### Abstract

Spatial and temporal variations in atmospheric carbon dioxide (CO<sub>2</sub>) reflect large-scale net carbon exchange between the atmosphere and terrestrial ecosystems. Soil heterotrophic respiration (HR) is one of the component fluxes that drive this net exchange but, given observational limitations, it is difficult to quantify this flux or to evaluate global-scale model simulations thereof. Here, we show that atmospheric CO<sub>2</sub> can provide a useful constraint on large-scale patterns of soil heterotrophic respiration. We analyze three soil model configurations (CASA-CNP, MIMICS and CORPSE) that simulate HR fluxes within a biogeochemical testbed that provides each model with identical net primary productivity (NPP) and climate forcings. We subsequently quantify the effects of variation in simulated terrestrial carbon fluxes (NPP and HR from the three soil testbed models) on atmospheric CO<sub>2</sub> distributions using a three-dimensional atmospheric tracer transport model. Our results show that atmospheric CO<sub>2</sub> observations can be used to identify deficiencies in model simulations of the seasonal cycle and interannual variability in HR relative to NPP. In particular, the two models that explicitly simulated microbial processes (MIMICS and CORPSE) were more variable than observations at interannual timescales and showed a stronger than observed temperature sensitivity. Our results prompt future research directions to use atmospheric CO<sub>2</sub>, in combination with additional constraints on terrestrial productivity or soil carbon stocks, for evaluating HR fluxes.

## 1. Introduction

Atmospheric CO<sub>2</sub> observations reflect net exchange of carbon between the land and oceans with  
40 the atmosphere. Observations of atmospheric CO<sub>2</sub> concentration have been collected *in situ*  
since the late 1950s (Keeling et al., 2011), and global satellite observations have become  
available within the last decade (Crisp et al., 2017; Yokota et al., 2009). The high precision and  
accuracy of *in situ* observations and the fact that these measurements integrate information about  
ecosystem carbon fluxes over a large concentration footprint make atmospheric CO<sub>2</sub> a strong  
45 constraint on model predictions of net carbon exchange (Keppel-Aleks et al., 2013). For  
example, at seasonal timescales, atmospheric CO<sub>2</sub> can be used to evaluate the growing-season  
net flux, especially in the Northern Hemisphere (Yang et al., 2007). At interannual timescales,  
variations in the atmospheric CO<sub>2</sub> growth rate are primarily driven by changes in terrestrial  
carbon fluxes in response to climate variability (Cox et al., 2013; Humphrey et al., 2018; Keppel-  
50 Aleks et al., 2014). Recent studies have hypothesized that soil carbon processes represent one of  
the key processes in driving these interannual variations (Cox et al., 2013; Wunch et al., 2013).  
Moreover, soil carbon processes represent one of the largest uncertainties in predicting future  
carbon-climate feedbacks, in part because non-permafrost soils contain an estimated 1500 to  
2400 PgC (Bruhwiler et al., 2018), at least a factor of three larger than the pre-industrial  
55 atmospheric carbon reservoir.

Soil heterotrophic respiration (HR), the combination of litter decay and microbial breakdown of  
organic matter, is the main pathway for CO<sub>2</sub> release from soil carbon pools to the atmosphere.  
Currently, insights on HR rates and controls are mostly derived from local-scale observations.  
60 For example, soil chamber observations can be used to measure soil respiration (which includes  
root and heterotrophic respiration fluxes) at spatial scales on the order of 100 cm<sup>2</sup> (Davidson et  
al., 2002; Pumpanen et al., 2004; Ryan and Law, 2005). Ecosystem respiration (combined  
autotrophic and heterotrophic respiration fluxes) can also be backed out from eddy covariance  
net ecosystem exchange observations at spatial scales around 1 km<sup>2</sup>, but with substantial  
65 uncertainty (Baldocchi 2008; Barba et al., 2018; Lavigne et al., 1997). Because fine-scale  
variations in environmental drivers such as soil type and soil moisture affect rates of HR, it is  
difficult to scale local respiration observations to zonal or global scales. Even with use of  
advanced techniques such as artificial neural networks, lack of information for remote or under-

sampled zones contributes uncertainty to bottom-up HR estimates (Bond-Lamberty et al., 2018;  
70 Zhao et al, 2017).

Local-scale observations reveal that HR is sensitive to numerous climate drivers, including  
temperature, moisture, and freeze-thaw state (Baldocchi 2008; Barba et al., 2018; Lavigne et al.,  
1997). Because of these links to climate, predicting the evolution of HR and soil carbon stocks  
75 within coupled Earth system models is necessary for climate predictions. Within prognostic  
models, heterotrophic respiration has been represented as a first-order decay process based on  
precipitation, temperature, and a linear relationship with available substrate (Jenkinson et al.,  
1990; Parton, 1993, Randerson et al., 1996). However, such representations may neglect key  
processes for the formation of soil and persistence of soil organic carbon (SOC) stocks  
80 (Lehmann and Kleber 2015; Schmidt et al. 2011; Rasmussen et al. 2018). More recently, models  
have begun to explicitly represent microbial processes into global-scale simulations of the  
formation and turnover of litter and SOC (Sulman et al., 2014; Wieder et al., 2013) as well as to  
evaluate microbial trait-based signatures on SOC dynamics (Wieder et al., 2015). These  
advances in the representation of SOC formation and turnover increase capacities to test  
85 emerging ideas about soil C persistence and vulnerabilities, but also increase the uncertainties in  
how to implement and parameterize these theories in models (Bradford et al. 2016; Sulman et al.  
2018; Wieder et al. 2018).

Given these uncertainties, developing methods to benchmark model representations of HR fluxes  
90 is an important research goal (Bond-Lamberty et al. 2018b) as model predictions for soil carbon  
change over the 21<sup>st</sup> century are highly uncertain (Schoor et al., 2018; Todd-Brown et al., 2014).  
A common method for model evaluation is to directly compare spatial or temporal variations in  
model properties (e.g., leaf area index) or processes (e.g., gross primary productivity) against  
observations (Randerson 2009; Turner et al., 2006). Such comparisons assess model fidelity  
95 under present day climate, but may not ensure future predictivity of the model. The use of  
functional response metrics, which evaluate the relationship between a model process and an  
underlying driver, may ensure that the model captures the sensitivities required to predict future  
evolution (Collier 2018, Keppel-Aleks et al., 2018). A third benchmarking approach is to use  
hypothesis-driven approaches or experimental manipulations to evaluate processes (Medlyn et

100 al., 2015). It is likely that these methods will have maximum utility when combined within a  
benchmarking framework (e.g., Collier, 2018; Hoffman et al., 2016) since they evaluate different  
aspects of model predictive capability.

Here, we hypothesize that atmospheric CO<sub>2</sub> data can be used to evaluate simulations of soil  
105 heterotrophic respiration and differentiate between the chemical and microbial parameterizations  
used in state-of-the-art models. Previous work has shown that atmospheric CO<sub>2</sub> observations are  
inherently sensitive to HR across a range of timescales. For example, at seasonal timescales,  
improving the parameterization for litterfall in the CASA model improved its phasing of the  
simulated atmospheric CO<sub>2</sub> annual cycle (Randerson et al., 1996). At interannual timescales,  
110 variations in the Northern Hemisphere CO<sub>2</sub> seasonal minimum are hypothesized to arise from  
variations in respiration (Wunch et al., 2013) and variations in the growth rate have been linked  
to tropical respiration and its temperature sensitivity (Anderegg et al., 2015). In this analysis, we  
simulate atmospheric CO<sub>2</sub> distributions using three different soil model representations that are  
part of a soil biogeochemical testbed (Wieder et al., 2018). The three sets of HR fluxes, were  
115 shown in Wieder et al., (2018) to have distinct patterns at seasonal timescales, are used as  
boundary conditions for a 3-dimensional atmospheric transport model. We evaluate temporal  
variability in the resulting CO<sub>2</sub> simulations against observations, quantify the functional  
relationships between CO<sub>2</sub> variability and temperature variability, and quantify the regional  
influences of land carbon fluxes on global CO<sub>2</sub> variability. The methods and results are  
120 presented in Section 2 and 3, and discussion of the implications for benchmarking and our  
understanding of drivers of atmospheric CO<sub>2</sub> variability are presented in Section 4.

