sub>4</sub> concentrations to increasing rainfall is not resulting in increasing CH<sub>4</sub> concentrations (Figure 5). When considering the periods of 1 or 1.5 weeks of accumulated rainfall there seems to be a pronounced decrease of CH<sub>4</sub> concentrations with increasing rainfall (Figure 5c and Table 6). This trend is no longer significant when considering the periods of 2 - 4 weeks of accumulated rainfall (Table 6). A closer inspection of the data reveals that the response to increasing rainfall seems to be different for individual rivers/estuaries. There is a clear negative relationship with rainfall for the Maludam, Sebuyau and Simunjan Rivers, whereas no obvious trends were observed for the other rivers (Figures 5c and d). Under the assumption that rainfall is a predictor for river discharge/high water we can argue that our results are in agreement with the often observed inverse relationship between CH<sub>4</sub> concentrations and river discharge (Anthony et al., 2012; Bouillon et al., 2014; Dinsmore et al., 2013; Hope et al., 2001). This relationship can be explained by an interplay of various processes such as: (i) decrease of CH<sub>4</sub> concentrations caused by a

higher water flow (i.e. dilution under the assumption that the net CH<sub>4</sub> production does not change significantly), (ii) higher flux across the river/atmosphere interface during periods of higher discharge (caused by an enlarged river surface area and/or a more turbulent water flow) (Alin et al., 2011), and  
 360 (iii) the enhancement of CH<sub>4</sub> oxidation during high waters: (Sawakuchi et al., 2016) showed that CH<sub>4</sub> oxidation in ‘blackwater’ rivers of the Amazon basin was maximal during the high water season.

#### 4.4 Emission estimates

The N<sub>2</sub>O flux densities from the six rivers studied here are comparable to the N<sub>2</sub>O flux densities from  
 365 other aqueous and soil systems reported from Borneo and other sites in SE Asia, see Table 4. The corresponding CH<sub>4</sub> flux densities are higher than the CH<sub>4</sub> flux densities reported for the Lupar and Saribas Rivers but much lower than the flux densities from drainage canals in Central Kalimantan and Sumatra (Jauhiainen and Silvennoinen, 2012) (Table 4). Our CH<sub>4</sub> flux densities are, however, comparable to recently published CH<sub>4</sub> eddy covariance measurements (Tang et al., 2018) in the  
 370 Maludam National Park, which is drained by the Maludam River, and measurements of the CH<sub>4</sub> release from peat soils when the water table is high and CH<sub>4</sub> from rice paddies (Couwenberg et al., 2010), see Table 4. The mean annual N<sub>2</sub>O and CH<sub>4</sub> emissions for the individual rivers were calculated by multiplying the mean flux density,  $F$ , for each river (Table 4) with the river surface area given in Table 2. The results are listed in Table 5. The resulting total annual N<sub>2</sub>O emissions for the rivers in  
 375 NW Borneo - including the emissions from the Lupar and Saribas Rivers (Müller et al., 2016a) - are 1.09 Gg N<sub>2</sub>O yr<sup>-1</sup> (0.7 Gg N yr<sup>-1</sup>). This represents about 0.3 – 0.7 % of the global annual riverine and estuarine N<sub>2</sub>O emissions of 166 – 322 Gg N<sub>2</sub>O (106 – 205 Gg N yr<sup>-1</sup>) recently estimated by (Maavara et al., 2019). The total annual CH<sub>4</sub> emissions from rivers in NW Borneo are 23.8 Gg CH<sub>4</sub> yr<sup>-1</sup>. This represents about 0.1 – 1 % of the global riverine and estuarine CH<sub>4</sub> emissions of 2300 – 33,400 Gg  
 380 CH<sub>4</sub> yr<sup>-1</sup> (the emission range is based on the minimum and maximum estimates given in (Bange et al., 1994; Bastviken et al., 2011; Borges and Abril, 2011; Stanley et al., 2016). However, we caution that our estimates are associated with a high degree of uncertainty because (i) our data are biased by the fact that for some rivers it was not possible to cover the entire salinity gradient, (ii) seasonal and interannual variabilities of the N<sub>2</sub>O and CH<sub>4</sub> concentrations are not adequately represented in our data  
 385 set, (iii) the wind speed-driven gas exchange in estuaries is not adequately represented, and (iv) the mean  $k_{600}$  used here is most probably too high (see Section 3.3) resulting in an overestimation of the emissions.

