16 **Abstract.** We report results from two Lagrangian drifter surveys off the Oregon coast, using  
17 continuous ship-board sensors to estimate mixed layer gross primary productivity (GPP),  
18 community respiration (CR), and net community production (NCP) from variations in biological  
19 oxygen saturation ( $\Delta O_2/Ar$ ) and optically-derived particulate organic carbon (POC). At the first  
20 drifter survey, conducted in a nearshore upwelling zone during the development of a  
21 microplankton bloom, net changes in  $\Delta O_2/Ar$  and [POC] were significantly decoupled.  
22 Differences in GPP and NCP derived from  $\Delta O_2/Ar$  ( $NCPO_2/Ar$ ) and POC ( $NCPOC$ ) time series  
23 suggest the presence of large POC losses from the mixed layer. At this site, we utilized the  
24 discrepancy between  $NCPO_2/Ar$  and  $NCPOC$ , and additional constraints derived from surface  
25 water excess nitrous oxide ( $N_2O$ ), to evaluate POC loss through particle export, DOC production  
26 and vertical mixing fluxes. At the second drifter survey, conducted in lower productivity,  
27 density-stratified offshore waters, we also observed offsets between  $\Delta O_2/Ar$  and POC-derived  
28 GPP and CR rates. At this site, however, net [POC] and  $\Delta O_2/Ar$  changes yielded closer  
29 agreement in NCP estimates, suggesting a tighter relationship between production and  
30 community respiration, and lower POC loss rates. These results provide insight into the  
31 possibilities and limitations of estimating productivity from continuous underway POC and  
32  $\Delta O_2/Ar$  data in contrasting oceanic waters. Our observations support the use of diel POC  
33 measurements to estimate NCP in lower productivity waters with limited vertical carbon export,  
34 and the potential utility of coupled  $O_2$  and optical measurements to estimate the fate of POC in  
35 high productivity regions with significant POC export.

36

## 37 **1 Introduction**

38

39 Marine primary productivity provides the main source of organic carbon to the ocean,  
40 supporting the vast majority of marine ecosystem biomass. On short time scales, a large fraction  
41 of this fixed organic carbon is converted back to  $CO_2$  through community respiration (CR). The  
42 difference between gross primary productivity (GPP) and CR – net community production  
43 (NCP) – sets an upper limit on the quantity of particulate organic carbon that can be exported out  
44 of the mixed layer as sinking particles, transferred to the dissolved organic carbon (DOC) pool,  
45 or consumed by upper trophic levels. Accurate assessment of NCP is thus critical to  
46 understanding trophic balance and the fate of organic carbon in the surface ocean. Traditional

47 incubation-based approaches to quantify GPP, net primary productivity (NPP) and CR are labor-  
48 intensive and prone to sample containment artifacts (Gieskes et al., 1979; Fogg and Calvario-  
49 Martinez, 1989; Marra, 2009; Quay et al., 2010), such that NCP remains challenging to quantify  
50 on ecologically-relevant time and space scales.

51 In recent years, automated *in situ* measurements of seawater optical properties have been  
52 increasingly used to estimate gross and net primary productivity from changes in optically-  
53 derived surface water POC concentrations (e.g., Graff et al., 2016; Burt et al., 2018). This  
54 approach is based on the relationship between POC concentrations and the particulate fraction of  
55 the beam attenuation coefficient ( $c_p$ ) (Siegel et al., 1989; Stramska and Dickey, 1992; Gardner et  
56 al., 1993; Claustre et al., 1999; Gernez et al., 2011), which can be used to resolve diurnal  
57 variations in POC. This diurnal variability results from the daytime accumulation of  
58 photosynthetically-produced organic carbon, and nighttime loss of fixed carbon through  
59 community respiration, and can thus be used to infer NCP on daily time-scales. The accuracy of  
60 this approach depends on the key assumption that variations in  $c_p$  capture most of the variability  
61 in POC concentration, and it has been shown that beam attenuation is most sensitive to particles  
62 with a diameter range of 0.5–20  $\mu\text{m}$  (Stramski and Kiefer 1991; Marra, 2002; Claustre et al.,  
63 2008). To date, most efforts to calculate daily NCP from  $c_p$  variability have focused on low  
64 productivity offshore regions, where particle sizes are small and POC losses through particle  
65 export are limited (Claustre et al., 2008; White et al., 2017). These studies have reported good  
66 agreement between optically-derived GPP estimates and independent estimates of NPP from  $^{14}\text{C}$   
67 incubations (White et al., 2017), suggesting a tight coupling between primary productivity and  
68 mixed layer POC dynamics over daily time scales.

