Abstract. High-latitude oceans have been identified as particularly vulnerable to ocean acidification if anthropogenic CO₂ emissions continue. Marine microbes are an essential part of the marine food web and are a critical link in biogeochemical processes in the ocean, such as the cycling of nutrients and carbon. Despite this, the response of Antarctic marine microbial communities to ocean acidification is poorly understood. We investigated the effect of increasing *f*CO₂ on the growth of heterotrophic nanoflagellates (HNF), nano- and picophytoplankton, and prokaryotes (heterotrophic bacteria and Archaea) in a natural coastal Antarctic marine microbial community from Prydz Bay, East Antarctica. At CO₂ levels $\geq 634 \mu\text{atm}$, HNF abundance was reduced, coinciding with increased abundance of picophytoplankton and prokaryotes. This increase in picophytoplankton and prokaryote abundance was likely due to a reduction in top-down control of grazing HNF. Nanophytoplankton abundance was elevated in the 634 μatm treatment, suggesting that moderate increases in CO₂ may stimulate growth. The taxonomic and morphological differences in CO₂-tolerance we observed are likely to favour dominance of microbial communities by prokaryotes, nano- and picophytoplankton. Such changes in predator-prey interactions with ocean acidification could have a significant effect on the food web and biogeochemistry in the Southern Ocean, intensifying organic matter recycling in surface waters, reducing vertical carbon flux, and reducing the quality, quantity and availability of food for higher trophic levels.

1 Introduction

Oceanic uptake of anthropogenic CO₂ has caused a ~ 0.1 unit decline in oceanic pH since pre-industrial times (Sabine, 2004; Raven et al., 2005), with $\sim 40\%$ of this uptake occurring in the Southern Ocean (Takahashi et al., 2012; Frölicher et al., 2015). In addition, the low overall water temperature and naturally low CaCO₃ saturation state of the Southern Ocean makes it particularly vulnerable to ocean acidification (Orr et al., 2005; McNeil and Matear, 2008). Close to the Antarctic continent, Southern Ocean waters are regions of high productivity, that provide an essential food source for the abundance of life in Antarctica (Arrigo et al., 2008). In recent decades, these waters have seen reductions in pH (Roden et al., 2013) and it is crucial that we

understand the impact of ocean acidification projections on the base of this essential food web. While large phytoplankton, such as diatoms and dinoflagellates, are often believed to be responsible for most of the energy transfer to higher trophic levels in this region, picophytoplankton, prokaryotes, mixotrophic phytoflagellates, microheterotrophs, and heterotrophic nanoflagellates (HNF) also play important roles in grazing and biogeochemical element cycling (Azam et al., 1991; Sherr and Sherr, 5 2002; Smetacek et al., 2004).

Marine microbes are a fundamental part of the marine food web and are a critical link in biogeochemical processes, such as the cycling of nutrients and carbon (Azam and Malfatti, 2007). Globally, it is estimated that ~80-100% of daily primary production is either consumed by grazers or lost via processes such as cell lysis and sinking (Behrenfeld, 2014). Grazing can profoundly affect phytoplankton abundance in marine ecosystems, with microzooplankton consuming on average 60-75% 10 of daily primary production (Landry and Calbet, 2004) and HNF grazing between 20-100% of daily bacterial production (Safi et al., 2007; Pearce et al., 2010). Prokaryotes salvage dissolved organic matter released from phytoplankton primary production, which is returned to the food web upon grazing by HNF (Pearce et al., 2010; Buchan et al., 2014). Prokaryotes also produce essential micronutrients and vitamins required for phytoplankton growth (Azam and Malfatti, 2007; Buchan et al., 2014; Bertrand et al., 2015) and are important in the supply of nutrients to microzooplankton in Antarctic waters over winter, 15 when primary productivity is low (Azam et al., 1991). This transfer of organic matter between primary producers, prokaryotes, and protozoa forms the microbial loop, upon which all life in the ocean relies (Azam et al., 1983; Fenchel, 2008).

In Antarctic waters, heterotrophic flagellates make a significant contribution to the top-down control of phytoplankton and prokaryote productivity. Their growth rates can exceed that of their prey and their grazing can significantly alter the microbial community composition (Bjørnsen and Kuparinen, 1991; Archer et al., 1996; Pearce et al., 2010). Despite their importance in 20 marine ecosystems, their response to ocean acidification remains largely unstudied (Caron and Hutchins, 2013). Of the few studies that have included heterotrophic flagellates, most have focused on the larger microzooplankton community (20-200 μm), reporting no changes in abundance or grazing rates with elevated CO_2 (Suffrian et al., 2008; Aberle et al., 2013; Davidson et al., 2016). However, indirect effects of ocean acidification on microzooplankton have been observed, through changes in the abundance and composition of their prey (Rose et al., 2009b). Difficulties in identification of HNF in natural seawater samples 25 has no doubt contributed to the scarcity of published studies on this group (Rose et al., 2004). A negative effect of increased CO_2 on HNF abundance was observed in a previous Antarctic mesocosm study, which the authors suggest led to a reduction in grazing mortality of picophytoplankton and prokaryotes (Thomson et al., 2016). In the present mesocosm study, Hancock et al. (2018) reported species-specific responses to ocean acidification amongst choanoflagellate species (bacterivorous HNF), exposing a hitherto unrecognised layer of complexity to predicting the effects of ocean acidification on microbial communities.

A global assessment of ocean acidification studies by Schulz et al. (2017) reported a general trend toward increased abundance of picophytoplankton with declining ocean pH. The cyanobacterium *Synechococcus* and picoeukaryotes in the prasino- 30 phyte class were identified as the key beneficiaries of increased CO_2 , possibly through down regulation of energetically costly CO_2 and HCO_3^- transporters (carbon concentrating mechanisms, CCMs) as CO_2 concentration increased in the relatively small diffusive boundary layer of these small cells (Beardall and Giordano, 2002). Unlike temperate oligotrophic ecosystems, 35 cyanobacteria are very rare in Antarctic waters, so the picophytoplankton community south of the Polar Front are composed

largely of eukaryotes (Wright et al., 2009; Lin et al., 2012; Flombaum et al., 2013; Liang et al., 2016). In this region, picophytoplankton can comprise up to 33% of total phytoplankton biomass (Wright et al., 2009; Lin et al., 2012). In coastal Antarctic waters, the abundance of picoeukaryotes was found to increase with elevated CO₂ concentration (Thomson et al., 2016). However, the authors suggested that this was likely due to a reduction in top-down control of the HNF community, rather than direct promotion of their growth. In a companion paper to the present study, Deppeler et al. (2018) reported a down-regulation of extracellular CCM activity in phytoplankton cells <10 µm in size at high CO₂ but it is not known whether this resulted in a concurrent increase in productivity for this size group as primary productivity measurements were performed on the whole community. Overall, primary productivity rates were significantly reduced in high CO₂ treatments (≥1140 µatm), suggesting CO₂ was not beneficial for phytoplankton growth at these levels.

Studies investigating natural marine microbial communities have shown prokaryotes are tolerant to ocean acidification and show little CO₂-induced effect on their abundance or productivity (Grossart et al., 2006; Allgaier et al., 2008; Paulino et al., 2008; Wang et al., 2016). Prokaryote abundance and production is generally linked to increased primary production, with peaks in abundance often occurring immediately after the peak of a phytoplankton bloom (Pearce et al., 2007; Buchan et al., 2014). This is likely due to an increase in availability of dissolved organic matter, released by phytoplankton during growth, viral lysis, or bacterial degradation of dead cells (Azam and Malfatti, 2007). A CO₂-induced increase in the production of organic matter and the formation of transparent exopolymer particles by phytoplankton was reported in a mesocosm study in a Norwegian fjord (Endres et al., 2014). This promoted bacterial abundance and stimulated enzyme production for organic matter degradation, suggesting that ocean acidification may increase the flow of carbon through the microbial loop in surface waters. Shifts in prokaryote community composition have also been reported, although with no significant change in total prokaryote abundance (Roy et al., 2013; Zhang et al., 2013; Bergen et al., 2016). Despite the apparent resilience of prokaryotes to ocean acidification, several authors suggest they may be indirectly affected by changes in substrate availability due to changes in phytoplankton composition and abundance (e.g. Piontek et al., 2010; Celussi et al., 2017). Given the critical role of heterotrophic prokaryotes in remineralisation and carbon flux, it is vital to better understand the direct and indirect effects of ocean acidification on their communities.