## 5 Summary and Conclusions

390 N<sub>2</sub>O and CH<sub>4</sub> were measured in the Rajang, Maludam, Sebuyau and Simuntan Rivers and Estuaries in NW Borneo during two campaigns in March and September 2017. The Rajang River was additionally sampled in August 2016 and the Samunsam and Sematan Rivers were additionally sampled in March

2017. The spatial and temporal variability of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  concentrations was large.  $\text{N}_2\text{O}$  concentrations (saturation) ranged from  $2.0 \text{ nmol L}^{-1}$  (28 %) in the Rajang River (at salinity = 0 in August 2016) to  $41.4 \text{ nmol L}^{-1}$  (570 %) in the Simunjan River (at salinity = 0 in March 2017).  $\text{CH}_4$  concentrations (saturation) were in the range from  $2.5 \text{ nmol L}^{-1}$  (106 %) in the Simunjan River (at salinity = 0 in September 2017) to  $1372 \text{ nmol L}^{-1}$  (57,459 %) in the Simunjan River (at salinity = 0 in March 2017).  $\text{N}_2\text{O}$  concentrations showed a positive linear correlation with rainfall. We conclude, therefore, that rainfall, which determines the  $\text{N}_2\text{O}$  production/consumption in the surrounding soils, is the main factor determining the riverine  $\text{N}_2\text{O}$  concentrations.  $\text{N}_2\text{O}$  production in the ‘blackwater’ rivers themselves seems to be low because of the low pH.  $\text{CH}_4$  concentrations were highest at salinity = 0 and most probably results from methanogenesis as part of the decomposition of organic matter under anoxic conditions.  $\text{CH}_4$  concentrations in the ‘blackwater’ rivers showed an inverse relationship with rainfall. We suggest that enhanced  $\text{CH}_4$  oxidation in combination with a higher flux across the river/atmosphere interface during periods of higher river flow (after rainfall events), is responsible for the reduction of the  $\text{CH}_4$  concentrations along the salinity gradient. The rivers and estuaries studied here were an overall net source of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  to the atmosphere. The total annual  $\text{N}_2\text{O}$  and  $\text{CH}_4$  emissions were  $1.09 \text{ Gg N}_2\text{O yr}^{-1}$  ( $0.7 \text{ Gg N yr}^{-1}$ ) and  $23.8 \text{ Gg CH}_4 \text{ yr}^{-1}$ , respectively. This represents about 0.3 – 0.7 % of the global annual riverine and estuarine  $\text{N}_2\text{O}$  emissions and about 0.1 – 1 % of the global riverine and estuarine  $\text{CH}_4$  emissions. Rivers and estuaries in NW Borneo contribute only 0.05 % ( $= 7.9 \cdot 10^2 \text{ km}^2$  including the surface areas of the Lupar and Saribas Rivers; (Müller et al., 2016a) to the global water surface area of rivers and estuaries ( $= 1.7 \cdot 10^6 \text{ km}^2$ ; (Maavara et al., 2019)). Therefore we conclude that rivers and estuaries in NW Borneo contribute significantly to the global riverine and estuarine emissions of both  $\text{N}_2\text{O}$  and  $\text{CH}_4$ .