69 Another approach to NCP quantification is based on autonomous measurements of  
70 surface water dissolved oxygen to argon ratios ( $\text{O}_2/\text{Ar}$ ). Argon normalization is used to correct  
71 for any physically-induced changes in  $\text{O}_2$  saturation, such that the derived saturation anomaly,  
72  $\Delta\text{O}_2/\text{Ar}$ , is a tracer of net biological  $\text{O}_2$  production (Kaiser et al., 2005; Tortell, 2005; Cassar et  
73 al., 2009). At steady-state, and in the absence of significant lateral advection and vertical mixing,  
74 the sea-air flux of excess biologically-produced  $\text{O}_2$  is equivalent to NCP. With the development  
75 of automated ship-board mass spectrometers, there has been a significant expansion of surface  
76 water  $\text{O}_2/\text{Ar}$  measurements. These data have been used to examine  $\text{O}_2$  variability resulting from  
77 diurnal variations of photosynthesis and respiration, and to infer NCP in a variety of oceanic

78 ecosystems (Reuer et al., 2007; Stanley et al., 2010; Tortell et al., 2011, 2014; Hamme et al.,  
79 2012; Nicholson et al., 2015; Manning et al., 2017). Recent efforts have shown that NCP  
80 estimates from  $\Delta O_2/Ar$  measurements can be corrected for vertical mixing using water column  
81  $N_2O$  measurements as a tracer (Cassar et al. 2014; Izett et al. 2018), but application of this  
82 methodology assumes that lateral advective fluxes of  $O_2$  are negligible.

83 Combined measurement of mixed layer POC and  $O_2$  dynamics holds the potential to  
84 better constrain surface water carbon budgets in biogeochemically dynamic regions at high  
85 spatial and temporal resolution. In net autotrophic systems, an increase in  $\Delta O_2/Ar$  reflects the  
86 accumulation of excess photosynthetic  $O_2$  in the mixed layer, but provides no direct insight into  
87 the fate of the resulting organic carbon. In the absence of particle export, grazing or DOC  
88 production, an increase in  $\Delta O_2/Ar$ , corrected for air-sea exchange and vertical mixing, should be  
89 matched by a parallel increase in POC accumulation measured by optical sensors. By  
90 comparison, high POC export, DOC production or grazing coupled to vertical migrations would  
91 act to decouple  $\Delta O_2/Ar$  from optically-derived POC measurements in the mixed layer.

92 Previous authors have used simultaneous  $O_2$  and  $c_p$  measurements on moorings to  
93 describe mixed layer  $O_2$  and POC dynamics in various marine environments (Stramska and  
94 Dickey, 1992; Kinkade et al., 1999; Dickey and Chang, 2002). However, few studies to date  
95 have compared estimates of primary productivity from simultaneous measurements on daily time  
96 scales. Briggs et al. (2018) and Alkire et al. (2012) were the first to explicitly combine  
97 concurrent measurements of  $O_2$  and POC from *in situ* autonomous sensors to quantify mixed  
98 layer productivity during a ~2-month Lagrangian study of the 2008 North Atlantic spring bloom.  
99 Tracking daily changes in mixed layer  $O_2$  and POC concentrations, Alkire et al. (2012)  
100 constructed a detailed budget of surface ocean organic carbon throughout the course of the  
101 bloom, using the difference between  $O_2$ -based NCP and net POC accumulation to assess the  
102 partitioning of NCP into different carbon pools (sinking particles, phytoplankton biomass, and  
103 DOC). Building on this work, Briggs et al. (2018) examined the role of respiration, particle  
104 export, and DOC production in decoupling  $O_2$  and POC dynamics through different bloom  
105 stages, demonstrating significant differences between GPP estimates derived from  $O_2$ , beam  
106 attenuation, and backscatter measurements. To our knowledge, such a detailed examination of  $O_2$   
107 and POC dynamics has not been reported for other marine systems.