## 2. Data and Methods

### 2.1 Observations and timeseries analysis

125 For this analysis we use reference CO<sub>2</sub> measurements from 34 marine boundary layer sites  
(MBL, Table S1) within the NOAA Earth System Research Laboratory sampling network  
(ESRL, Fig. 1; Dlugokencky et al., 2016). These sites were chosen to minimize the influence of  
local anthropogenic emissions and had at least 50% data coverage over the 29-year period  
between 1982 and 2010. We detrend all timeseries data using a third-order polynomial fit to  
130 remove the impact of annually increasing atmospheric concentration in our seasonal and

interannual calculations (SFig. 1). Using the detrended CO<sub>2</sub> data, we calculate a period median annual cycle by averaging all observations for a given calendar month. To calculate CO<sub>2</sub> interannual variability (CO<sub>2</sub> IAV), the median annual cycle is subtracted from the detrended timeseries (SFig. 1, Fig. 4). We diagnose the magnitude of CO<sub>2</sub> IAV using one standard  
135 deviation, unless otherwise noted. Model simulated CO<sub>2</sub> seasonality and interannual variability is calculated using the same methods.

Following the approach in Keppel-Aleks et al., 2018, we aggregate site specific CO<sub>2</sub> by averaging measurement timeseries across six latitude zones (Fig.1, solid lines): Northern  
140 Hemisphere high latitudes (61 to 90°N), midlatitudes (24 to 60°N), tropics (1 to 23°N), Southern Hemisphere tropics (0 to 23°S), and extratropics (24 to 60°S and 61 S to 90 S). The global mean CO<sub>2</sub> timeseries is constructed as an area-weighted average of these six atmospheric zones.

## 2.2 Soil testbed representations of heterotrophic respiration

145 We used a soil biogeochemical testbed (Wieder et al., 2018), which generates daily estimates of soil carbon stocks and fluxes at global scale without the computational burden of running a full land model. The testbed is a chain of model simulations where soil models with different structures can be run under the same forcing data, including the same net primary productivity (NPP) fluxes, soil temperature, and soil moisture. Each testbed soil model in this analysis  
150 produces unique gridded heterotrophic respiration (HR) values based on its own underlying mechanism and soil C stocks. Currently, we are running with a carbon-only configuration of the testbed. From the testbed output we calculate the net ecosystem productivity (NEP) as the difference between HR and NPP, specifically HR-NPP, to account for the opposite sign convention between the component fluxes.

155

For the simulations described in this paper, the chain starts with the Community Land Model 4.5 (CLM4.5; Oleson et al., 2013), run with satellite phenology with CRU-NCEP climate reanalysis as forcing data (Jones et al., 2013; Kalnay et al., 1996; Le Quéré et al., 2018). In this simplified formulation of CLM, a single plant functional type is assumed in each 2° by 2° gridcell. Daily  
160 values for gross primary productivity (GPP), soil moisture, soil temperature, and air temperature from CLM4.5 are passed to the Carnegie-Ames Stanford Approach terrestrial model (CASA-

CNP; Potter et al. 1993; Randerson et al., 1996; Randerson et al., 1997; Wang et al., 2010). The CASA-CNP plant model uses the data from CLM4.5 to calculate NPP and carbon allocation to roots, wood, and leaves. This module also determines the timing of litterfall. Finally, metabolic  
165 litter, structural litter, and decomposing coarse woody debris (CWD) are then passed to the soil biogeochemical models.

The three soil models make distinct assumptions about microbial processes. More details regarding these formulations and their implementation in the testbed are found in Wieder et al.  
170 (2018), but we provide brief descriptions here. The CASA-CNP soil model computes first-order, linear decay rates modified by soil temperature and moisture, implicitly representing microbial activity and soil carbon turnover through a cascade of organic matter pools (CASA: Randerson et al., 1997; CASA-CNP: CASA carbon cycling with additional nitrogen, and phosphorus cycling, Wang et al. 2010). These include metabolic and structural litter, as well as a fast, slow, and  
175 passive soil carbon pools. The Microbial-Mineralization Carbon Stabilization model (MIMICS; Wieder et al., 2014; Wieder et al., 2015) explicitly represents microbial activity with a temperature-sensitive reverse Michaelis-Menten kinetics (Buchkowski et al., 2017; Moorhead and Weintraub, 2018) but has no soil moisture controls. The decomposition pathway is set up with two litter pools (identical to those simulated by CASA-CNP), three soil organic matter  
180 pools (available, chemically and physically protected), and two microbial biomass pools for copiotrophic (fast) and oligotrophic (slow) microbial functional groups. The Carbon, Organisms, Rhizosphere, and Protection in the Soil Environment model (CORPSE) is also microbially explicit and uses reverse Michaelis-Menten kinetics, but it assumes different microbial and soil carbon pools. Surface litter and soil C pools are considered separately, but only soil C has a  
185 parallel set of physically protected pools that are isolated from microbial decomposition. CORPSE includes a temperature dependent Maximum Reaction Velocity ( $V_{\max}$ ) parameter, but also includes a term for the soil moisture controls on decomposition rates that uses volumetric liquid soil water content. For all three models, soil texture inputs were also derived from the CLM surface data set (Oleson et al., 2013). We acknowledge that one potential limitation of the  
190 approach is a lack of vertical resolution in terms of temperature or frozen fraction of soil moisture (Koven et al. 2013).

While this modeling approach contains necessary simplifications, it provides the ability to query the role of structure in driving differences in fluxes. Model output includes daily net primary  
195 production (NPP) from CASA-CNP and HR simulated by CASA-CNP, CORPSE and MIMICS. Daily fluxes between 1982 and 2010 are averaged to monthly values and masked into land regions that align with the CO<sub>2</sub> sampling zones (section 2.1, Fig. 1, color fill): Northern Hemisphere high latitudes (NHL; 61 to 90°N), midlatitudes (NML; 24 to 60°N), tropics (NT; 1 to 23°N), Southern Hemisphere tropics (ST; 0 to 23°S), and extratropics (SE; 24 to 90°S) – here  
200 the two Southern Hemisphere extratropical regions were combined into one flux area since Antarctic carbon fluxes are negligible. Land-area integrated flux timeseries are then used for seasonal and interannual calculations (method described in section 2.1). However, the raw daily fluxes between 1980 and 2010 are used as boundary conditions to an atmospheric transport model, again separated by latitude zones listed above, to simulate the imprint of these different  
205 soil model configurations on monthly atmospheric CO<sub>2</sub>.

### 2.3 GEOS-Chem atmospheric transport modeling of CO<sub>2</sub>

We simulate the imprint of the testbed fluxes on atmospheric CO<sub>2</sub> using GEOS-Chem, a 3-D atmospheric transport model. We run the GEOS-Chem v12.0.0 CO<sub>2</sub> simulation between 1980  
210 and 2010 at a resolution of 2.0° in latitude by 2.5° in longitude with 47 vertical levels. The model is driven by hourly meteorological fields from the Modern-Era Retrospective analysis for Research and Application version 2 (MERRA2) reanalysis data (Gelaro et al., 2017; <https://gmao.gsfc.nasa.gov/reanalysis/MERRA-2/>), with the dynamic timestep set to be 600 seconds. The model is initialized with a globally-uniform atmospheric CO<sub>2</sub> mole fraction equal  
215 to 350 ppm. Results of the first two years (1980 and 1981) are reserved for model spin-up, and we analyze the monthly average outputs for the period 1982–2010. To minimize influence of land-atmosphere boundary layer dynamics and the influence of anthropogenic emissions, we sample the resulting GEOS-Chem simulations at the 3<sup>rd</sup> vertical level for grid cell points with latitude and longitude values closest to 34 marine boundary layer (MBL) sites within the NOAA  
220 ESRL network. We calculated the latitude zone averaging, median annual cycle and interannual variability calculations using the methods described for observed CO<sub>2</sub> (see section 2.1). Aggregating CO<sub>2</sub> from individual sites is consistent with our hypothesis that atmospheric CO<sub>2</sub> may provide constraints on large-scale, rather than local, patterns of heterotrophic respiration. As

such, averaging simulated and observed CO<sub>2</sub> across latitude zones smooths local information  
225 while retaining information about regional scale fluxes.