A natural community of marine microbes from Prydz Bay, East Antarctica was exposed to *f*CO₂ levels up to 1641 µatm in 650 l minicosms, during the 2014/15 austral summer. In the present study, the abundance of HNF, nanophytoplankton (2-20 µm), picophytoplankton (0.2-2 µm), and heterotrophic prokaryotes were measured by flow cytometry to determine whether CO₂ had an effect on the growth rate and abundance of each of these microbial groups; and whether predator-prey interactions between these communities could be inferred. A range of additional measurements were also taken during this 18 day study, of which many findings have been published elsewhere (Deppeler et al., 2018; Hancock et al., 2018; Petrou et al., 2019). These studies reported that high CO₂ levels caused: reductions in photosynthetic performance, primary productivity, and particulate organic matter production (Deppeler et al., 2018); decreased abundance of microplanktonic diatoms (>20 µm) and *Phaeocystis antarctica* (Hancock et al., 2018); and reduced diatom silicification (Petrou et al., 2019). In contrast, there was no CO₂-induced effect on bacterial productivity (Deppeler et al., 2018) or the abundance of nano-sized diatoms, which were dominated by *Fragilariopsis* sp. (≤20 µm, Hancock et al., 2018). Henceforth, these studies will be referred to as "coincident

studies". A previous minicosm study took place at the same location over the 2008/09 austral summer (henceforth referred to as "complementary studies"; Davidson et al., 2016; Thomson et al., 2016; Westwood et al., 2018). We utilised a similar experimental design to this previous minicosm study, but added an initial CO₂ acclimation period at low light to determine whether this acclimation would alter the response previously reported.

5 2 Methods

2.1 Minicosm

A natural microbial assemblage from Prydz Bay, Antarctica was incubated in six 650 l polythene tanks (minicosms) and exposed to six CO₂ treatments; ambient (343 µatm), 506, 634, 953, 1140, and 1641 µatm. Before commencement of the experiment, all minicosms were acid washed with 10% vol:vol AR HCl, rinsed thoroughly with MilliQ water, and finally
10 rinsed with seawater from the sampling site. Seawater to fill the minicosms was collected from amongst the decomposing fast ice in Prydz Bay at Davis Station, Antarctica (68° 35' S 77° 58' E) on 19th November, 2014. A 7000 l polypropylene reservoir tank was filled by helicopter, using multiple collections in a thoroughly rinsed 720 l Bambi bucket. The seawater was then gravity fed from the reservoir to the minicosms through Teflon-lined hose, fitted with a 200 µm pore size Arkal filter to exclude metazooplankton that would significantly graze the microbial community. Microscopic analysis showed that very
15 few metazooplankton and nauplii passed through the pre-filter and they were seldom observed throughout the experiment (see Hancock et al., 2018). Thus, it is unlikely that their grazing affected the CO₂-induced trends in community composition in our study. All minicosms were filled simultaneously to ensure uniform distribution of microbes.

The six minicosms were housed in a temperature-controlled shipping container, with the water temperature in each minicosm maintained at 0.0 ± 0.5 °C. The temperature in each minicosm was maintained by offsetting the cooling of the shipping
20 container against warming of the tank water with two 300 W Fluval aquarium heaters connected via Carel temperature controllers and a temperature control program. Each minicosm was sealed with an acrylic lid and the water was gently mixed by a shielded high-density polyethylene auger, rotating at 15 rpm.

Minicosms were illuminated by two 150 W HQI-TS (Osram) metal halide lamps on a 19:5 h light:dark cycle. Low intensity light (0.9 ± 0.22 µmol photons m⁻² s⁻¹) was provided for the first 5 d to slow phytoplankton growth while the CO₂ levels
25 were gradually raised to the target concentration for each minicosm (see below). Following this 5 d CO₂ acclimation period, light was progressively increased over 2 d to a final light intensity of 90.5 ± 21.5 µmol photons m⁻² s⁻¹. The microbial assemblages were then incubated for 10 d with samples taken at regular intervals (see below) and no further addition of nutrients or seawater (except for the small volume required for carbonate chemistry modification, see below). For further details on minicosm setup see Deppeler et al. (2018).

2.2 Carbonate chemistry calculation and manipulation

Carbonate chemistry was measured throughout the experiment, allowing the fugacity of CO₂ ($f\text{CO}_2$) to be manipulated to the desired values over the first 5 d of acclimation and then maintained for the remainder of the experiment. Samples were taken daily from each minicosm in 500 ml glass-stoppered bottles (Schott Duran) following the guidelines of Dickson et al. (2007), with sub-samples for dissolved inorganic carbon (DIC, 50 ml glass-stoppered bottles) and pH on the total scale (pH_T, 100 ml glass stoppered bottles) gently pressure filtered (0.2 μm) following Bockmon and Dickson (2014). For each minicosm, DIC was measured in triplicate by infrared absorption on an Apollo SciTech AS-C3 analyser equipped with a Li-cor LI-7000 detector calibrated with five prepared sodium carbonate standards (Merck Suprapur) and daily measurements of a certified reference material batch CRM127 (Dickson, 2010). DIC measurements were converted to μmol kg⁻¹ using calculated density from known sample temperature and salinity.

Measurements of pH_T were performed using the pH indicator dye m-cresol purple (Acros Organics) following Dickson et al. (2007) and measured by a GBC UV-vis 916 spectrophotometer at 25 °C in a 10 cm thermostated cuvette. A syringe pump (Tecan Cavro XLP 6000) was used for sample delivery, dye addition, and mixing to minimise contact with air. An offset for dye impurities and instrument performance (+0.003 pH units) was determined through measurement of pH_T of CRM127 and comparison with the calculated pH_T from known DIC and total alkalinity (TA), including silicate and phosphate. Salinity was measured in situ using a WTW197 conductivity meter and used with measured DIC and pH_T to calculate practical alkalinity (PA) at 25 °C, using the dissociation constants for carbonic acid determined by Mehrbach et al. (1973) and Lueker et al. (2000). Total carbonate chemistry speciation was then calculated for in situ temperature conditions from measured DIC and calculated PA.

During the acclimation period, the $f\text{CO}_2$ in each minicosm was adjusted daily in increments until the target level was reached, after which $f\text{CO}_2$ was kept as constant as possible for the remainder of the experiment. Twice-daily measurements of pH were performed in the morning (before sampling) and the afternoon using a portable, NBS-calibrated probe (Mettler Toledo) to determine the amount of DIC to be added to the minicosm. Adjustment of the $f\text{CO}_2$ in each minicosm was performed by addition of a calculated volume of 0.2 μm filtered CO₂-saturated natural seawater to 1000 ml infusion bags and drip-fed into the minicosms at ~50 ml min⁻¹. One minicosm was maintained close to the $f\text{CO}_2$ of the initial (ambient) sea water (343 μatm) and was used as the control treatment, against which the effects of elevated $f\text{CO}_2$ were measured. The mean $f\text{CO}_2$ levels in the other five minicosms were 506, 634, 953, 1140, and 1641 μatm. For further details of the carbonate chemistry sampling methods, calculations, and manipulation see Deppeler et al. (2018).

2.3 Nutrient analysis

Concentrations of the macronutrients nitrate plus nitrite (NO_x), soluble reactive phosphorus (SRP), and molybdate reactive silica (silicate) were measured in each minicosm during the experiment. Samples were taken on days 1, 3, and 5 during the CO₂ acclimation period and every 2 days for the remainder of the experiment (days 8-18). Samples were obtained following the protocol of Davidson et al. (2016). Briefly, seawater samples were filtered through 0.45 μm Sartorius filters into 50 ml

Falcon tubes and frozen at -80 °C for analysis in Australia. Determination of the concentration of NO_x, SRP, and silicate were performed by Analytical Services Tasmania, using flow injection analysis.

2.4 Flow Cytometry

Flow cytometric analyses were performed daily to determine the abundance of small protists (HNF, pico- and nanophytoplankton, and prokaryotes) in each minicosm during the experiment. Samples were pre-filtered through a 50 µm mesh (Nitex), stored in the dark at 4 °C, and analysed within 6 h of collection, following Thomson et al. (2016). Samples were analysed using a Becton Dickinson FACScan flow cytometer until day 15 after which, the instrument broke down and analysis was performed on a Becton Dickinson FACSCalibur. Both instruments were fitted with a 488 nm laser and MilliQ water was used as sheath fluid for all analyses. PeakFlow Green 2.5 µm beads (Invitrogen) were added to samples as an internal fluorescence and size standard. Final cell numbers were calculated from event counts on bivariate scatter plots divided by the analysed volume.

The analysed volume for each flow cytometer was calibrated by measuring the weight change of 1 ml seawater run for 1, 2, 3, 4, 5, and 10 min at high and low flow settings on each instrument. This weight change was converted to ml by dividing by 1.027, the density of seawater at 4 °C with salinity 34.3 PSU (Table S1). A linear regression was fitted to each data set and the analysed sample volume was determined by entering the sample run time (x) into the equations (Table S2). Average flow rates in ml min⁻¹ for each instrument at both flow settings was determined by dividing each analysed volume by the run time. The standard deviation for all mean flow rates on both instruments was <0.004. Details of instrument flow rates and equations for flow cytometry counts can be found in Table S2.