108        Here, we present new results from a field study of diel variability in  $\Delta\text{O}_2/\text{Ar}$  and optical  
109 properties in two contrasting near-shore regions of the Subarctic North Pacific. Using ship-board  
110 automated sensors deployed along a Lagrangian drifter track, we resolved fine-scale temporal  
111 patterns in biological oxygen production and POC concentration in a high productivity coastal  
112 upwelling zone over the continental slope and in lower productivity stratified waters offshore.  
113 The biogeochemical differences between both sites provided a unique opportunity to compare  
114 GPP, CR and NCP estimates derived from  $\Delta\text{O}_2/\text{Ar}$  and POC in contrasting trophic regimes. We  
115 expected to observe significant differences between  $\Delta\text{O}_2/\text{Ar}$  and POC-derived GPP, CR, and  
116 NCP estimates in the higher productivity site, reflecting greater carbon export capacity and DOC  
117 production. By comparison, we hypothesized that discrepancies in these rates would be smaller  
118 at the lower productivity site, reflecting a tighter coupling between  $\text{O}_2$  and POC dynamics.

119        The results of this investigation extend the results from the 2008 North Atlantic bloom to  
120 a high productivity coastal upwelling environment where vertical mixing fluxes significantly  
121 influence the surface water mass balance. These dynamic systems play a disproportionately  
122 important role in marine biogeochemical cycling, but they pose significant challenges for  
123 interpreting time series of ecosystem metabolism. Furthermore, our study results further expand  
124 applications of a recent field approach to correcting NCP for vertical mixing (Izett et al., 2018),  
125 suggesting that this approach has significant merit in reconstructing productivity estimates from  
126 a variety of mixed layer tracers. We discuss the implications of our coupled  $\text{O}_2$ -POC  
127 measurements for understanding biological carbon cycling in marine waters, and suggest some  
128 approaches to improve the utility of these measurements for evaluating the fate of marine  
129 primary productivity across marine trophic gradients.

130

## 131 **2 Methods**

132

### 133 **2.1 Field site and Lagrangian surveys**

134

135        Field studies were conducted on board the R/V *Oceanus* in August 2017, during a  
136 transect through the Northeast Subarctic Pacific Ocean. Two Lagrangian drifters were deployed  
137 off the Oregon coast, allowing us to track diurnal patterns in phytoplankton productivity and  
138 particulate organic carbon cycling in two distinct water masses (Fig. 1). Underway temperature

139 and salinity measurements, collected by a Seabird SBE 45 thermosalinograph, as well as satellite  
140 (Aqua MODIS) and ship-based chlorophyll-a (Chl-a) observations, were used to guide the  
141 specific location and timing of the drifter deployments. Drifter 1 was deployed on 20 August  
142 2017 (~9:30 PDT), ~40 km from the Oregon coast ( $44.54^{\circ}$  N,  $124.58^{\circ}$  W), in the vicinity of an  
143 upwelling feature detected based on low sea surface temperature, and elevated salinity and [Chl-  
144 a]. The drifter, consisting of a beacon, GPS transmitter and 5 m drogue, was recovered at ~18:30  
145 on 23 August 2017 ( $44.40^{\circ}$  N,  $124.55^{\circ}$  W) for a total deployment of 3 days and 9 hours. Upon  
146 recovery, the drogue was missing, implying the potential for some erratic sub-surface drifting  
147 (discussed below). Drifter 2 was deployed approximately 200 km from shore ( $43.75^{\circ}$  N,  $126.50^{\circ}$  W)  
148 in a relatively warm and low salinity water mass, with low Chl-a concentrations. This  
149 second drifter was deployed at ~07:45 on 24 August 2017, and was recovered after 2 days and  
150 six hours at ~14:00 on 26 August 2017 at  $43.80^{\circ}$  N,  $126.99^{\circ}$  W. Because the *Oceanus* lacks a  
151 dynamic positioning system, the ship was not always able to perfectly track the drifter locations.  
152 To correct for these positional offsets, we discarded any observations obtained when the ship  
153 was more than 1.5 km away from the drifter location. This filtered dataset resulted in underway  
154 measurements (Sect. 2.2) every ~15 minutes during the two drifter deployments, yielding 325  
155 and 218 quality-controlled underway observations for drifters 1 and 2, respectively.