The environment of Borneo (and SE Asia) is affected by rapid changes due to (i) anthropogenic activities such as conversion of peatland into oil palm plantations etc. (see e.g. (Austin et al., 2018; McAlpine et al., 2018; Schoneveld et al., 2019)) and (ii) climatic changes (see e.g. (Sa’adi et al., 2017a, b; Tang, 2019)) which, in turn, could significantly affect  $\text{N}_2\text{O}$  and  $\text{CH}_4$  emissions from soils (see e.g. (Jauhiainen et al., 2016; Oktarita et al., 2017)). But little is known about how these changes will affect  $\text{N}_2\text{O}$  and  $\text{CH}_4$  emissions from aqueous systems such as rivers and estuaries in the future. The obvious relationship of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  concentrations and rainfall could be used to predict future concentrations and its associated emissions to the atmosphere. However, the trends of rainfall and river discharge in Borneo show a high local variability and no general common trend (Sa’adi et al., 2017a; Tang, 2019). Therefore, predictions of future trends of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  emissions will be associated with high degree of uncertainty. In order to improve our knowledge to predicted future changes of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  riverine/estuarine emissions we suggest establishing regular measurements in the rivers and along the salinity gradients. This will help deciphering the temporal and spatial variability of  $\text{N}_2\text{O}$  and  $\text{CH}_4$  emissions from tropical rivers and estuaries. Moreover, studies of the

relevant production/consumption pathways (and their main driving factors) for both gases are required. A suitable framework for this could be the recently published concept of the global N<sub>2</sub>O Ocean Observation Network (N<sub>2</sub>O-ON) (Bange et al., 2019).

## 435 6 Acknowledgments

We would like to thank the Sarawak Forestry Department and Sarawak Biodiversity Centre for permission to conduct collaborative research in Sarawak waters under permit numbers NPW.907.4.4(Jld.14)-161, Park Permit No WL83/2017, and SBC-RA-0097-MM. We are very grateful  
440 to the boatmen who helped us to collect samples, in particular Lukas Chin, Captain Juble, and their crew during the Rajang River and Eastern Region cruises, and Minhad and Pak Mat while sampling the Western Region. We are grateful to Claire Evans and Joost Brandsma for their participation in planning the overall research project and helping to lead expeditions to the Maludam, Sebuyau, and Simunjan Rivers. Faddrine Yang, Gonzalo Carrasco, Florina Richard, and Fakharuddin Muhamad  
445 assisted greatly during fieldwork and with logistics. We thank Edwin Sia and Faddrine Holt for the fantastic support of the N<sub>2</sub>O/CH<sub>4</sub> sampling during the fieldwork campaigns. We acknowledge the help of Lasse Sieberth with the N<sub>2</sub>O/CH<sub>4</sub> measurements. We thank two anonymous reviewers for their comments which helped to improve the manuscript significantly. M.M. acknowledges funding through Newton-Ungku Omar Fund (NE/P020283/1), MOHE FRGS 15 Grant  
450 (FRGS/1/2015/WAB08/SWIN/02/1) and SKLEC Open Research Fund (SKLEC-KF201610).

### Author contribution

MM, CHS, AM and HWB designed the study. CHS performed the sample preparation during the campaigns. DB and JK performed the N<sub>2</sub>O/CH<sub>4</sub> measurements with support from AK. HWB prepared  
455 the ms with contributions from all co-authors.

### Competing interests

The authors declare that they have no conflict of interests.

### 460 Data availability

All N<sub>2</sub>O/CH<sub>4</sub> data presented here are archived in and available from the MEMENTO (the MarineE MethanE and NiTrous Oxide) database: <https://memento.geomar.de>.

Table 2: Summary of the environmental settings of the river basins. Based on the area percentage of oil palm, logging and our own surveys and observations, we classified the river basins into undisturbed (U) and disturbed (D). All areas are given in km<sup>2</sup>.