2.4.1 Pico- and nanophytoplankton abundance

Three pseudoreplicate 1 ml samples for pico- and nanophytoplankton abundance were prepared from each minicosm seawater sample. Each sample was placed in a beaker of ice and run for 3 min at a high flow rate of 36.5 µl min⁻¹ for the FACScan and 67.2 µl min⁻¹ for the FACSCalibur, resulting in an analysed volume of 0.1140 and 0.2036 ml, respectively. Phytoplankton populations were separated into regions based on their chlorophyll autofluorescence in bivariate scatter plots of red (FL3) versus orange fluorescence (FL2; Fig. 1a). The pico- and nanophytoplankton communities were determined from relative cell size in side scatter (SSC) versus FL3 fluorescence bivariate scatter plots (Fig. 1b). Cyanobacteria, which have high orange and low red fluorescence due to possessing phycoerythrin, were not evident in FL3 versus FL2 scatter plots and were deemed absent in this study. Final cell counts in cells l⁻¹ were calculated from event counts in the phytoplankton regions and analysed volume.

2.4.2 Heterotrophic nanoflagellate abundance

Heterotrophic nanoflagellate (HNF) abundance was determined using LysoTracker Green (Invitrogen) staining following the protocol of Thomson et al. (2016). A 1:10 working solution of LysoTracker Green was prepared daily by diluting the commercial stock into 0.22 µm filtered seawater. For each minicosm sample, 10 ml of seawater was stained with 7.5 µl of working

solution to a final stain concentration of 75 nM. Stained samples were then incubated in the dark on ice for 10 min. Triplicate 1 ml sub-samples were taken from the stained sample and run for 10 min at a high flow rate of 36.5 $\mu\text{l min}^{-1}$ for the FACScan and 67.2 $\mu\text{l min}^{-1}$ for the FACSCalibur, resulting in an analysed volume of 0.4043 and 0.7006 ml, respectively.

LysoTracker Green stained HNF abundances were determined in green fluorescence (FL1) versus forward scatter (FSC) plots after removal of phytoplankton and detritus particles following Rose et al. (2004) and Thomson et al. (2016) and shown in Fig. 2. Phytoplankton were identified by high chlorophyll autofluorescence in bivariate scatter plots of FL3 versus FSC fluorescence (Fig. 2a) and detritus was identified by high SSC in FL1 fluorescence versus SSC plots (Fig. 2b). HNF abundance was then determined in a bivariate plot of FL1 fluorescence versus FSC with phytoplankton and detritus particles removed. Mixotrophic species would have been excluded from HNF counts, due to their chlorophyll fluorescence in FL3 versus FSC plots. Remaining particles larger than the 2.5 μm PeakFlow Green beads were counted as HNF (Fig. 2d). Final cell counts in cells l^{-1} were calculated from event counts and analysed volume.

2.4.3 Prokaryote abundance

Prokaryote abundance measurements relate to heterotrophic prokaryotes only, as autotrophic prokaryotes were not present in the minicosms (see above). Samples for prokaryote abundance were stained for 20 min with 1:10,000 dilution SYBR Green I (Invitrogen) following Marie et al. (2005). Three pseudoreplicate 1 ml samples were prepared from each minicosm seawater sample and were run for 3 min at a low flow rate of 7.5 $\mu\text{l min}^{-1}$ for the FACScan and 15.6 $\mu\text{l min}^{-1}$ for the FACSCalibur, resulting in an analysed volume of 0.0254 and 0.0478 ml, respectively. Prokaryote abundance was determined from SSC versus FL1 fluorescence bivariate scatter plots (Fig. 3). Final cell counts in cells l^{-1} were calculated from event counts and analysed volume. High background noise was observed on the flow cytometer on day 1, likely due to suspended detritus from when the minicosm tanks were filled, which obscured cell counts at this time. Background interference had cleared on day 2, allowing analysis to start from this day.

2.5 Statistical analysis

Microbial community growth in the minicosms was measured in six unreplicated CO_2 treatments and thus, triplicate sub-samples from individual minicosms represent within-treatment pseudoreplicates. Therefore, means and standard error of these pseudoreplicate samples only provide the within-treatment sampling variability for each procedure. For the purpose of analysis, we treated pseudoreplicates as independent to provide an informal assessment of the difference among treatments.

A generalized additive model (GAM) was fitted to each CO_2 treatment over time to visually assess temporal changes in the abundance of each microbial group using the *mgcv* and *ggplot2* packages in R (Wood, 2011; R Core Team, 2016; Wickham, 2016). Taking into account the pseudo-replicated sampling method, further statistical analysis of these curves was not performed. For growth rate analysis, a linear regression model was fitted on natural log-transformed data for each CO_2 treatment over the incubation period during which each microbial group sustained steady-state logarithmic growth. Growth rates for each treatment were determined from the slope estimate of the linear model. An omnibus test of differences between the linear models for each CO_2 treatment was assessed by ANOVA to determine significant differences between the growth

trends for each microbial group. The lack of replication in our study and limited number of time points at which each minicosm was sampled means that the trends within treatments are indicative and the statistical differences among treatments should be interpreted conservatively. The significance level for all tests was set at <0.05 .

3 Results

5 3.1 Carbonate chemistry

The carbonate chemistry of the initial seawater was measured as a pH_T and DIC of 8.08 and $2187 \mu\text{mol kg}^{-1}$, respectively, resulting in a calculated $f\text{CO}_2$ of $356 \mu\text{atm}$ and a PA of $2317 \mu\text{mol kg}^{-1}$ (Fig. 4, S1; Table S1). Measurements of carbonate chemistry during the acclimation period showed a stepwise increase in $f\text{CO}_2$, after which the CO_2 level remained largely constant, with treatments ranging from 343 to $1641 \mu\text{atm}$ and a pH_T range from 8.10 to 7.45 (Fig. 4; Table 1). Some decline
10 in $f\text{CO}_2$ was observed in the high CO_2 treatments towards to the end of the experiment indicating that the addition of CO_2 -saturated seawater was insufficient to fully compensate for its out-gassing into the headspace and drawdown by phytoplankton photosynthesis.

3.2 Nutrients

There was little variance in nutrient concentrations among all treatments at the start of the experiment (Table S1). Concentra-
15 tions of NO_x fell from $26.2 \pm 0.74 \mu\text{M}$ on day 8 to below detection limits on day 18 (Fig. 5a), with the $1641 \mu\text{atm}$ treatment being drawn down the slowest. SRP concentrations were drawn down in a similar manner as NO_x , falling from $1.74 \pm 0.02 \mu\text{M}$ to $0.13 \pm 0.03 \mu\text{M}$ on day 18 in all treatments (Fig. 5b). Silicate was replete throughout the experiment in all treatments, with initial concentrations of $60.0 \pm 0.91 \mu\text{M}$ falling to $43.6 \pm 2.45 \mu\text{M}$ (Fig. 5c). Silicate draw-down was highest in the $634 \mu\text{atm}$ and lowest in the $1641 \mu\text{atm}$ treatment.

20 3.3 Picophytoplankton abundance

Picophytoplankton abundance did not change during the CO_2 acclimation period, remaining at $\sim 2.04 \pm 0.02 \times 10^6 \text{ cells l}^{-1}$. Cell numbers increased in all treatments from day 8, with treatments $\leq 506 \mu\text{atm}$ peaking on day 12 and all higher CO_2 treatments continuing to grow until day 13 (Fig. 6a). Steady-state logarithmic growth rates were calculated between days 8 to 12 (Fig. S2) and are presented in Table 2. The omnibus test of trends in $f\text{CO}_2$ treatment over time for picophytoplankton steady-
25 state growth indicated there was a significant difference between treatments ($F_{5,78} = 2.85$, $p < 0.01$; Table S3). Examining the significance of the individual linear model terms indicated that only the $953 \mu\text{atm}$ growth rate was significantly different to the control ($p < 0.01$; Table 3), with a higher growth rate of 0.32 (Table 2). Despite the similarity in growth rates among treatments, there was a difference between peak abundances. The highest were observed in the 953 and $1641 \mu\text{atm}$ treatments, which reached $8.11 \pm 0.05 \times 10^6 \text{ cells l}^{-1}$ (Fig. 6a). The 634 and $1140 \mu\text{atm}$ treatments peaked slightly lower at 7.06 ± 0.03
30 $\times 10^6 \text{ cells l}^{-1}$ and following this, the control ($343 \mu\text{atm}$) and $506 \mu\text{atm}$ treatments peaked at $5.28 \pm 0.17 \times 10^6 \text{ cells l}^{-1}$ and

$4.47 \pm 0.13 \times 10^6$ cells l^{-1} , respectively. After reaching their peak, cell numbers rapidly declined in all treatments until day 18, falling to $0.50 \pm 0.01 \times 10^6$ cells l^{-1} . The 506 μatm treatment was excluded from analysis on day 18 due to high background noise on the flow cytometer, which caused artificially elevated counts.