We isolate the imprint of NPP and three representations of HR on the spatial and temporal  
evolution of atmospheric CO<sub>2</sub> by using daily testbed results as boundary conditions (section 2.2).  
We also separately tag CO<sub>2</sub> originating from the five flux zones delineated in the previous  
230 section (Fig. 1). Overall, we track 20 CO<sub>2</sub> tracers in total (4 sets of fluxes and 5 flux regions)  
within the GEOS-Chem model. Throughout the manuscript, we refer to CO<sub>2</sub> originating from  
these NPP and HR component fluxes as CO<sub>2</sub><sup>NPP</sup> and CO<sub>2</sub><sup>HR</sup>, respectively. For the atmospheric  
CO<sub>2</sub> simulations, we used the sign convention that a positive flux indicates a flux into the  
atmosphere. Therefore, CO<sub>2</sub><sup>NEP</sup>, indicating CO<sub>2</sub> from net ecosystem production (NEP), is  
235 calculated from the addition of CO<sub>2</sub><sup>NPP</sup> and CO<sub>2</sub><sup>HR</sup>. The same notation will be used to denote the  
testbed ensemble sources. For example, CO<sub>2</sub><sup>HR</sup> simulated from CORPSE fluxes is defined as  
CO<sub>2</sub><sup>CORPSE HR</sup>, similarly for CO<sub>2</sub><sup>CORPSE NEP</sup>. We note that the net CO<sub>2</sub> response from the model  
(i.e., CO<sub>2</sub><sup>NEP</sup>) is approximately equivalent to observations in terms of seasonal and interannual  
variations, although we neglect ocean fluxes and emissions from fossil fuels, land use and land  
240 cover change, and fire. Previous studies have demonstrated that NEP drives most of the  
atmospheric CO<sub>2</sub> seasonality (> 90%; Nevison et al., 2008; Randerson et al., 1997) and  
interannual variability (e.g., Rayner et al. 2008; Battel et al. 2000).

#### 2.4 Global temperature sensitivity and separation of regional influences

245 For insight on a functional climate response, we investigate the global temperature sensitivity of  
the atmospheric CO<sub>2</sub> growth rate and the testbed ensemble fluxes. Variability in the CO<sub>2</sub> growth  
rate anomaly was calculated as the difference between timestep  $n$  and  $n-1$  for the monthly and  
annual interannual variability (IAV) timeseries. Testbed flux timeseries were averaged to  
monthly resolution and interpolated (averaged between months) to match the monthly initiation  
250 of each corresponding CO<sub>2</sub> growth rate anomaly timeseries. Following Arora et al. (2013), we  
calculate temperature sensitivity ( $\gamma$ ) using an ordinary linear regression for the timeseries of  
temperature interannual variability (T IAV) with 1) atmospheric CO<sub>2</sub> growth rate anomalies, and  
2) land flux IAV (see section 2.2). For atmospheric CO<sub>2</sub> growth rate anomalies, each timeseries  
was converted from ppm y<sup>-1</sup> to PgC y<sup>-1</sup> based on the global mass of atmospheric dry air. Thus, all

255 global sensitivity values are reported in units of  $\text{PgC y}^{-1} \text{K}^{-1}$ . A reference global temperature  
sensitivity value for the  $\text{CO}_2$  growth rate was calculated for 1982 to 2010 using ESRL  $\text{CO}_2$   
observations and the Climatic Research Unit's gridded temperature product (CRU TS4; Jones et  
al., 2012). The CRU TS4 historical product was used because it consists of directly interpolated  
station data.

260

We also assess the influence of individual regions on the global mean signal for both component  
land fluxes (NPP, HR) and simulated atmospheric  $\text{CO}_2$  ( $\text{CO}_2^{\text{NPP}}$ ,  $\text{CO}_2^{\text{HR}}$ ,  $\text{CO}_2^{\text{NEP}}$ ). To quantify  
each region's contribution to global variability we calculate the ratio of regional IAV magnitude  
to global IAV magnitude, which we define as relative standard deviation ( $\sigma_{\text{REL}}$ ). For each flux  
265 and  $\text{CO}_2$  region (NHL, NML, NT, ST, SE), this ratio is calculated from the standard deviation of  
each monthly IAV timeseries. However, for the regional values of simulated  $\text{CO}_2$  IAV, we  
identify the global mean response to a single region's fluxes. That is, the  $\text{CO}_2$  IAV averaged  
across all six  $\text{CO}_2$  regions but sourced only from testbed fluxes in the NHL, or NML, etc.,  
without influence from the other flux regions. We then take the standard deviation of this  
270 regionally-selected global mean IAV for the ratio to total global  $\text{CO}_2$  IAV magnitude (derived  
from all global fluxes). To measure the strength of each region's impact on global values, we use  
the same regional-global partitioning to calculate correlation coefficients ( $r$ ) for the timeseries of  
component flux IAV and  $\text{CO}_2$  IAV. Thus, if an individual region were responsible for all  
observed global flux or  $\text{CO}_2$  variability, it would have both  $\sigma_{\text{REL}}$  and  $r$  values equal to 1 in this  
275 comparison. The value for  $\sigma_{\text{REL}}$  decreases with the magnitude of regional variability, and  $r$   
decreases if the variability is not coherent with the global signal, even if the magnitude of  
variability is high.

### 3. Results

#### 280 3.1 Seasonal imprint of heterotrophic respiration

The three soil carbon models in the testbed impart different fingerprints on atmospheric  $\text{CO}_2$   
variability. Both  $\text{CO}_2^{\text{NPP}}$  and  $\text{CO}_2^{\text{HR}}$  show largest seasonality in the NHL, with seasonal  
amplitudes decaying toward the tropics and Southern Hemisphere. In the NHL, the peak-to-  
trough amplitude of  $\text{CO}_2^{\text{NPP}}$  is  $39 \pm 2$  ppm, with a seasonal maximum in April and a seasonal  
285 minimum in August (Fig. 2a). The seasonal cycles for  $\text{CO}_2^{\text{HR}}$  simulated from all testbed models

are out of phase with that of  $\text{CO}_2^{\text{NPP}}$ , and there are large amplitude differences in  $\text{CO}_2^{\text{HR}}$  among the model ensemble members. Specifically, the NHL amplitude of  $\text{CO}_2^{\text{CORPSE HR}}$  is  $28 \pm 3$  ppm, while the amplitudes for  $\text{CO}_2^{\text{MIMICS HR}}$  and  $\text{CO}_2^{\text{CASA-CNP HR}}$  are only  $17 \pm 1$  ppm, accounting for about 40-70% of the amplitude from  $\text{CO}_2^{\text{NPP}}$  (Table 1). However, in all latitude bands, the largest  $\text{CO}_2^{\text{HR}}$  amplitude comes from the microbially explicit models – CORPSE for the Northern Hemisphere and MIMICS for the Southern Hemisphere (Table 1). The amplitudes of  $\text{CO}_2^{\text{NPP}}$  and  $\text{CO}_2^{\text{HR}}$  decrease further south, but the amplitude ratio of  $\text{CO}_2^{\text{HR}}$  to  $\text{CO}_2^{\text{NPP}}$  in NML and NT remains about 0.4-0.7 (Fig. 2b-c; Table 1). In the Southern Hemisphere tropics, the amplitude of  $\text{CO}_2^{\text{NPP}}$  was smaller than that the Northern Hemisphere, however amplitude of  $\text{CO}_2^{\text{HR}}$  was similar to the NT values (Table 1). In the Southern Hemisphere extratropics, the amplitudes for all components were less 3 ppm (Table 1).