156

## 157 **2.2 Underway measurements**

158

159 Continuous underway measurements of surface seawater optical properties were  
160 collected using Seabird (formerly Wetlabs) ECO-BB3 and ac-s sensors, following the methods  
161 outlined in detail by Burt et al. (2018). Water was collected from the ship's seawater supply  
162 system with a nominal intake of 5 m depth. Our instrument package included fully automated  
163 data collection, and hourly filtered blanks ( $0.2\mu\text{m}$ ), which provided measurements of dissolved  
164 seawater optical properties used to infer particulate absorption ( $a_p$ ) and beam attenuation ( $c_p$ ) at  
165 82 wavelengths between 400 and ~735 nm, and backscatter ( $b_{bp}$ ) at 470 nm, 532 nm, and 650  
166 nm. The BB-3 and ac-s measurements were binned into 1-minute intervals. Prior to binning, the  
167 absorption and beam attenuation data were first sub-sampled every 50 data acquisition cycles  
168 (~12.5 seconds) to enable faster processing time. The optical measurements were accompanied  
169 by continuous surface photosynthetically active radiation (PAR) and windspeed data obtained

170 from a Biospherical QSR-220 PAR sensor and Gill WindObserver II ultrasonic wind sensor  
171 mounted on the ship's bow.

172 Chlorophyll-a (Chl-a) concentrations were derived from the particulate absorption line  
173 height at 676 nm ( $a_{LH}$ ) (Roesler and Barnard, 2013). Five-minute match-ups between underway  
174  $a_{LH}$  and discrete filtered [Chl-a] measurements from the entire cruise transect (Sect. 2.4) were  
175 used to derive a best fit coefficient for the linear relationship between  $a_{LH}$  and [Chl-a] ( $r^2=0.87$ ,  
176  $n=58$ ,  $p<0.01$ ). Particulate organic carbon (POC) concentrations ( $\mu\text{g/L}$ ) were derived from  
177 particulate beam attenuation at 660 nm ( $c_p,660$ ), using the empirical model in Graff et al. (2015).  
178 Similarly, phytoplankton organic carbon ( $C_{ph}$ ) concentrations were calculated, using an empirical  
179 relationship between particulate backscatter at 470 nm ( $b_{bp,470}$ ) and  $[C_{ph}]$  in  $\mu\text{g/L}$  (Graff et al.,  
180 2015). We used a limited set of 5m discrete measurements ( $n=6$ ; Sect. 2.4) to evaluate the  
181 relationship between POC concentrations and  $c_p$  at 660nm, and the applicability of the Graff et  
182 al. (2015) model to our observations. As shown in Fig. S1, the POC measurements were  
183 significantly correlated to  $c_p$  ( $r^2=0.88$ ,  $p<0.05$ ), with a slope and intercept of  $391.6 \pm 201.6$  and  
184  $36.7 \pm 79.1$ , respectively. This slope was not significantly different from that of the Graff et al.  
185 algorithm (419.8) although our y-intercept was higher. Notwithstanding the relatively small  
186 number of discrete POC samples, and some scatter around the regression line, the similarity of  
187 our POC- $c_p$  calibration to that reported by Graff et al. (2015) suggests that our optically-derived  
188 POC estimates are reasonably robust.

189 To obtain information on the particle size spectrum, we derived the wavelength-  
190 dependent slope of particulate backscatter by fitting the three  $b_{bp}$  coefficients (470 nm, 532 nm,  
191 650 nm) to an exponential equation (Stramska et al., 2003; Loisel et al., 2006; Kostadinov et al.,  
192 2009). Finally, to assess interference of inorganic minerals on POC, and  $C_{ph}$  variability, we  
193 calculated the wavelength-specific bulk refractive index ( $\eta_p$ ) from backscatter/total scatter ratios  
194 ( $\frac{b_{bp}}{c_p - a_p}$ ) and the wavelength-dependent  $c_p$  slope, following the approach of Boss et al. (2001),  
195 Twardowski et al. (2001) and Sullivan et al. (2005).