3.4 Nanophytoplankton abundance

5 Nanophytoplankton abundance declined during the CO_2 acclimation period in all treatments, falling from a mean initial abundance of $1.19 \pm 0.03 \times 10^6$ cells l^{-1} to $0.96 \pm 0.02 \times 10^6$ cells l^{-1} on day 7. Following acclimation, nanophytoplankton abundance increased in all treatments until day 15, after which growth plateaued (Fig. 6b). Steady-state logarithmic growth rates were calculated between days 9 to 15 (Fig. S2) and are presented in Table 2. There was a significant difference between growth trends among CO_2 treatments ($F_{5,113} = 5.92$, $p < 0.01$; Table S4), with significance due to enhanced growth rates in
10 treatments $\geq 634 \mu\text{atm}$ (Table 3). In the 634 μatm treatment, cell numbers were substantially higher than all other treatments from day 12 through to day 18, reaching a final abundance of $8.83 \pm 0.24 \times 10^6$ cells l^{-1} (Fig. 6b). Enhanced growth rates in treatments $\geq 953 \mu\text{atm}$ also led to cell numbers exceeding the control by day 15, averaging $5.61 \pm 0.12 \times 10^6$ cells l^{-1} . Between days 15 and 18, abundance in treatments $\geq 953 \mu\text{atm}$ dipped and then recovered to a final abundance of $6.64 \pm 0.06 \times 10^6$ cells l^{-1} . It is uncertain whether the large dip in abundance on day 16 was due to a reduction in cell numbers in the tanks
15 or associated with the change in flow cytometer on this day. Growth rates in the control and 506 μatm treatments were the slowest (0.22-0.23, Table 2), displaying less of a plateau in growth between days 15-18 and reaching a final abundance of $5.96 \pm 0.15 \times 10^6$ cells l^{-1} , only slightly less than the $\geq 953 \mu\text{atm}$ treatments.

3.5 Heterotrophic nanoflagellate abundance

HNF abundance was initially low ($0.94 \pm 0.04 \times 10^5$ cells l^{-1}) and remained steady throughout the CO_2 acclimation period
20 (Fig. 6c), with a small dip in cell numbers observed in the treatments $\geq 953 \mu\text{atm}$ on day 7 (Fig. S2). From day 8, HNF abundance increased in all treatments until day 15, with cell numbers in the control and 506 μatm treatments consistently higher than all other treatments ($\geq 634 \mu\text{atm}$; Fig. 6c). From day 15 to 18, the control, 634, 953, and 1641 μatm treatments continued to rise, while abundance in the 506 and 1140 μatm treatments stabilised. Steady-state logarithmic growth rates were calculated between days 8 to 15 (Fig. S2) and are presented in Table 2. The omnibus test of trends in $f\text{CO}_2$ treatment over
25 time showed there was a significant difference between the treatments ($F_{5,131} = 5.40$, $p < 0.01$; Table S5), due to significant differences in growth trends of the 506 and 1641 μatm treatments (Table 3). Examining the growth rates of each of these treatments revealed that the 506 μatm treatment was slower than the control (0.32, $p = 0.02$), while the 1641 μatm treatment was faster (0.40, $p = 0.02$; Table 2, 3). The slower growth rate of the 506 μatm treatment appears to be due to a higher initial abundance on day 8 ($2.42 \pm 0.35 \times 10^5$ cells l^{-1}) than the control ($1.86 \pm 0.05 \times 10^5$ cells l^{-1}). Despite a higher growth rate
30 in the 1641 μatm treatment, cell numbers in the highest CO_2 treatments, 1140 and 1641 μatm , remained consistently lower than the control throughout the entire growth period (days 8 and 18), reaching abundances on day 18 of only $2.12 \pm 0.02 \times 10^6$ and $2.62 \pm 0.11 \times 10^6$ cells l^{-1} , respectively (Fig. 6c). The 506 μatm treatment plateaued after day 16, with a final abundance similar to the 1641 μatm treatment, at 2.66 ± 0.02 cells l^{-1} . In contrast, the 634 and 953 μatm treatments continued to rise,

exceeding the control after day 16 and reaching $3.42 \pm 0.08 \times 10^6$ cells l^{-1} on day 18, with the control treatment slightly lower at $3.13 \pm 0.04 \times 10^6$ cells l^{-1} .

3.6 Prokaryote abundance

Prokaryote abundance was similar in all fCO_2 treatments at the start of the acclimation period ($2.10 \pm 0.04 \times 10^8$ cells l^{-1}) and increased after day 4 in treatments $\geq 634 \mu atm$, while abundance in treatments $\leq 506 \mu atm$ remained unchanged (Fig. 6d). Due to the large fluctuation in cell numbers between days 4 to 7 in treatments $\geq 634 \mu atm$, steady-state logarithmic growth was not observed (Fig. S2). However, prokaryote growth rates were calculated from linear regression between days 4 to 8 to assess differences in prokaryote growth among treatments during the CO_2 acclimation period (Table 2). There was a significant difference between growth trends among CO_2 treatments ($F_{5,77} = 3.59$, $p < 0.01$; Table S6). Treatments $\geq 953 \mu atm$ all displayed significant differences in growth trends and were faster than the control (Table 2, 3). Between days 7 and 11, prokaryote cell numbers remained steady in all treatments, with abundance higher than the control in treatments $\geq 634 \mu atm$ (Fig. 6d). During this time, abundance was highest in treatments $\geq 953 \mu atm$, with an average abundance of $3.17 \pm 0.03 \times 10^8$ cells l^{-1} , followed by the 634 μatm treatment, at $2.53 \pm 0.05 \times 10^8$ cells l^{-1} . The control and 506 μatm had similar abundances, averaging $2.12 \pm 0.03 \times 10^8$ cells l^{-1} . From day 12, prokaryote cell numbers declined rapidly in all treatments, falling to $0.58 \pm 0.05 \times 10^7$ cells l^{-1} by day 18.

3.7 Microbial community interaction

Although grazing experiments were not performed, interactions between HNF and their phytoplankton and prokaryote prey were assessed visually. There appeared to be no correlation between HNF and nanophytoplankton abundance, as nanophytoplankton only displayed higher cell numbers than the control in the 634 μatm treatment, which showed no relationship to the CO_2 -induced reduction in HNF abundance at levels $\geq 634 \mu atm$. In contrast, the co-occurrence of slowed HNF growth with increased picophytoplankton abundance between days 8 and 13 in CO_2 treatments $\geq 634 \mu atm$ suggested that the picophytoplankton communities may have been released from grazing pressure. This hypothesis of a reduction in grazing pressure by HNF at increased CO_2 was further supported by the observation that above a threshold HNF abundance there was a rapid decline in both the picophytoplankton and prokaryote abundance, irrespective of treatment and the duration of incubation. For picophytoplankton, cell numbers rapidly declined when HNF abundance reached $0.87 \pm 0.02 \times 10^6$ cells l^{-1} (Fig. 7a) and for prokaryotes it occurred once HNF abundance had reached $0.32 \pm 0.02 \times 10^6$ cells l^{-1} (Fig. 7b). Interestingly, the rate of decline in picophytoplankton and prokaryote abundances in the fCO_2 treatments $\geq 634 \mu atm$ was greater than the control and 506 μatm treatments. Despite this, only HNF in the 634 and 953 μatm treatments reached abundances as high as the control at the conclusion of the experiment, suggesting that high CO_2 ($\geq 1140 \mu atm$) continued to have a negative effect on HNF growth (Fig. 6c).

4 Discussion

Mesocosm experiments are useful in assessing the effects of environmental perturbations on multiple trophic levels of a marine ecosystem (Riebesell et al., 2008). Our results suggest that there are both direct effects of elevated CO₂ on nanophytoplankton and indirect effects of trophic interactions occurring between HNF and their prokaryotic and picoplanktonic prey that can significantly alter the composition and abundance of organisms at the base of the food web.

Exposing cells to a gradual change in CO₂ during an acclimation period allows cells an opportunity to adjust their physiology to environmental change and may alleviate some of the stress experienced when changes are imposed rapidly (Dason and Colman, 2004). However, little is known about the time scales required for the changes in physiology necessary to optimise cellular tolerance of CO₂-induced stress. In addition, acclimating and adapting microbial communities over the years to decades anticipated for anthropogenic ocean acidification, whilst retaining similar taxonomic composition to natural communities, is unachievable in current experimental designs. Acknowledging these limitations, a gradual increase in *f*CO₂ over 5 days was included in this study to assess whether acclimation would moderate the previously observed response of Antarctic microbial communities that were exposed to rapid changes in CO₂ (Davidson et al., 2016; Thomson et al., 2016; Westwood et al., 2018).