The phasing of  $\text{CO}_2^{\text{HR}}$  is an important driver of the overall comparison between  $\text{CO}_2^{\text{NEP}}$  and observed  $\text{CO}_2$  seasonality (Fig. 3). When the contributions of NPP and HR seasonality are considered together (i.e.,  $\text{CO}_2^{\text{HR}} + \text{CO}_2^{\text{NPP}}$ ), the simulated amplitude of  $\text{CO}_2^{\text{NEP}}$  is larger than the observed  $\text{CO}_2$  across all latitude bands (Fig. 3). The largest mismatch is in the NHL zone, where the observed mean annual cycle is  $15 \pm 0.9$  ppm, while the peak-to-trough  $\text{CO}_2^{\text{NEP}}$  ranges from  $23 \pm 1.3$  ppm for CORPSE to  $33 \pm 1.4$  ppm for MIMICS (Fig. 3a). The smaller  $\text{CO}_2^{\text{NEP}}$  amplitude simulated by CORPSE is due to the large  $\text{CO}_2^{\text{HR}}$  seasonality that counteracts the seasonality in NPP (Fig. 2a-b). Furthermore,  $\text{CO}_2^{\text{MIMICS HR}}$  and  $\text{CO}_2^{\text{CASA-CNP HR}}$  have similar amplitudes in the NHL (Fig. 2a; Table 1), but the  $\text{CO}_2^{\text{NEP}}$  amplitude from these two models differs ( $33 \pm 1.2$  ppm versus  $26 \pm 1$  ppm, respectively; Fig. 3a; Table 1). This occurs because  $\text{CO}_2^{\text{MIMICS HR}}$  peaks one-month later than  $\text{CO}_2^{\text{CASA-CNP HR}}$ , and has a zero-crossing that is more closely aligned with the trough of  $\text{CO}_2^{\text{NPP}}$  (Fig. 2a), leading to the larger amplitude in  $\text{CO}_2^{\text{MIMICS NEP}}$  (Fig. 3a; Table 1). Although the amplitude mismatch decreases towards the south (Fig. 3b-f), the overall bias in the Northern Hemisphere suggests that either the seasonality of NPP is too large, or that all testbed models underestimate the seasonality of HR. Within the ST region, ensemble  $\text{CO}_2^{\text{HR}}$  minima are opposite to that in  $\text{CO}_2^{\text{NPP}}$ , leading to a small annual cycle in simulations whereas the double peak in the ESRL observations may reflect fluxes not accounted for in our framework (Figs. 2d, 3d).

### 3.2 Interannual imprint of heterotrophic respiration

The testbed ensemble reasonably simulates the magnitude and timing of interannual variability (IAV) compared with CO<sub>2</sub> observations (Fig. 4). Across the six latitude bands analyzed, simulated CO<sub>2</sub><sup>NEP</sup> IAV generally falls within one standard deviation of the median variation from observations for most of the study period (Fig. 4). Taking a closer look at the CO<sub>2</sub> from the component fluxes (NPP and HR), across all six latitude bands, the CO<sub>2</sub><sup>NPP</sup> IAV standard deviation is between 0.9 and 1.1 ppm for component fluxes (Fig. 5a). CO<sub>2</sub><sup>CASA-CNP HR</sup> IAV shows similar standard deviation as CO<sub>2</sub><sup>NPP</sup> IAV, whereas the standard deviations of CO<sub>2</sub><sup>CORPSE HR</sup> and CO<sub>2</sub><sup>MIMICS HR</sup> range from 0.7-1.4 ppm and 0.5-1.1 ppm, respectively (Fig. 5a). Combining the CO<sub>2</sub> responses from component fluxes to CO<sub>2</sub><sup>NEP</sup> reveals a latitudinal gradient in IAV standard deviation similar to that of ESRL observations, with largest standard deviation found in the northern extratropics (Fig. 5b). Among the three testbed models, the standard deviation of CO<sub>2</sub><sup>CASA NEP</sup> agrees best with observations across all latitude bands (CO<sub>2</sub><sup>CASA NEP</sup>: 0.5-0.9 ppm; ESRL: 0.6-1.0 ppm; Fig. 5b). CO<sub>2</sub><sup>CORPSE NEP</sup> overestimates IAV by up to 30% in NHL and NML, but agrees better with observations in the tropics and Southern Hemisphere. CO<sub>2</sub><sup>MIMICS NEP</sup> overestimates IAV standard deviations across all latitude bands (Fig. 5b). Interestingly, in the NHL, the overestimation is 20% even though CO<sub>2</sub><sup>MIMICS HR</sup> shows similar IAVs as CO<sub>2</sub><sup>NPP</sup> (both 1.1 ppm; Fig.5). This suggests that the phasing of CO<sub>2</sub><sup>MIMICS HR</sup> IAV relative to CO<sub>2</sub><sup>NPP</sup> contributes to CO<sub>2</sub><sup>MIMICS NEP</sup> bias.

Both global NPP and HR fluxes are sensitive to temperature variations at interannual timescales, with increased build-up of CO<sub>2</sub> in the atmosphere at higher temperatures. Since these temperature sensitivities cannot be directly constrained from observations, we calculate temperature sensitivities for the CO<sub>2</sub> resulting from these component fluxes as well as from NEP. For CASA-CNP, the temperature sensitivity ( $\gamma$ ) for globally integrated NPP and HR fluxes is 2.5 PgC yr<sup>-1</sup> K<sup>-1</sup> and 1.7 PgC yr<sup>-1</sup> K<sup>-1</sup>; respectively (Fig. 6a). The temperature sensitivity of HR was higher for the microbially explicit models: 2.1 PgC yr<sup>-1</sup> K<sup>-1</sup> for CORPSE and 4.2 PgC yr<sup>-1</sup> K<sup>-1</sup> for MIMICS (Fig. 6a). For any given testbed flux (NPP, HR, or NEP), the temperature sensitivity of the resulting global mean CO<sub>2</sub> growth rate anomaly is higher than that of the underlying flux IAV. For example, the temperature sensitivity of the globally integrated NPP flux IAV ( $\gamma_{NPP}$ ) is 2.5 PgC yr<sup>-1</sup> K<sup>-1</sup> whereas  $\gamma_{CO_2^{NPP}}$  is 3.2 PgC yr<sup>-1</sup> K<sup>-1</sup>. The apparent

amplification of the temperature sensitivity was even larger for HR. For example, the temperature sensitivity of MIMICS HR IAV ( $\gamma_{HR}^{MIMICS}$ ) was  $4.2 \text{ PgC yr}^{-1} \text{ K}^{-1}$ , whereas  $\gamma_{CO_2}^{MIMICS HR}$  was  $7.7 \text{ PgC yr}^{-1} \text{ K}^{-1}$  (Fig. 6a). The resulting testbed  $CO_2^{NEP}$  overestimates the temperature sensitivity of the observed atmospheric  $CO_2$  growth rate anomaly ( $6.1 \pm 2.5 \text{ PgC yr}^{-1} \text{ K}^{-1}$ ; Fig. 6b). CASA-CNP and CORPSE have temperature sensitivities within the range of the observed sensitivity, but  $\gamma_{CO_2}^{MIMICS NEP}$  is 80% larger than observed value ( $10.9 \text{ PgC yr}^{-1} \text{ K}^{-1}$ ; Fig. 6b). We note that the  $\gamma_{HR}$  and  $\gamma_{CO_2}^{HR}$  is an emergent property that reflects both direct and indirect temperature influences, including the impact of temperature variability on NPP and litterfall (Table S3).