River	Areas					Remarks	Classification
	Total Basin	Peatland <sup>1</sup>	Oil palm plantations <sup>2</sup>	Logging <sup>3</sup>	River water surface <sup>4</sup>		
Rajang	50,000 <sup>5</sup>	3844	4514	29,379	455 <sup>5</sup>	The longest river in Malaysia. Major town is Sibul (163,000 population). Smaller townships are Kapit, Kanowit and Sarikei. There is a large number of villages and longhouses (traditional buildings inhabited by local communities) located along the river and its tributaries. Two hydroelectric power plants were built at two tributaries in the upper Rajang basin. The river mouth is surrounded by peat lands, and most of these peat lands have been converted to commercial oil palm plantations.	D
Maludam	197	172	16	0	0.36	The upstream of the river is surrounded by the Maludam National Park. The Maludam Peninsula is bordered by the Lupar and Saribas Rivers and is the biggest undisturbed peat forest in Malaysia. The National Park had been subjected to selective logging before it was gazetted as a totally protected area in 2000. Well preserved peat land. There are oil palm cultivations near the few villages.	U
Sebuyau	538	288	24	0	2.11	Major town is Sebuyau (14,000 population), surrounded by a few villages. Other agricultural activities were observed.	U
Simunjan	788	346	240	0	4.73	Major town is Simunjan (22,000 population), a few villages. Two streams combine to form the main Simunjan River. One of the streams passes an oil palm mill which discharges into the river.	D
Sematan	287	0	0	0	1.47	Major town is Sematan (7,600 population), small villages. We observed agricultural activities by the local people.	U
Samunsa m	163	0	0	0	0.85	Well preserved tropical forest. Some peat in the upper catchment area.	U

<sup>1</sup> Estimate is based on 'Wetlands International'. "Malaysia peat lands". Accessed through Global Forest Watch on 22<sup>nd</sup> November 2018 ([www.globalforestwatch.org](http://www.globalforestwatch.org)).

<sup>2</sup> Estimate is based on 'Oil palm concessions'. Accessed through Global Forest Watch on 22<sup>nd</sup> November 2018 ([www.globalforestwatch.org](http://www.globalforestwatch.org)).

<sup>3</sup> Estimate is based on 'Managed forest concessions'. Accessed through Global Forest Watch on 22<sup>nd</sup> November 2018 ([www.globalforestwatch.org](http://www.globalforestwatch.org)).

<sup>4</sup> Area estimates are based on the length and width of the primary course and main tributaries of the rivers. Length and width of the rivers were estimated using Google Earth (multiple readings).

<sup>5</sup> Estimate from (Staub et al., 2000).

## Figure Captions

Figure 1: Map of the study area with locations of the sampling stations. Sampling stations from August 2016 are displayed in red circles, from March 2017 in blue triangles, and from September 2017 in green diamonds. Major cities are highlighted in bold plus symbols. Inset is adapted from (Staub et al., 2000).

Figure 2: N<sub>2</sub>O saturations along the salinity gradients of (a) Rajang, (b) Maludam, (c) Sebuyau, (d) Simunjan, (e) Sematan and (f) Samunsam. The dashed lines indicate the equilibrium (100%) saturation. The open circles depict measurements from August 2016, the filled red circles depict measurements from March 2017 and the filled blue circles depict measurements from September 2017.

Figure 3: Concentrations of N<sub>2</sub>O (a) and CH<sub>4</sub> (b) from rivers/estuaries along the pH gradients. The open red squares depict data from August 2016, the filled red squares depict data from March 2017 and the filled blue triangles depict data from September 2017. The vertical bars in (a) and (b) roughly indicate salinity = 0. Concentrations to the left of the vertical bar are at salinity = 0 and concentrations to the right of the vertical bars are at salinity >0. The horizontal bar in (a) indicates the equilibrium concentration of N<sub>2</sub>O. Please note that in August 2016 only the Rajang River was sampled.

Figure 4: CH<sub>4</sub> saturations along the salinity gradients of (a) Rajang, (b) Maludam, (c) Sebuyau, (d) Simunjan, (e) Sematan and (f) Samunsam. The dashed lines indicate the equilibrium (100%) saturation. The open circles depict measurements from August 2016, the filled red circles depict measurements from March 2017 and the filled blue circles depict measurements from September 2017.

Figure 5: Average N<sub>2</sub>O and CH<sub>4</sub> concentrations for the individual rivers and estuaries vs. the accumulated rainfall amount during one (a, c) and three weeks (b, d) before the dates of sampling. We also included the average N<sub>2</sub>O and CH<sub>4</sub> concentrations for the Lupar, Saribas Rivers and Saribas tributary from (Müller et al., 2016a).