The results of the current study were similar to those in the complementary studies that lacked acclimation (Davidson et al., 2016; Thomson et al., 2016; Westwood et al., 2018). Thus, it appears that an acclimation period had no discernible effect on the response of the community to enhanced CO₂. Hancock et al. (2018), in their coincident study on microbial community composition, did observe a significant change in the community composition between days 1 and 3 but no difference was found between individual treatments. Therefore, this initial change was attributed to acclimation of the community to the minicosm tanks and not a response to increasing CO₂. This lack of community-level acclimation, through selection of CO₂-tolerant species in high-CO₂ treatments, may be due to an ineffective acclimation or alternatively, indicative of a community already adapted to the highly variable CO₂ at the study site. Here, CO₂ levels have been measured to vary by ~450 µatm throughout the year, with highest CO₂ levels experienced at the end of winter and low CO₂ levels during the austral summer when there is strong CO₂ draw-down due to high primary productivity (Gibson and Trull, 1999; Roden et al., 2013). Marine organisms exposed to highly variable environments such as this have been shown to be more tolerant of changes in CO₂ (Boyd et al., 2016).

It is also possible that the acclimation under low light conditions did not allow the cells to adjust their physiology effectively and that much of the acclimation occurred after the light levels were increased. Indeed, in our coincident study measuring phytoplankton productivity and photophysiology, phytoplankton cell health (measured by photochemical quantum yield; F_v/F_m) was high during the low light acclimation period and a CO₂-induced decline in health was observed when light intensity was increased between days 5 and 8 (Deppeler et al., 2018). Synergistic effects of CO₂ and light stress have been observed in a number of phytoplankton studies, with declines in growth, productivity, and F_v/F_m reported under combined high CO₂ and light intensity conditions (e.g. Gao et al., 2012a, b; Li et al., 2015; Trimborn et al., 2017). Deppeler et al. (2018) did note that the phytoplankton community appeared to acclimate to this light and CO₂ stress over time, with F_v/F_m increasing in all treatments after day 12. HNF and prokaryotes are not reliant on light for growth but displayed similar growth patterns to Thomson

et al. (2016)'s complementary study with no acclimation. With increasing CO₂ levels, prokaryote abundance increased and HNF growth was limited. Consequently, it is likely that cellular physiology did not change in any microbial group during the acclimation period. Despite this, the similarity of our results with those previously reported does allow us to gain a more comprehensive understanding of the seasonal and temporal effects of ocean acidification on the marine microbial community in this region.

Top-down grazing pressure on the microbial community is an important dynamic in the growth and composition of the microbial community in the Southern Ocean (Smetacek et al., 2004). Our experimental design included pre-screening of the natural seawater community through a 200 µm mesh, which may have modified trophic dynamics by removing macrozooplankton grazers and thus, reduce top-down grazing pressure on microheterotrophs. We chose to exclude macrozooplankton in order to remove an environmental factor that could differentially alter the mortality of microbes among CO₂ treatments. Small differences in the abundance of large grazers among the tanks could have greatly affected the growth and composition of the microbial community, to the point of removing all protists from the tanks, masking any CO₂-induced effects. We recognise that removing higher trophic levels is a limitation of minicosm experiments to simulate the full dynamics of in situ communities. However, pre-screening by <200 µm allowed for greater control of our experiment by allowing us to vary only one environmental factor so we could focus of the effect of CO₂ on microbial community dynamics.

4.1 Heterotrophic nanoflagellates

Our study indicates that HNF abundance is negatively affected by elevated CO₂. HNF abundance was reduced when CO₂ levels were $\geq 634 \mu\text{atm}$ and remained lower than the ambient treatment at levels $\geq 1140 \mu\text{atm}$. These observations are consistent with complementary studies in Prydz Bay, Antarctica, that reported a reduction in HNF abundance when CO₂ was $\geq 750 \mu\text{atm}$ in both high and low nutrient conditions (Davidson et al., 2016; Thomson et al., 2016). These results contrast with those reported by Moustaka-Gouni et al. (2016) from a Baltic Sea mesocosm study, who found high CO₂ concentration (1040 ppm) had little effect on the HNF community. Interestingly, they also demonstrated that HNF communities form complex food webs and trophic interactions between species can change with environmental conditions and prey availability. We were unable to determine whether species-specific sensitivities led to the reduction in HNF abundance with high CO₂. However, Hancock et al. (2018) reported a CO₂-related change in the relative abundances of choanoflagellate species at CO₂ levels $\geq 634 \mu\text{atm}$ (see 4.4 below). Therefore, it is possible that other CO₂-induced changes to the HNF community composition may have occurred. The consistency of reduced abundance of HNF with increased CO₂ over the austral summer and between years indicate that ocean acidification alone may significantly alter the HNF growth and community structure by 2050 (following RCP8.5 projections, IPCC, 2013). However, it must be acknowledged that a number of environmental factors will influence microbial communities with the onset of climate change (see Deppeler and Davidson, 2017) and the sequence and severity of these additional stressors will be important in determining the nature and magnitude of the effect of ocean acidification on this community.

Increased top-down control by heterotrophic dinoflagellates and ciliates on the HNF community may have led to the lower abundance of HNF in the high CO₂ treatments. Hancock et al. (2018) saw no effect of CO₂ on the composition or abundance of the microheterotrophic community in their coincident study. Although, they did acknowledge that microheterotroph abundance

was low in all treatments (~1% of all cells) and therefore, any CO₂ response may not have been apparent. Low abundances of heterotrophic dinoflagellates and ciliates in all treatments would suggest that grazing pressure on HNF was low and thus, any reduction in HNF abundance at higher CO₂ levels were not likely caused by increased grazing from larger taxa. Few other studies have investigated the effect of ocean acidification on heterotrophic protists and as yet there are no reports of direct effects of elevated CO₂ on microheterotrophic grazing rates, abundance, or taxonomic composition (Suffrian et al., 2008; Aberle et al., 2013). One study by Rose et al. (2009a) did report an increase in microzooplankton abundance when a natural North Atlantic microbial community was exposed to high CO₂ (690 ppm). However, this increased abundance was believed to be an indirect effect of CO₂-induced promotion of phytoplankton abundance and a change in the phytoplankton community composition, as opposed to a direct effect of ocean acidification on microzooplankton physiology. A shift in the dominant nanophytoplankton taxa was reported by Hancock et al. (2018), with a threshold in this change appearing between 634-953 µatm (see 4.2 below). The prymnesiophyte *Phaeocystis antarctica* was dominant in treatments ≤634 µatm, whilst in higher CO₂ treatments, *P. antarctica* was considerably reduced, resulting in a shift in dominance to the diatom *Fragilariopsis* sp. (<20 µm size). Low microzooplankton grazing rates have been reported in Antarctic waters dominated by colonial *P. antarctica* (Safi et al., 2007; Caron et al., 2000; Pearce et al., 2010), suggesting that a shift in dominance to more palatable small diatom species with increasing CO₂ may lead to a concurrent increase in microzooplankton and subsequent increase in HNF grazing.

It is difficult to evaluate the potential reasons for reduced abundance of the HNF community in high CO₂ treatments as the mechanism(s) responsible for CO₂ sensitivity in HNFs are unstudied (Caron and Hutchins, 2013). Heterotrophs do not require CO₂ for growth, thus increased [H⁺] from lowered pH is likely the dominant driver of the effects observed (Sommer et al., 2015). The CO₂ sensitivity of heterotrophic flagellates may be governed by the effectiveness of the mechanism(s) they possess to regulate intracellular pH (Pörtner, 2008). However, little is known about the pH sensitivities of heterotrophic flagellates. Among the few studies on flagellates, a decline in pH influenced the swimming behaviour of a harmful algal bloom causing raphidophyte (Kim et al., 2013) and an inability to control intracellular pH disrupted the growth of the autotrophic dinoflagellates *Amphidinium carterae* and *Heterocapsa oceanica* (Dason and Colman, 2004). Disruption of flagella motility has also been observed in marine invertebrate sperm, due to inhibition of the internal pH gradients required to activate signalling pathways (Nakajima, 2005; Morita et al., 2010; Nakamura and Morita, 2012). Whilst these examples do not provide evidence for direct inhibition of HNF growth, they do highlight the diverse sensitivities of flagellates to changes in pH that require further investigation. Size may also play a part in CO₂ sensitivity, with size-related declines in the external pH boundary layer meaning small cells are likely to be more affected by lower ocean pH (Flynn et al., 2012). As heterotrophs respire CO₂ and do not photosynthesise, it is likely that pH would be even lower at the cell surface than for autotrophs. This may explain why HNFs showed reduced growth rates in our study while the larger microheterotrophs may have been unaffected (see Hancock et al., 2018).