### 3.3 Geographic origins of $CO_2$ IAV

The interannual variability (IAV) in global NPP and HR originate from different geographic regions. The IAV in global NPP fluxes are dominated by variations within the NT and ST regions, with relative standard deviation  $\sigma_{REL} \sim 0.5$  and correlation coefficient  $r \sim 0.6$  (Fig. 7a-b). The NML region also has a similar contribution to the NT in magnitude, but with a lower timing coherence ( $r = 0.44$ ; Fig. 7a-b). In contrast to the dominance of the tropics in IAV of global NPP, the NML region contributes most to IAV in global HR, with  $\sigma_{REL} \geq 0.6$  and  $r \sim 0.8$  for all three testbed models (Fig. 7c-d). The NHL region is also important in driving global HR flux variability based on CORPSE model results ( $\sigma_{REL} = 0.59$  and  $r = 0.82$ ; Fig. 7c-d). Despite high NPP variability in the tropics, the magnitude of tropical HR variability is only about 10-30% of global HR variability, and the timing coherence with the global signal is generally low ( $r < 0.45$ ; Fig. 7a-b). MIMICS HR IAV is the exception for the ST measuring close to 40% of global HR IAV magnitude and relatively high correlation ( $r = 0.58$ ; Fig. 7a-b). Together, the tropics and NML contribute roughly equally to the magnitude of global NEP variability ( $\sigma_{REL}$  between 0.44-0.55; Fig. 7e). Although the NML and NT show relatively high timing coherence (0.41-0.55), the ST shows the strongest timing coherence with global NEP IAV ( $r > 0.7$ ; Fig. 7f).

Atmospheric transport modifies patterns of IAV in fluxes, emphasizing tropical flux patterns and de-emphasizing northern hemisphere flux patterns. For example, the role of ST in driving global  $CO_2^{NPP}$  variability is amplified compared to the underlying fluxes, as the timing coherence with the global signal increases from  $r = 0.64$  for flux IAV to  $r = 0.88$  for  $CO_2^{NPP}$  IAV for this region

(Fig. 7b). Conversely, the role of NML is dampened, with timing coherence decreasing to  $r =$   
380  $0.33$  for  $\text{CO}_2^{\text{NPP}}$  IAV versus  $r = 0.44$  for NPP IAV (Fig. 7b). Similarly, timing coherence for  
tropical  $\text{CO}_2^{\text{HR}}$  IAV is substantially higher than that for HR fluxes in ST and NT ( $>0.7$ ),  
although the atmospheric transport impact differs across the three testbed models (Fig. 7d). In  
contrast to closely aligned NML correlation values for  $\text{CO}_2^{\text{HR}}$  and HR ( $r \sim 0.8-0.9$ ), NML  $\text{CO}_2^{\text{HR}}$   
IAV shows  $\sigma_{\text{REL}}$  between  $0.45$  and  $0.58$ , a decrease from the HR IAV contribution (NML HR  
385 IAV  $\sigma_{\text{REL}}$  range:  $0.57$  to  $0.74$ ; Fig. 7c). For  $\text{CO}_2^{\text{NEP}}$  IAV, the regional contribution is more  
consistent with similar  $\sigma_{\text{REL}}$  and  $r$  to flux IAV (Fig. 7e-f).

#### 4. Discussion

Modeled differences in heterotrophic respiration impart discernible signatures on atmospheric  
390  $\text{CO}_2$ . We analyzed the atmospheric  $\text{CO}_2$  response to soil heterotrophic respiration (HR) using a  
soil testbed ensemble with three plausible representations of HR (CASA-CNP, CORPSE,  
MIMICS) and a 3-D atmospheric transport model. Results show that HR phasing is important for  
ecosystem carbon flux (NEP) at both seasonal and interannual timescales. Regional patterns of  
HR variability provide non-negligible contributions to global  $\text{CO}_2$  variability. Here we discuss  
395 these findings in more detail as well as implications for the use of  $\text{CO}_2$  observations for flux  
evaluation and model benchmarking.

##### 4.1 Impacts of heterotrophic respiration on seasonality

Our evaluation of  $\text{CO}_2$  simulated using testbed fluxes revealed that all testbed models  
400 overestimated the mean annual cycle amplitude of atmospheric  $\text{CO}_2$  observations. In the  
Northern Hemisphere, the bias was largest for MIMICS, as the  $\text{CO}_2^{\text{MIMICS NEP}}$  amplitude was  
overestimated by up to 100% (Fig. 3). The mismatch was smallest in  $\text{CO}_2^{\text{CORPSE NEP}}$ , which was  
within 70% of the observed annual cycle amplitude where CORPSE simulates the largest  
seasonal HR fluxes (Fig. 3a-c, Table1). We note that the mismatch across all three testbed  
405 formulations could be due to overestimation of the NPP flux used by all three testbed models, or  
underestimation of HR seasonality. However, an advantage of the testbed approach is that,  
because all of the models are driven by the same NPP and climate variables, the differences in  
the HR flux amplitudes arise from structural differences in the testbed. In the Southern  
Hemisphere, in contrast to the large differences found in the Northern Hemisphere, the simulated

410 CO<sub>2</sub> annual cycle amplitudes were similar across all three models, with small absolute mismatches (about 1 ppm) compared to observations.

One challenge in using atmospheric CO<sub>2</sub> to evaluate HR representation in soil models is the influence of productivity (NPP) on both HR fluxes and atmospheric CO<sub>2</sub> variations. The seasonal diagnostics we present are very sensitive to the phasing of HR fluxes relative to NPP. For example, in NHL a one-month lag in the seasonal maximum of CO<sub>2</sub><sup>HR</sup> between MIMICS and CASA-CNP (Fig. 2) leads to a 7 ppm difference in the overall amplitude of CO<sub>2</sub><sup>NEP</sup>— this despite identical amplitudes of CO<sub>2</sub><sup>HR</sup> for the two models (Fig. 3). Although the substantial impacts of subtle phase differences complicate benchmarking, the sensitivity reveals interesting and important differences related to model structural choices (i.e. first order versus microbially explicit). Wieder et al., (2018) noted that the microbially explicit models in the testbed had seasonal HR fluxes that peaked in the fall, about a month later than the HR fluxes simulated by CASA-CNP. The timing of CASA-CNP fluxes largely depend on soil temperature (highest HR flux when temperature is highest), whereas MIMICS and CORPSE have maximum HR fluxes set by trade-offs between the timing of maximal temperature and maximal microbial biomass, which is more tightly linked with litterfall (Fig. 7 from Wieder et al., 2018). Thus, phasing of HR is a sensitive diagnostic for benchmarking, especially if additional constraints on the magnitude and phasing of NPP are available.

430 In this study, determining the unique contribution from HR was possible since NPP was common among the three soil models used in the testbed, but the contribution of NPP will need to be resolved for model evaluation in other contexts. Long-term records of vegetation productivity at regional and global scales have been observed via satellite vegetation indices (Hicke et al., 2002; Meroni et al., 2009; Running et al., 2004), and more recently chlorophyll fluorescence (Frankenberg et al., 2011; Guan et al., 2016; Kohler et al., 2018; Li et al., 2018). Our study underscores the importance of developing methods to use these datasets together with atmospheric CO<sub>2</sub> to inform the dynamics of carbon cycling and its component fluxes.

#### 4.2 Impacts of heterotrophic respiration on interannual variability

440 Similar to the analyses on seasonal cycles, the testbed ensemble simulations showed a higher  
CO<sub>2</sub> IAV associated with explicit microbial representation (Fig. 5). This is especially true for  
CO<sub>2</sub><sup>CORPSE</sup> in the NHL and NML (Fig. 5a). Interestingly, in the tropics and SE, CO<sub>2</sub><sup>MIMICS HR</sup>  
IAV is only slightly higher than that of CO<sub>2</sub><sup>CASA-CNP HR</sup> or CO<sub>2</sub><sup>CORPSE HR</sup>, but IAV of CO<sub>2</sub><sup>MIMICS</sup>  
445 <sup>NEP</sup> was 20-30% higher than that of other models. Further, in these regions MIMICS HR IAV  
also shows an inverse, but highly correlated relationship with NPP IAV ( $R^2 > 0.60$ , Table S3).  
This suggests that the large IAV of CO<sub>2</sub><sup>MIMICS NEP</sup> may result from differences in phasing  
between NPP and MIMICS HR fluxes, similar to phasing between MIMICS NPP and HR  
affecting the shape of the CO<sub>2</sub><sup>NEP</sup> annual cycle in NHL. In the NHL, all testbed models show HR  
IAV is correlated with both NPP IAV and temperature IAV ( $R^2$  of 0.32 to 0.77; Table S3).  
450 Additionally, NPP IAV is sensitive to temperature variability ( $\gamma = 0.15$ ,  $R^2 = 0.43$ ; Table S3).  
Thus better diagnostics for atmospheric CO<sub>2</sub> IAV owing to HR requires additional constraints on  
NPP fluxes, especially at high latitudes.