196 In addition to optical measurements, the seawater biological oxygen saturation anomaly  
197 ( $\Delta\text{O}_2/\text{Ar}$ ) was measured at a ~20 second resolution using a membrane inlet mass spectrometer  
198 connected to the ship's seawater intake. The seawater ratio of dissolved  $\text{O}_2$  and Ar was  
199 determined by diverting a continuous flow of water across a dimethylsilicone membrane  
200 interfaced with a Hiden Analytical HAL20 triple filter quadropole mass spectrometer. The  $\text{O}_2/\text{Ar}$

201 ratio of air-equilibrated standards ( $[O_2/Ar]_{eq}$ ), incubated at ambient sea surface temperature, was  
202 measured every two hours. Values of  $\Delta O_2/Ar$  were thus calculated as the percent deviation of  
203 seawater  $O_2/Ar$  measurements from the air-equilibrated ratio, using  $\Delta O_2/Ar = 100\% *$   
204  $([O_2/Ar]_{meas} / [O_2/Ar]_{eq} - 1)$  (Tortell, 2005; Tortell et al., 2011).

205

## 206 **2.3 Mixed layer depth**

207

208 Over the course of both drifter deployments, we conducted regular sampling casts (every  
209 six to ten hours) to examine depth profiles of seawater hydrography and biogeochemical  
210 variables. Temperature, salinity, dissolved  $O_2$  concentrations and Chl-a fluorescence profile data  
211 from the CTD casts were measured by a Seabird-SBE 38 temperature sensor, Seabird-SBE 4  
212 conductivity sensor, SBE 43 dissolved  $O_2$  sensor, and a Seabird ECO fluorometer, respectively,  
213 and binned into 1 m intervals. Vertical profiles at the drifter 1 site showed relatively weak  
214 density stratification, likely as a result of recent upwelling. For this reason, we estimated mixed  
215 layer depths ( $z_{mld}$ ) based on visible inflection points in the dissolved  $[O_2]$ , fluorescence and  
216 density profiles, assuming that dissolved  $O_2$  concentrations and fluorescence are relatively  
217 uniform in the mixed layer. Within a single CTD cast, mixed layer depths varied by up to 28%  
218 across all three profile measurements. The [Chl-a] fluorescence profiles had the most well-  
219 defined inflection points, and we thus used these data to estimate  $z_{mld}$  at all casts. Excluding  
220 fluorescence profiles from the first day (Sect. 3.1), and two casts at 6am and midnight on second  
221 and third 24-hour intervals, respectively, which displayed relatively noisy density profiles, an  
222 average  $z_{mld}$  value ( $19 \pm 2$  m) was derived and applied to all subsequent analyses.

223 In comparison to the drifter 1 site, CTD cast profiles during drifter deployment 2 showed  
224 larger density gradients. We thus computed  $z_{mld}$  using a density difference criterion of 0.25  
225 kg/m<sup>3</sup> (Thomson et al., 2003; de Boyer Montégut et al., 2004) from median values within the  
226 upper-most 4–6 m of the profile. We found that this critical density criterion was necessary to  
227 capture the depth of inflection in  $O_2$  and [Chl-a]. In all CTD casts except one, density difference-  
228 based  $z_{mld}$  values were within 5 meters of the values derived from the inflection points on density  
229 profiles. An average  $z_{mld}$  value estimated from the density-difference approach ( $22 \pm 5$  m) was  
230 applied to all subsequent analyses.

231

232 **2.4 Discrete samples**

233

234 Concentrations of phosphate ( $[PO_{43-}]$ ), dissolved silica ( $[SiO_2]$ ), and nitrate and nitrite  
235 ( $[NO_3^- + NO_2^-]$ , were measured in seawater samples collected from daily Niskin bottle casts.  
236 Following collection, nutrient samples were filtered through 0.2  $\mu$ m pore polycarbonate  
237 membranes and immediately frozen at -80°C on board the ship. These samples were stored at  
238 -20°C until subsequent colorimetric laboratory analyses (Murphy and Riley, 1962; Riley, 1977)  
239 with a Lachat QuikChem 8500 Series 2 Flow Injection Analysis System.

240 Concentrations of nitrous oxide ( $N_2O$ ) were measured in discrete samples collected in  
241 Niskin bottles during both drifter deployments (Fig. S2), following methods outlined in (Capelle  
242 et al., 2015). These  $N_2O$  measurements were used to correct NCP estimates for vertical mixing  
243 (see Sect. 2.6), following the approach described by Cassar et al. (2014) and Izett et al. (2018).  
244 Profile samples from the first day of drifter deployment 1 (August 20) were omitted from  
245 calculations, as underway surface temperature and salinity measurements indicated intrusion of  
246 an external water mass (further discussed in Sect. 3.1) (Fig. S3). Three profiles collected from  
247 12:00 (PDT) CTD casts during the following three days of the deployment (August 21, 22 and  
248 23) were applied to the NCP mixing correction at drifter station 1 (Sect. 2.6.1).