4.2 Nano- and picophytoplankton

An increase in picophytoplankton abundance was observed in our study when CO₂ levels were ≥634 µatm (Fig. 6a), agreeing with other ocean acidification studies globally that have reported an increase in abundance of picophytoplankton at elevated

CO₂ levels (e.g. Brussaard et al., 2013; Schulz et al., 2013; Biswas et al., 2015; Crawford et al., 2017). However, studies on phytoplankton communities in other Antarctic regions have reported shifts towards larger diatom species (Ross Sea; Feng et al., 2010; Tortell et al., 2008) or no change (Antarctic Peninsula; Young et al., 2015). This variability in response among sites in Antarctic waters may be due to factors such as differences in microbial community seasonal succession or study methods that excluded picophytoplankton analysis. The increase in picophytoplankton abundance at CO₂ levels $\geq 634 \mu\text{atm}$ reported here is similar to the findings of Thomson et al. (2016) in their complementary study at the same site, indicating that this response is consistent across seasons and between years. It has been suggested that increased abundance of picophytoplankton may be due to increases in productivity derived from more readily-available CO₂ at the cell surface, allowing more passive diffusion of CO₂ into the cell, and thus, reduced requirements for energy-intensive carbon concentrating mechanisms (CCMs; Riebesell et al., 1993; Paulino et al., 2008; Schulz et al., 2013; Calbet et al., 2014). Down-regulation of CCMs in the high CO₂ treatment (1641 μatm) in small cells ($<10 \mu\text{m}$) was reported in our coincident study (Deppeler et al., 2018). However, it is uncertain whether this resulted in increased primary productivity for this size group, as primary productivity measurements were performed on the whole community. Instead, primary productivity was significantly reduced when CO₂ levels were $\geq 1140 \mu\text{atm}$, suggesting CCM down-regulation did not have a significant positive effect on growth.

The larger cell surface area to volume ratio in small cells, allowing increased nutrient utilisation in nutrient-limited environments, has also been invoked to explain the increased abundance of picophytoplankton with elevated CO₂ (Schulz et al., 2013). Size-related differences in growth rates may allow picophytoplankton to establish a bloom faster than larger phytoplankton species (e.g. Newbold et al., 2012). However, this is not seen in nutrient-replete East Antarctic waters, where early summer blooms are dominated by large diatoms, such as *Thalassiosira* sp. and *Fragilariopsis* sp. ($>20 \mu\text{m}$), and the prymnesiophyte *P. antarctica* in its colonial life-stage (Davidson et al., 2010). It was also not observed in this study, where only the 953 μatm treatment displayed a significantly enhanced picophytoplankton growth rate (Table 3). Increased rates of nutrient draw-down were observed in the 634-953 μatm CO₂ treatments (Fig. 5), suggesting that moderate increases in CO₂ may stimulate phytoplankton growth, but further increases in CO₂ ($\geq 1140 \mu\text{atm}$) led to significant reductions in primary productivity (Deppeler et al., 2018).

Nanophytoplankton abundance was highest in the 643 μatm treatment, with significantly increased growth rates in treatments $\geq 634 \mu\text{atm}$ (Fig. 6b; Table 3). This was likely due to favourable conditions, including the inhibition of growth of larger phytoplankton species, that allowed nano-sized phytoplankton to thrive at higher CO₂ levels (Hancock et al., 2018). The initial decline in nanophytoplankton abundance in all treatments between days 1 and 7 may have been due to acclimation of the community to the minicosms or grazing by microzooplankton. Increasing light intensity had a temporary inhibitory effect on growth at CO₂ levels $\geq 1140 \mu\text{atm}$ between days 8 and 9 (Fig. S2), suggesting that the significantly enhanced growth rates in these treatments between days 9 and 15 may have been caused by an increase in relative abundance of more tolerant species. Interestingly, whilst no negative effect of CO₂ was observed on the overall nanophytoplankton abundance, there were very strong species-specific responses to increasing CO₂, resulting in a significant change in community structure. In their coincident study, Hancock et al. (2018) identified the most abundant nanophytoplankton species present in the minicosms as *Fragilariopsis* sp. ($<20 \mu\text{m}$) and *P. antarctica* in its colonial form. These species displayed a CO₂-related threshold in dom-

inance around 634 μatm , with a shift from *P. antarctica* to *Fragilariopsis* sp. in the high CO_2 treatments. Thus, it is likely that the relative fitness of both of these species was increased with a moderate increase in CO_2 level, explaining the higher abundance observed at 634 μatm CO_2 . Increased abundance of *Fragilariopsis* sp. with elevated CO_2 has also been observed in other ocean acidification studies on natural Antarctic microbial communities (Hoppe et al., 2013; Davidson et al., 2016).

5 Therefore, increasing CO_2 may not result in a change in total nanophytoplankton abundance but may instead result in a shift in the summer nanophytoplankton community composition, with increased abundance of small diatoms over *P. antarctica* colonies.

There is an increased understanding of the prevalence of mixotrophy in the marine microbial community (Mitra et al., 2014; Stoecker et al., 2017; Gast et al., 2018). Therefore, it is possible that mixotrophic nanoflagellates were included in our
10 nanophytoplankton counts, due to the presence of chlorophyll in their cells. Mixotrophs are able to utilise both autotrophic and heterotrophic methods of energy production and consumption, although the range methods employed can be diverse (Stoecker et al., 2017). It is currently unknown how mixotrophic phytoflagellates will respond to ocean acidification. Caron and Hutchins (2013) speculated that autotrophic energy production may be more efficient with increasing levels of CO_2 , owing to increased availability of dissolved inorganic carbon species, an essential substrate for photosynthesis, with lower pH. However, the
15 simultaneous increase in $[\text{H}^+]$ may have negative effects on both heterotrophic and autotrophic cellular mechanisms, causing multiple stresses to mixotrophic physiology. As molecular methods are allowing for better identification of mixotrophic species, further research into how these species respond to increasing CO_2 may now be possible (Gast et al., 2018).

4.3 Prokaryotes

The prokaryote community responded favourably to increasing CO_2 , displaying increased abundance when CO_2 levels were
20 $\geq 634 \mu\text{atm}$ (Fig. 6d). This increase in prokaryote abundance with elevated CO_2 was also observed in complementary studies at Prydz Bay, who reported consistent increases in prokaryote abundance and production with CO_2 levels $\geq 780 \mu\text{atm}$, in high and low nutrient conditions spanning early to late-summer (Thomson et al., 2016; Westwood et al., 2018). An increase in prokaryote abundance with increasing CO_2 has also been reported in Arctic mesocosms (Endres et al., 2014; Engel et al., 2014). Although in other studies, CO_2 had no influence on the prokaryote community (Grossart et al., 2006; Allgaier et al.,
25 2008; Paulino et al., 2008; Newbold et al., 2012). Thus, it is anticipated that heterotrophic prokaryotes will tolerate increasing CO_2 levels and in some instances, may thrive (reviewed in Hutchins and Fu, 2017). Like HNF, prokaryotes do not require CO_2 for growth, although it appears they may be more resistant to large variations in pH. Despite this, there is evidence that CO_2 may induce changes in community composition, selecting for more tolerant or rare species (Krause et al., 2012; Roy et al., 2013; Zhang et al., 2013; Bergen et al., 2016). This may be related to differential responses of phylogenetic groups to
30 maintaining pH homeostasis in either acid and alkaline conditions (Padan et al., 2005; Bunse et al., 2016). The mechanisms for transporting H^+ out of the cell are energetically demanding and may reduce the energy available for growth. Whether these energy demands are increased or decreased with ocean acidification depends upon the different strategies for pH homeostasis employed by individual prokaryote species (Teira et al., 2012). In addition to this, significant increases in growth efficiency

with elevated CO₂ may not result in an increase in productivity or abundance (Teira et al., 2012). Instead, these changes may affect dissolved organic carbon consumption, with potential impacts on organic matter cycles (Endres et al., 2014).

4.4 Community interactions

The coincidence of the increase in picophytoplankton and prokaryote abundances with reduced HNF suggests that these communities were being released from grazing pressure at CO₂ levels $\geq 634 \mu\text{atm}$. Grazing rates in East Antarctica are on average, 62% of primary production per day, up to a maximum of 220% (Pearce et al., 2010). In addition, >100% of prokaryote production can be removed by micro- and nanoheterotrophs when chlorophyll *a* concentration and prokaryote abundance is high (Pearce et al., 2010). The rapid decline in abundance we observed in picophytoplankton and prokaryotes after 12 days incubation is entirely consistent with the rapid rates of grazing observed in other Antarctic marine microbial communities in this region. In relation to *f*CO₂, it is reasonable to hypothesise that the lower abundances of these prey in the control and 506 μatm treatments may have been due to stronger top-down control on the community as opposed to a reduction in growth rate. Grazing control of the picophytoplankton community has been proposed in other mesocosm studies to explain both positive (Paulino et al., 2008; Rose et al., 2009a) and negative (Meakin and Wyman, 2011; Newbold et al., 2012) changes in picophytoplankton abundance, although they were not confirmed by HNF counts. In our minicosm study, the rapid decline in prokaryote abundance coincided with a dramatic increase in choanoflagellate abundance, bacterivorous eukaryotes, between days 14 and 16 (Hancock et al., 2018). Furthermore, picophytoplankton and prokaryotes in all CO₂ treatments both declined after HNF abundance appeared to reach a critical threshold (Fig. 7), suggesting that at this point their growth was unable to exceed the top-down control of grazing. Thomson et al. (2016) and Westwood et al. (2018), in their complementary studies, also noted that higher numbers of prokaryotes coincided with reduced HNF abundance across differing microbial community compositions and nutrient availabilities in Prydz Bay, suggesting that this response is likely to be consistent on both seasonal and temporal scales.