The high IAV in CO<sub>2</sub><sup>MIMICS NEP</sup> is consistent with this model having the highest global  
455 temperature sensitivity overestimating observed value by 80% (Fig. 6b). CORPSE, the other  
microbially explicit model, had a 30% higher temperature sensitivity in CO<sub>2</sub><sup>NEP</sup> than observed  
globally (Fig. 6b). This large bias in temperature sensitivity demonstrates the structural  
uncertainty associated with current HR parameterization, and highlights the need for continued  
investigation of model microbial representation to improve the functional relationship with  
460 temperature in soil models.

### 4.3 Implications for model benchmarking using atmospheric CO<sub>2</sub>

Our results provide useful insights for model benchmarking using atmospheric CO<sub>2</sub>. On a global  
scale, interannual variability (IAV) of simulated atmospheric CO<sub>2</sub> was shown to be affected by  
465 the variability in component fluxes (NPP, HR) from different land regions (Figs. 5-7). The  
tropics dominate IAV in global NPP, while northern extratropics dominate the IAV in global HR  
(Fig. 7a-d). Taken together, NEP variability reflects roughly equal contributions from northern  
hemisphere temperate ecosystems (NML) and tropical ecosystems (NT and ST; Fig. 7e-f). These  
results suggest that the interannual variability of atmospheric CO<sub>2</sub> results from two different  
470 processes (respiration and productivity) across multiple ecoclimate regions, whereas previous

studies have mostly identified tropical (e.g. Cox et al., 2013; Wang et al., 2013) or subtropical, semi-arid regions (e.g. Ahlstrom et al., 2015; Poulter et al., 2014) as dominant controls on the global CO<sub>2</sub> IAV.

475 Our analysis underscores that patterns of variability in atmospheric CO<sub>2</sub> are tied not only to variabilities in the underlying fluxes, but also to atmospheric transport. For example, we showed that the temperature sensitivity of CO<sub>2</sub> growth rate anomalies was larger than the sensitivity estimated from the fluxes themselves (Fig. 6). The enhanced temperature sensitivity for CO<sub>2</sub><sup>HR</sup> was larger than for that of CO<sub>2</sub><sup>NPP</sup>, which suggests that the geographic origin of the fluxes  
480 relative to dominant patterns of transport affects the result (Fig. 6a). This transport enhancement of the apparent temperature sensitivity of CO<sub>2</sub> growth rate anomalies is consistent with results from Keppel-Aleks et al. (2018). While these results may be tied to the choice of GEOS-Chem to simulate atmospheric transport, they do underscore that (1) atmospheric CO<sub>2</sub> must be simulated from land fluxes to be use as a benchmark and (2) atmospheric observations should not be  
485 assumed to be a direct proxy for fluxes themselves.

We employed several benchmarking approaches, including timeseries comparison and functional response to temperature, to evaluate if CO<sub>2</sub> patterns reflect underlying representations of soil heterotrophic respiration. We found that soil heterotrophic respiration leaves non-negligible  
490 imprints on atmospheric CO<sub>2</sub>, leaving open the possibility of more explicitly accounting for respiration variability using atmospheric CO<sub>2</sub> observations. Given that HR links to NPP, soil C pools, and temperature, we recommend synergistically using datasets that reflect these variables (instead of identifying metrics in isolation). This could provide better model process evaluation if implemented in a larger benchmarking framework, such as the International Land Model  
495 Benchmarking Project (ILAMB; Collier, 2018; Hoffman et al., 2016). Model development will be crucial in the next decade of carbon cycle research, but so will tools to test mechanistic understanding and elucidate a coherent picture of the land-atmosphere carbon response to a changing climate.

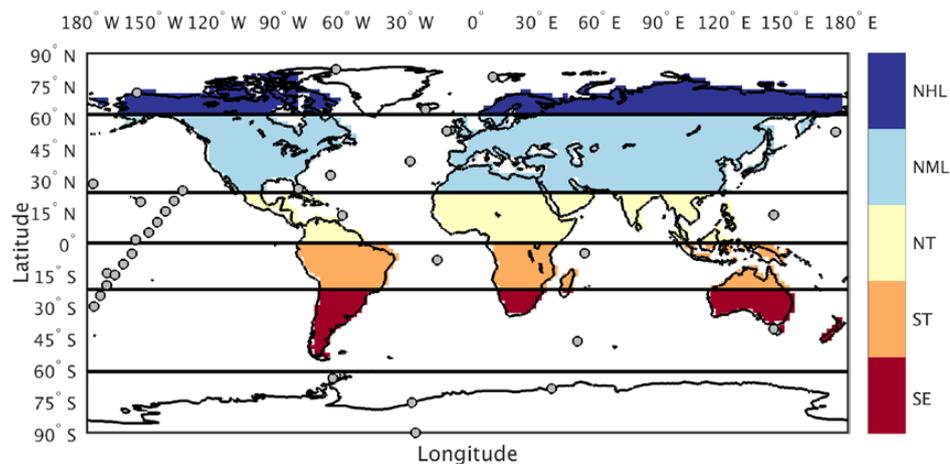

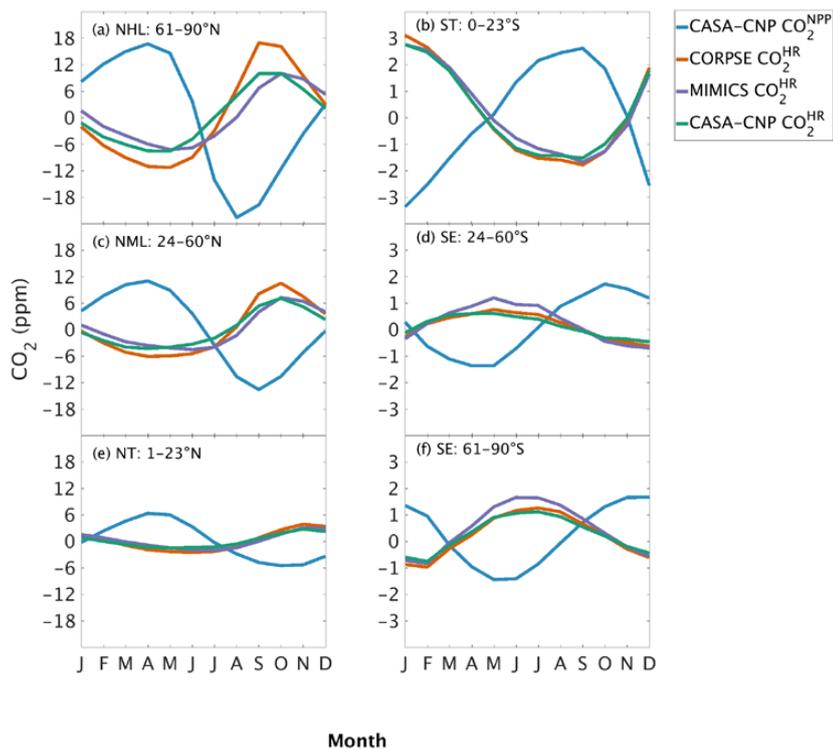

Figure 1. Tagged flux regions and marine boundary layer CO<sub>2</sub> observing sites used in our analysis. The 5 tagged flux regions are shown in color fill: Northern High Latitude (NHL), Northern Mid-Latitude (NML), Northern Tropics (NT), Southern Tropics (ST) and Southern Extratropics (SE). For sampling simulated CO<sub>2</sub> consistent with the tagged flux regions, we aggregate marine boundary layer sites (filled circles) into 6 latitude bands defined by the black lines.