249 Surface (~5 m) discrete seawater samples were collected either from Niskin bottles or  
250 from the ship's surface seawater intake system for HPLC analysis of Chl-a concentrations and  
251 other phytoplankton pigments. Single or duplicate samples were filtered onto 25 mm GF/F  
252 filters, flash-frozen in liquid nitrogen, and stored at -80°C until analysis, following the  
253 methodology described in Schuback et al. (2016). Additional samples were collected from the  
254 seawater intake for size-fractionated Chl-a analysis (Zeng et al., 2018). These samples were  
255 filtered through stacked 47 mm filters (0.2  $\mu$ m, 2  $\mu$ m and 20  $\mu$ m pore size) separated by a mesh  
256 spacer. Filtered samples were extracted in 5 mL of 90% acetone at 4°C until analysis within 24–  
257 48 hours using a Turner Trilogy Fluorometer on board the ship.

258 Discrete samples for POC analysis were collected at two depths from several CTD casts.  
259 Surface samples were collected at both drifter sites from 5 m depth, while deeper samples were  
260 collected at near the base of the euphotic zone (~1% PAR), corresponding to 40–60 m at drifter  
261 site 1, and 100–120 m at drifter site 2. POC samples (~1–4 L) were filtered through a pre-  
262 combusted (450 °C) Whatman GF/F filter (nominal pore size ~ 0.7  $\mu$ m), and stored at -80°C

263 until laboratory analysis. Prior to analysis, samples were thawed and dried at 50°C overnight,  
264 fumigated with concentrated hydrochloric acid for 48 hours, and dried again at 50°C overnight.  
265 POC concentrations in samples (and blank combusted filters treated as described above) were  
266 quantified using an *Elementar* vario MICRO cube CHNS analyzer. Blank-corrected discrete  
267 POC concentrations were used to validate application of the [POC] model in Graff et al. (2015)  
268 to our underway  $c_p$  data (Sect. 2.2; Fig. S1).

269

## 270 **2.5 Net Primary Productivity**

271

272 Daily-integrated net primary productivity (NPP) was calculated in two ways. First,  
273 carbon uptake was determined from 24-hour  $^{14}\text{C}$ -incubations with 5 m triplicate seawater  
274 samples collected from early morning CTD casts. Measurements were made on two different  
275 mornings during drifter deployment 1 and on one morning during drifter deployment 2. The  
276 measurements were conducted following the protocol outlined in Hoppe et al. (2017). Depth-  
277 integrated NPP was calculated by multiplying the derived 24-hour volumetric carbon fixation  
278 rate by the average mixed layer depth for the respective drifter period.

279 Second, daily-integrated net primary productivity was also estimated as a product of  $[\text{C}_{\text{ph}}]$   
280 values derived from  $b_{\text{bp}}$ , and phytoplankton growth rates according to the carbon-based  
281 production model (CbPM) (Behrenfeld et al., 2005; Westberry et al., 2008; Graff et al., 2016;  
282 Burt et al., 2018). In these calculations, daily-averaged  $[\text{C}_{\text{ph}}]$ ,  $[\text{Chl-a}]/[\text{C}_{\text{ph}}]$ , and mixed layer  
283 irradiance ( $E_g$ ) calculated from the MODIS-derived surface PAR matched to drifter location  
284 were used to calculate growth rates and NPP every 24 hours. Chlorophyll-a concentrations were  
285 derived from absorption line height,  $[\text{C}_{\text{ph}}]$  values from  $b_{\text{bp}}$  (Sect. 2.2), and light extinction  
286 coefficients ( $K_d$ ) obtained from  $[\text{Chl-a}]$  to calculate  $E_g$  (Morel et al., 2007). An average mixed  
287 layer depth for each drifter period was applied to estimate mixed layer NPP (Sect. 2.3).