Species-specific differences in the sensitivity of HNF to CO₂ may lead to significant changes in the composition of the picophytoplankton and prokaryote communities. HNF food webs are complex and successional changes in taxa occur during phytoplankton blooms (Moustaka-Gouni et al., 2016). In their coincident study, Hancock et al. (2018) observed species-specific differences in the CO₂ tolerances of choanoflagellate species, where *Bicosta antennigera* displayed significant CO₂ sensitivity at levels $\geq 634 \mu\text{atm}$ while other choanoflagellate species (principally *Diaphanoeca multiannulata*) were unaffected. This change in HNF community composition with increased CO₂ did not affect the total prokaryote abundance but may have implications for the prokaryotic community composition through selective grazing. Changes in prokaryote community composition have been observed in other mesocosm studies (Roy et al., 2013; Zhang et al., 2013; Bergen et al., 2016). There is also evidence that different prokaryote phylogenetic groups have preferences for organic substrates produced by different phytoplankton taxa (Sarmiento and Gasol, 2012), leading to the possibility that future changes in prokaryote community composition could impact organic matter recycling.

As viral abundance was not determined in our study, we cannot exclude viral lysis as an explanation for the rapid decline in picophytoplankton and prokaryote abundance. Viral lysis can account to up to 25% of daily production, although grazing by

micro- and nanoheterotrophs can be twice as high (Evans et al., 2003; Pearce et al., 2010). In an Arctic mesocosm study, the decline of a picophytoplankton bloom coincided with a large increase in viral abundance (Brussaard et al., 2013). However, later in the study, picophytoplankton were heavily also grazed by microzooplankton. Bacteriophages are the dominant viruses in the Prydz Bay area (Pearce et al., 2007; Thomson et al., 2010; Liang et al., 2016), with viral abundance displaying no correlation to picophytoplankton (Liang et al., 2016). This suggests that viral lysis was unlikely to be the main cause of the decline in picophytoplankton numbers but may have affected the prokaryotes.

5 Conclusions

The results of this study show how ocean acidification can exert both direct and indirect influences on the interactions among trophic levels within the microbial loop. Our study reinforces findings in near shore waters off East Antarctica that HNF abundance is reduced when CO_2 is $\geq 634 \mu\text{atm}$, irrespective of temporal changes in the physical and biological environment among seasons and years (Davidson et al., 2016; Thomson et al., 2016; Westwood et al., 2018). This likely resulted in a decline in grazing mortality of picophytoplankton and prokaryotes, allowing these communities to increase in abundance. HNF are an important link in carbon transfer to higher trophic levels as they are grazed upon by microzooplankton and thereafter by higher trophic organisms (Azam et al., 1991; Sherr and Sherr, 2002). Grazing is also a critical determinant of phytoplankton community composition and standing stocks (Sherr and Sherr, 2002). Therefore, the changes in predator-prey interactions with ocean acidification we observed in this study could have significant effects on the food web and biogeochemistry in coastal Antarctic waters.

Our results, together with those of the coincident studies by Deppeler et al. (2018) and Hancock et al. (2018), indicate it is likely that increasing CO_2 will cause a shift away from blooms dominated by large diatoms and *P. antarctica* towards communities increasingly dominated by prokaryotes, nano-sized diatoms, and picophytoplankton. Large phytoplankton cells contribute significantly to deep ocean carbon sequestration (Tréguer et al., 2018). They are also the preferred food source for higher trophic organisms, especially the Antarctic krill *Euphausia superba* (Haberman et al., 2003; Meyer et al., 2003; Schmidt et al., 2006). *E. superba* have been found to graze less efficiently on phytoplankton cells $< 10 \mu\text{m}$ (Quetin and Ross, 1985; Kawaguchi et al., 1999; Haberman et al., 2003). Thus, a shift to smaller-celled communities will likely alter the structure of the Antarctic food web. Furthermore, increases in prokaryote abundance will likely intensify the breakdown of organic matter in surface waters, further contributing in a decline in the sequestration of carbon from summer phytoplankton blooms into the deep ocean.

Data availability. Experimental data used for analysis are available via the Australian Antarctic Data Centre.

Environmental data: Deppeler, S.L., Davidson, A.T., Schulz, K.: Environmental data for Davis 14/15 ocean acidification minicosm experiment, Australian Antarctic Data Centre, <http://dx.doi.org/10.4225/15/599a7dfe9470a>, 2017, (updated 2017).

Flow cytometry data: Deppeler, S.L., Schulz, K.G., Hancock, A., Pascoe, P., Mckinlay, J., Davidson, A.T. (2018, updated 2018) Data for manuscript 'Ocean acidification reduces growth and grazing of Antarctic heterotrophic nanoflagellates' Australian Antarctic Data Centre, <http://dx.doi.org/10.4225/15/5b234e4bb9313>, 2018 (updated 2018)

5 Microscopy data: Hancock, A.M., Davidson, A.T., Mckinlay, J., Mcminn, A., Schulz, K., Van Den Enden, D. (2017, updated 2018) Ocean acidification changes the structure of an Antarctic coastal protistan community Australian Antarctic Data Centre, <http://dx.doi.org/10.4225/15/592b83a5c7506>, 2018 (updated 2018)

Author contributions. AD conceived and designed the experiments. AD led and oversaw the minicosm experiment and PP, SD, and AH performed the experiments. SD and AD performed the data analysis. KS performed the carbonate system measurements and manipulation. JM provided statistical guidance. SD wrote the manuscript with all other authors providing contributions and critical review of the manuscript.

10 *Competing interests.* The authors declare that they have no conflict of interest.

Acknowledgements. This study was funded by the Australian Government, Department of Environment and Energy as part of Australian Antarctic Science Project 4026 at the Australian Antarctic Division and an Elite Research Scholarship awarded by the Institute for Marine and Antarctic Studies, University of Tasmania. We would like to thank Prof. Dave Hutchins and Prof. Scarlett Trimborn for valuable comments on an earlier version of this manuscript. We gratefully acknowledge the assistance of AAD technical support in designing and equipping the minicosms and Davis Station expeditioners in the summer of 2014/15 for their support and assistance.

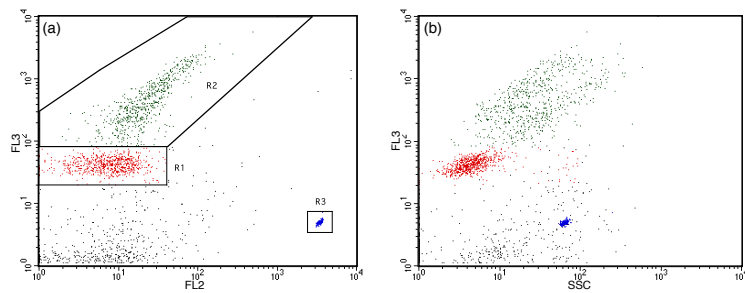

Figure 1. Nano- and picophytoplankton regions identified by flow cytometry. (a) Two separate regions identified based on red (FL3) versus orange (FL2) fluorescence scatter plot. (b) Picophytoplankton (R1) and nanophytoplankton (R2) communities determined from side scatter (SSC) versus FL3 fluorescence scatter plot. PeakFlow Green 2.5 μm beads (R3) used as fluorescence and size standard.

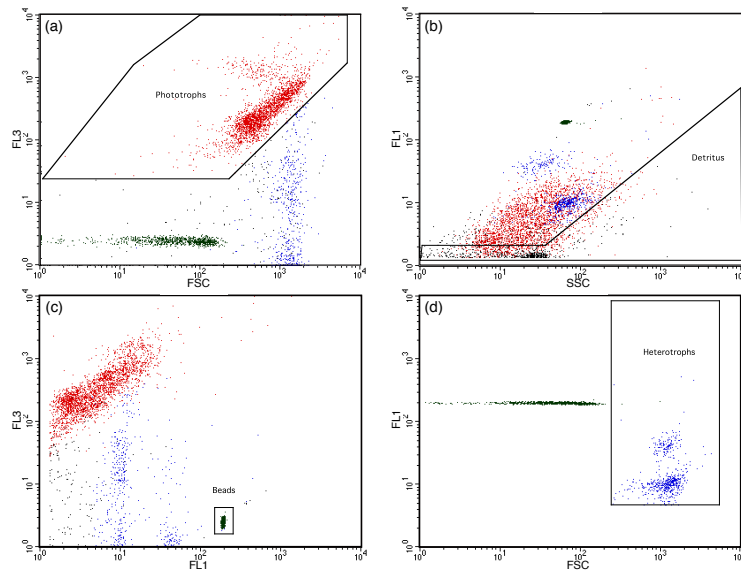

Figure 2. LysoTracker Green-stained heterotrophic nanoflagellates identified by flow cytometry. (a) Phytoplankton identified based on red (FL3) versus forward scatter (FSC) fluorescence scatter plots. (b) Detritus particles identified from high side scatter (SSC) versus LysoTracker Green fluorescence (FL1). (c) PeakFlow Green 2.5 μm beads identified from high FL1 versus FL3 fluorescence. (d) Phytoplankton and detritus from (a) and (b) removed from FL1 and FSC plot and remaining LysoTracker Green-stained particles $>2.5 \mu\text{m}$ were counted as heterotrophic nanoflagellates.