**Figure 2: Climatological annual cycle (median) of atmospheric  $\text{CO}_2$  simulated from individual flux components ( $\text{CO}_2^{\text{NPP}}$ ,  $\text{CO}_2^{\text{HR}}$ ) between 1982 and 2010 for atmospheric sampling bands in the Northern Hemisphere (a-c) and Southern Hemisphere (d-f). Note the change in y-axis scale between the two hemispheres.**

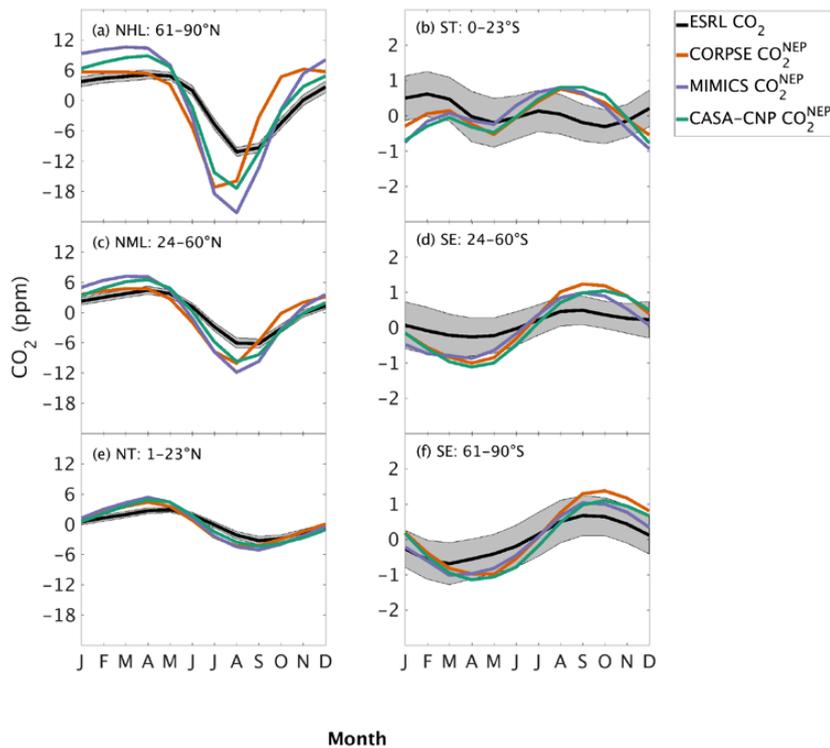

Figure 3. Climatological annual cycle (median) of CO<sub>2</sub> for observations (black) and global net ecosystem productivity flux (CO<sub>2</sub><sup>NEP</sup>, colors) between 1982 and 2010 for six atmospheric sampling bands in the Northern Hemisphere (a-c) and Southern Hemisphere (d-f). Note the change in y-axis scale between the two hemispheres. Shading on the observed line represents one standard deviation due to interannual variability in the seasonal cycle.