288

## 289 **2.6 Quantification of GPP, CR and NCP**

290

291 Gross primary productivity (GPP), community respiration (CR) and net community  
292 production (NCP) rates were calculated based on linear regressions of  $\Delta\text{O}_2/\text{Ar}$  and POC against  
293 time (dt in units of days) over subsequent day (D) and night (N) intervals during both drifter

294 deployments. Daytime was defined as the period during which PAR levels exceeded  $20 \mu\text{mol}$   
295 quanta  $\text{m}^{-2}\text{s}^{-1}$ . The average length of the day-time period was  $13.6 \pm 0.14$  hours over the two  
296 drifter deployments. In the following sections,  $t_d$  represents the day length normalized to 24  
297 hours, and  $t_n$  analogously represents the fractional night length, equivalent to  $1-t_d$ . All daily rates  
298 were integrated through the mixed layer using the average  $z_{\text{mld}}$  for each drifter period, as  
299 described in Sect. 2.3.

300

### 301 **2.6.1 O<sub>2</sub>/Ar-derived rates**

302

303 Quantification of  $\text{GPP}_{\text{O}_2/\text{Ar}}$ ,  $\text{CRO}_{\text{O}_2/\text{Ar}}$ , and  $\text{NCP}_{\text{O}_2/\text{Ar}}$  rates from diurnal cycles in  $\Delta\text{O}_2/\text{Ar}$   
304 (Ferrón et al., 2015) requires corrections for gas exchange and, potentially, vertical mixing  
305 fluxes. For these calculations, we first computed the rate of change in  $\Delta\text{O}_2/\text{Ar}$  ( $d\text{O}_{2\text{Bio}}/dt$ ) using  
306 linear regression analysis within successive day or night intervals. We then derived estimates for  
307 the air-sea gas exchange ( $J_{\text{ex}}$ ) and vertical mixing fluxes ( $F_{\text{mix}}$ ) over the respective time interval  
308 to isolate the NCP contribution to observed  $\Delta\text{O}_2/\text{Ar}$  changes (Izett et al., 2018; Tortell et al.,  
309 2014). A negative  $J_{\text{ex}}$  indicates net transfer of  $\text{O}_2$  from the atmosphere to the mixed layer, while a  
310 negative  $F_{\text{mix}}$  indicates vertical transfer of  $\Delta\text{O}_2/\text{Ar}$ -depleted to the mixed layer, both in units of  
311  $\text{mmol m}^{-2} \text{d}^{-1}$ . Gross  $\text{O}_2$  production rates were converted into carbon units using a photosynthetic  
312 quotient (PQ) for new production of 1.4 for drifter period 1 calculations and a PQ for regenerated  
313 production of 1.1 for drifter period 2 (Laws, 1991). Community respiration rates were converted  
314 into carbon units using the same PQ values, and considered constant over each respective day  
315 length period (i.e.,  $t_d + t_n$ ). This assumption of an equivalent respiratory quotient (RQ) and PQ  
316 within each drifter period is reasonable given the wide range of respiration ratios reported in  
317 prior studies across a range of oceanic environments (Anderson and Sarmiento, 1994; Robinson  
318 and Williams, 1999; Robinson et al., 1999; Hedges et al., 2002; Robinson et al., 2002; Lønborg  
319 et al., 2011; Daneri et al., 2012; Fernández-Urruzola et al., 2014). Moreover, Robinson and  
320 Williams (1999) estimated lower RQ values at lower productivity stations in the Arabian Sea,  
321 suggesting that it is reasonable to assume a lower RQ value (equivalent to  $\text{PQ} = 1.1$ ) at drifter site  
322 2.

323

324  $NCP_{\frac{O_2}{Ar}, D \text{ or } N} = z_{mld} \frac{dO_{2bio}}{dt} \Big|_{D \text{ or } N} + J_{ex} \Big|_{D \text{ or } N} - F_{mix}$  (1)

325

326  $GPP_{O_2/Ar} = \frac{t_d(NCP_{\frac{O_2}{Ar}, D} - NCP_{\frac{O_2}{Ar}, N})}{PQ(t_d + t_N)}$  (2a)

327  $CR_{O_2/Ar} = \frac{NCP_{\frac{O_2}{Ar}, N}}{PQ(t_d + t_N)}$  (2b)

328  $NCP_{\frac{O_2}{Ar}, 24hr} = \frac{t_d NCP_{\frac{O_2}{Ar}, D} + t_N NCP_{\frac{O_2}{Ar}, N}}{PQ(t_d + t_N)}$  (2c)