Figure 3. Prokaryote regions identified by flow cytometry. (a) SYBR-Green I-stained high DNA (HDNA) and low DNA (LDNA) prokaryote regions identified from side scatter (SSC) versus green fluorescence (FL1) scatter plots. (b) Prokaryote cells determined from high FL1 versus low red (FL3) fluorescence. PeakFlow Green 2.5 μm beads used as fluorescence and size standard.

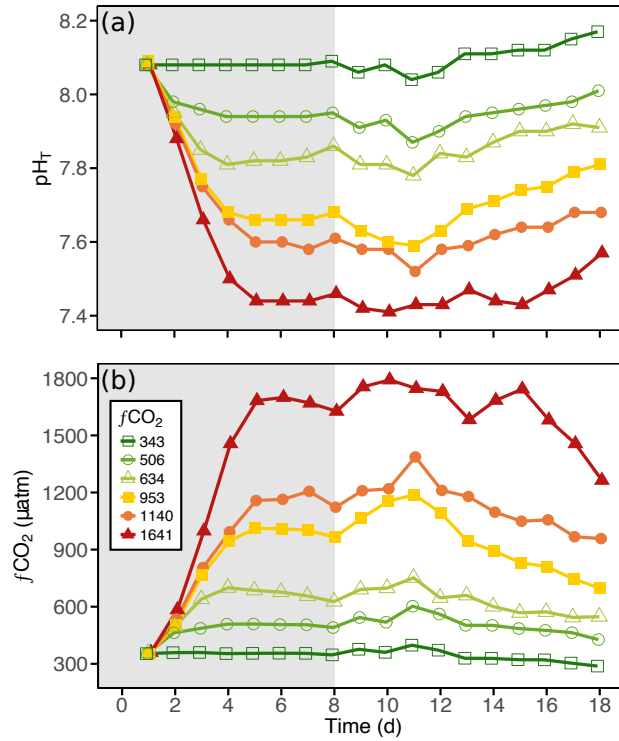

Figure 4. The (a) pH on the total scale (pH_T) and (b) fugacity of CO₂ (fCO₂) carbonate chemistry conditions in each of the minicosm treatments over time. Grey shading indicates CO₂ and light acclimation period.

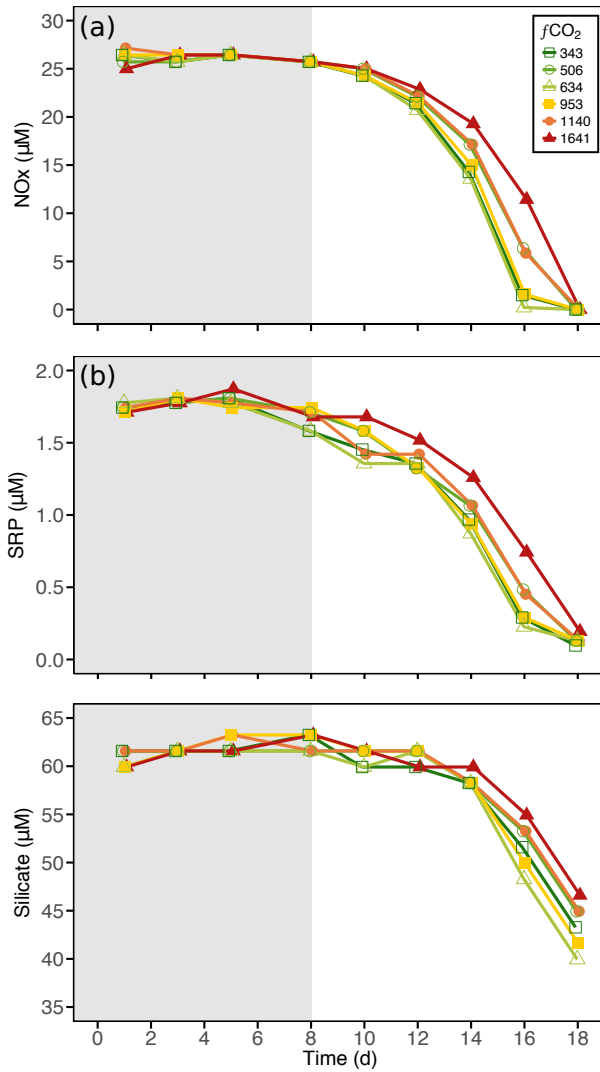

Figure 5. Nutrient concentration in each of the minicosm treatments over time. (a) Nitrate + nitrite (NO_x), (b) soluble reactive phosphorus (SRP), and (c) molybdate reactive silica (Silicate). Grey shading indicates CO₂ and light acclimation period.

Figure 6. Generalized additive model fits for (a) picophytoplankton, (b) nanophytoplankton, (c) heterotrophic nanoflagellates (HNF), and (d) prokaryotes in each of the minicosm treatments over time. Shading above and below fitted lines (grey) displays 95% confidence interval for model predictions. Grey shading on plot background indicates CO_2 and light acclimation period.

Figure 7. Heterotrophic nanoflagellate (HNF) abundance (y-axis) on the day before (a) picophytoplankton and (b) prokaryote abundance declined (shown on x-axis) in each of the minicosm treatments. Error bars display standard error of pseudoreplicate samples of HNFs (grey) and picophytoplankton/prokaryotes (black). Dotted line indicates threshold heterotrophic nanoflagellate abundance of (a) $0.87 \pm 0.02 \times 10^6$ cells l^{-1} and (b) $0.32 \pm 0.02 \times 10^6$ cells l^{-1} .

Table 1. Mean carbonate chemistry conditions in minicosms

Tank	$f\text{CO}_2$ (μatm)	pH_T	DIC ($\mu\text{mol kg}^{-1}$)	PA ($\mu\text{mol kg}^{-1}$)
1	343 ± 30	8.10 ± 0.04	2188 ± 6	2324 ± 11
2	506 ± 43	7.94 ± 0.03	2243 ± 8	2325 ± 10
3	634 ± 63	7.85 ± 0.04	2270 ± 5	2325 ± 12
4	953 ± 148	7.69 ± 0.07	2314 ± 11	2321 ± 11
5	1140 ± 112	7.61 ± 0.04	2337 ± 5	2320 ± 10
6	1641 ± 140	7.45 ± 0.04	2377 ± 8	2312 ± 10

Data are mean \pm one standard deviation of triplicate pseudoreplicate measurements, $f\text{CO}_2$; fugacity of CO_2 , pH_T ; pH on the total scale, DIC; dissolved inorganic carbon, PA; practical alkalinity

Table 2. Steady-state logarithmic growth rates in $f\text{CO}_2$ treatments

	Days	343 μatm	506 μatm	634 μatm	953 μatm	1140 μatm	1641 μatm
Pico	8-12	0.25	0.21	0.29	0.32	0.25	0.26
Nano	9-15	0.23	0.22	0.30	0.27	0.28	0.29
HNF	8-15	0.36	0.32	0.37	0.37	0.34	0.40
Prok	4-8	-0.02	0.02	0.04	0.09	0.08	0.09

Bold text denotes treatments with trends in steady-state logarithmic growth significantly different to the control (343 μatm , $p < 0.05$), shown in Table 3. Days; days from which the linear regression for growth rates was modelled, shown in Fig. S2. Pico; picophytoplankton, Nano; nanophytoplankton, HNF; heterotrophic nanoflagellates, Prok; prokaryotes.

Table 3. ANOVA results comparing trends in steady-state logarithmic growth for each $f\text{CO}_2$ treatment over time against the control

	F	Adjusted R ²	506 p-value	634 p-value	953 p-value	1140 p-value	1641 p-value
Pico	$F_{11,78} = 113.8$	0.94	0.17	0.13	<0.01	0.87	0.47
Nano	$F_{11,114} = 552.6$	0.98	0.45	<0.01	<0.01	<0.01	<0.01
HNF	$F_{11,131} = 518.6$	0.98	0.02	0.30	0.32	0.39	0.02
Prok	$F_{11,77} = 9.334$	0.51	0.21	0.06	<0.01	<0.01	<0.01

Bold text denotes significant p-values (<0.05). Pico; picophytoplankton, Nano; nanophytoplankton, HNF; heterotrophic nanoflagellates, Prok; prokaryotes.