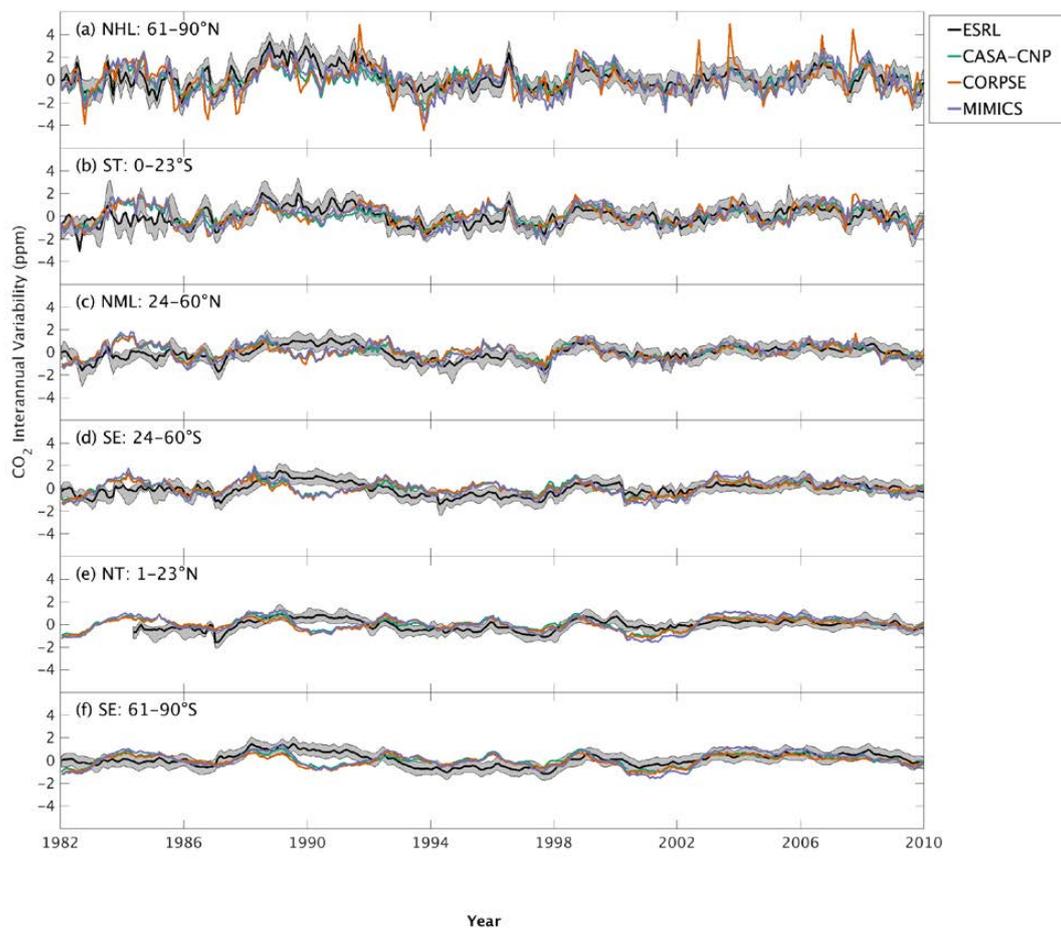

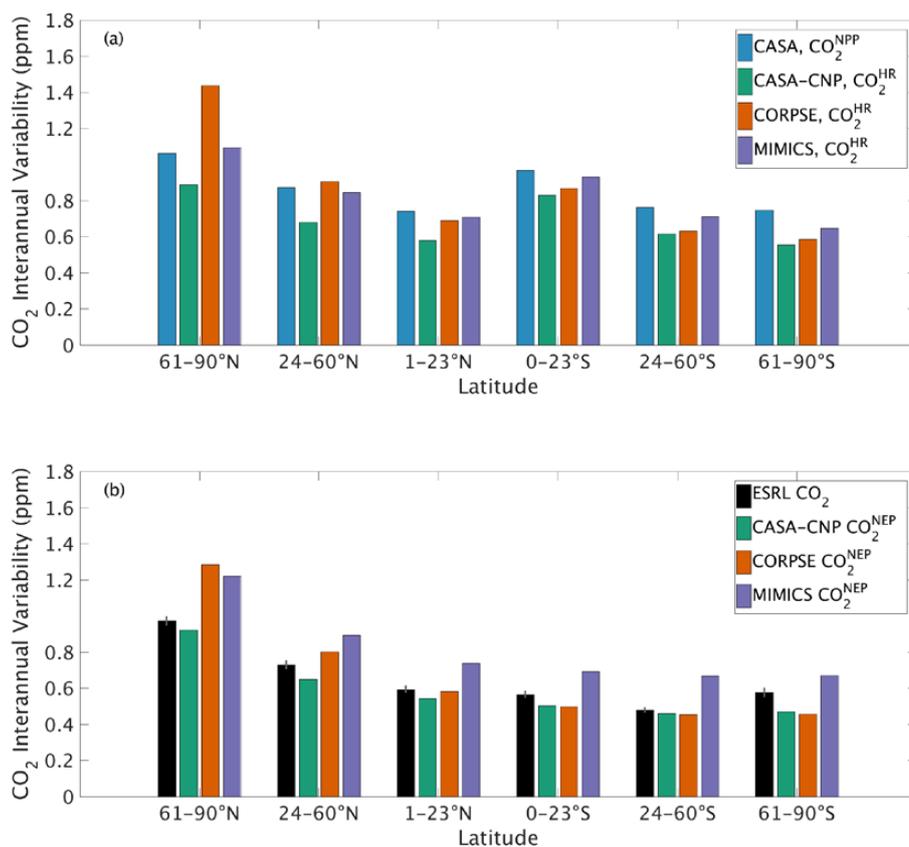

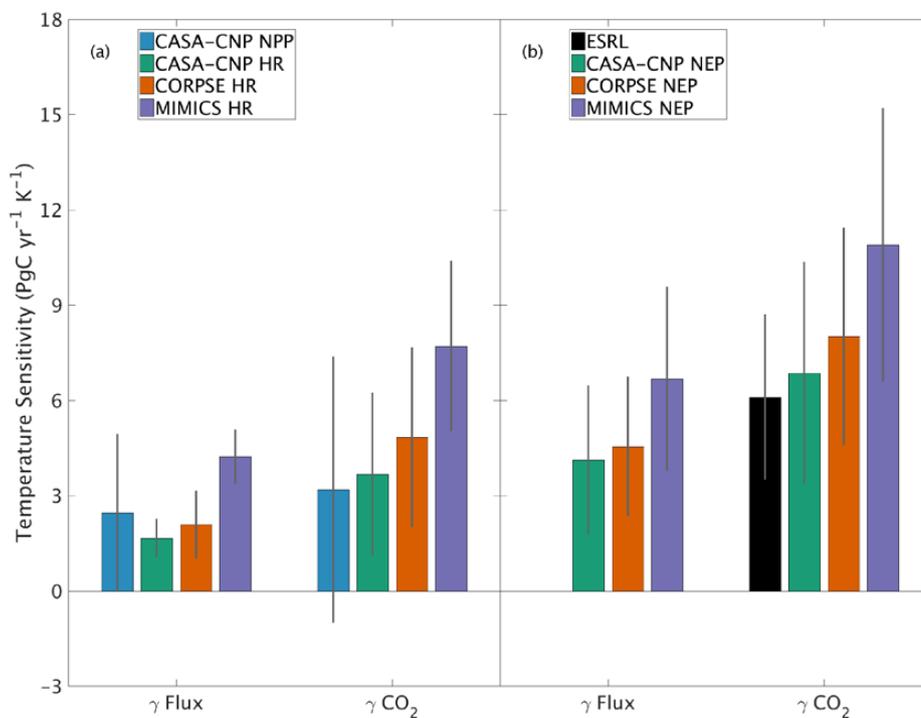

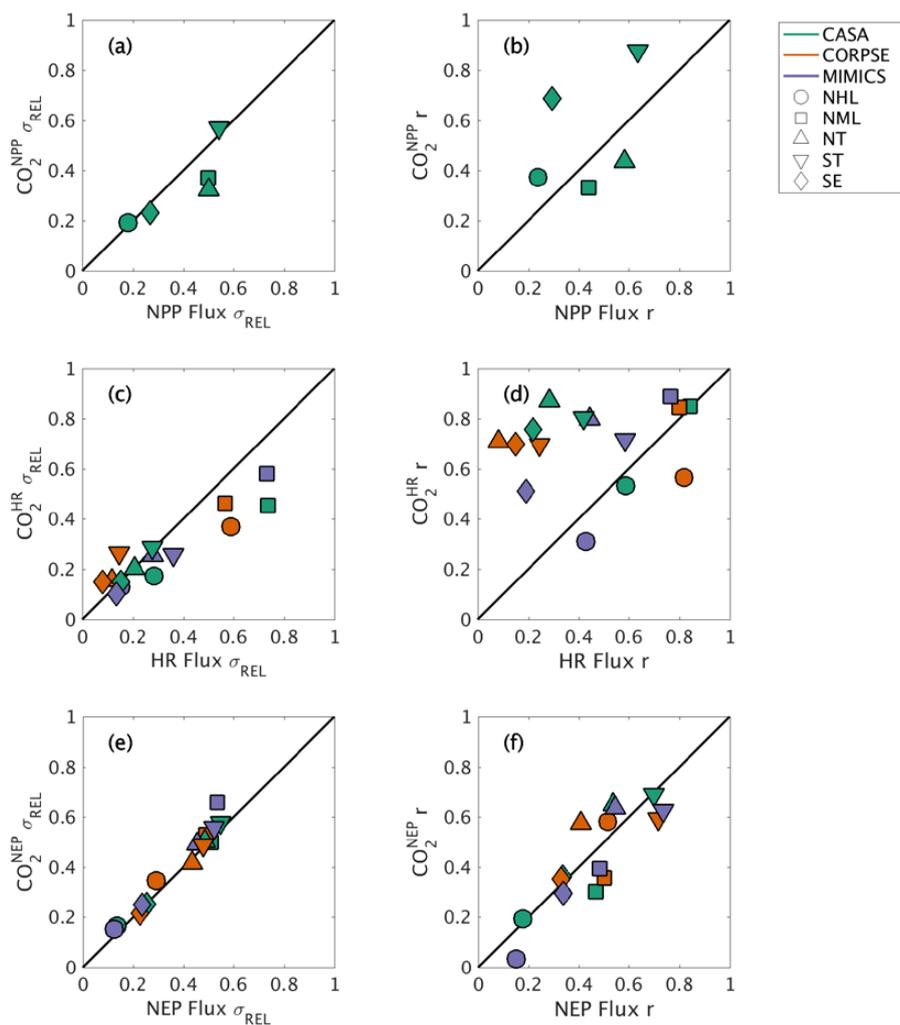

Figure 4. Interannual variability of CO<sub>2</sub> from global net ecosystem productivity (CO<sub>2</sub><sup>NEP</sup> IAV) for testbed models (colors) and marine boundary layer observations from the NOAA ESRL network (black). Gray shading outlines one standard deviation of observed CO<sub>2</sub> interannual variability. High-latitude, mid-latitude and tropical land belts are shown for the Northern Hemisphere (a-c) and Southern Hemisphere (d-f).

**Figure 5: Magnitude of CO<sub>2</sub> interannual variability** resulting from (a) individual flux components (CO<sub>2</sub><sup>NPP</sup> IAV, CO<sub>2</sub><sup>HR</sup> IAV) and (b) global net ecosystem productivity (CO<sub>2</sub><sup>NEP</sup> IAV). Observed CO<sub>2</sub> IAV from NOAA ESRL network are shown with black bars whereas colors represent simulated data. Errorbars shown on the observed IAV represent two standard deviations, calculated as the median magnitude after removing a 12 month sliding window from the IAV timeseries.

**Figure 6: Temperature sensitivity ( $\gamma$ )** calculated for interannual variability (IAV) of CASA-CNP air temperature and (a) flux IAV and corresponding  $\text{CO}_2$  growth rate anomalies, (b) NEP IAV and  $\text{CO}_2^{\text{NEP}}$  growth rate anomalies. Reference sensitivity value (black) was calculated using NOAA ESRL  $\text{CO}_2$  and CRU TS4 air temperature. Sensitivity values were calculated as the ordinary linear regression coefficient between IAV timeseries for 1982 to 2010. Errorbars represent the 95% confidence interval for coefficient values.

**Figure 7: Comparison of regional and global interannual variability (IAV) from land fluxes and resulting atmospheric CO<sub>2</sub> between 1982 and 2010.** (a, c, e) Normalized ratio taken between regional IAV and global IAV magnitude. (b, d, f) Linear correlation between regional IAV and global IAV. The scatterplot shows a direct comparison of ratio and correlation values for land flux values (x-axes) and corresponding CO<sub>2</sub> (y-axes). Shapes denote the source regions for both land fluxes and CO<sub>2</sub> response.