329

330  $O_{2bio} = \Delta \frac{O_2}{Ar} \frac{1}{100\%} O_{2eq}$  (3)

331

332  $J_{ex} = k_{o_2} O_{2bio}$  (4)

333

334  $F_{mix, O_2/Ar} = k_{mix} \frac{dO_{2bio}}{dz} = k_{N2O} N_2 O_{bio} \frac{dO_{2bio}}{dN2O_{bio}}$  (5)

335

336  $k_{mix} = k_{N2O} N_2 O_{bio} \left( \frac{dN2O_{bio}}{dz} \right)^{-1}$  (6)

337

338  $N_2 O_{bio} = N_2 O_{meas} - N_2 O_{eq} - N_2 O_{thermal}$  (7)

339

340 Equilibrium concentrations of O<sub>2</sub> and N<sub>2</sub>O ([O<sub>2</sub>]<sub>eq</sub> and [N<sub>2</sub>O]<sub>eq</sub>) were calculated using the  
 341 salinity and temperature-dependent equations of Garcia and Gordon (1992) and Weiss and Price  
 342 (1980), respectively, and sea surface temperature and salinity from the ship's thermosalinograph.  
 343 Estimates of surface excess N<sub>2</sub>O saturation, [N<sub>2</sub>O]<sub>bio</sub>, included a heat flux correction to account  
 344 for solubility changes (Keeling and Shertz, 1992; Jin et al., 2007; Izett et al., 2018). Non-  
 345 weighted piston velocities (k<sub>O<sub>2</sub></sub> and k<sub>N<sub>2</sub>O</sub>; units of m d<sup>-1</sup>) were calculated using the diffusive air  
 346 sea gas flux and Schmidt number parameterizations of Wanninkhof (2014) and Raymond et al.  
 347 (2012), and ship-based wind speed data 10 m above the sea surface. Daytime and nighttime  
 348 estimates for the gas exchange term, J<sub>ex</sub>, were calculated using day/night average [O<sub>2</sub>]<sub>eq</sub>, ΔO<sub>2</sub>/Ar,  
 349 and k<sub>O<sub>2</sub></sub> values. Vertical gas gradients ( $\frac{dN2O_{bio}}{dz}$  and  $\frac{dO_{2bio}}{dN2O_{bio}}$ ) were estimated from our discrete

350 N<sub>2</sub>O measurements and Rosette O<sub>2</sub> profiles over the upper 100 m of the water column, following  
351 Izett et al. (2018).

352 At drifter site 1, daily F<sub>mix</sub> values were calculated using daily [N<sub>2</sub>O]<sub>bio</sub>, daily vertical  
353 gradient and daily average k<sub>N2O</sub> values, and converted to carbon units using a PQ of 1.4.  
354 Denitrification should not have been a source of N<sub>2</sub>O within the upper 100 m of the water  
355 column because measured O<sub>2</sub> concentrations were consistently greater than the threshold value  
356 of ~50 mmol m<sup>-3</sup> (e.g., Hopkinson and Barbeau, 2007). Likewise, we assumed no lateral  
357 advection of N<sub>2</sub>O into drifter site 1, as there were little differences in the mixing ratio  
358 [O<sub>2</sub>]<sub>bio</sub>/[N<sub>2</sub>O]<sub>bio</sub> across profile measurements (Fig. S2). While the August 22 CTD cast did  
359 exhibit a more anomalous [O<sub>2</sub>]<sub>bio</sub>/[N<sub>2</sub>O]<sub>bio</sub> profile relative to the other two cast profiles, inclusion  
360 of these data had little impact on the vertical mixing correction. At drifter site 2, we assumed that  
361 vertical mixing was negligible due to the presence of strong density stratification, and therefore  
362 did not calculate a mixing flux correction at this site. In any case, the presence of a sub-surface  
363 O<sub>2</sub> maximum (Fig. S2) at this site would limit the application of the N<sub>2</sub>O correction (Izett et al.,  
364 2018).

365

## 366 2.6.2 Optically-derived rates

367

368 We used the approach of Claustre et al. (2008) and White et al. (2017) to calculate daily-  
369 integrated GPP<sub>POC</sub>, CR<sub>POC</sub>, and NCP<sub>POC</sub> from daytime and nighttime changes in POC (dPOC/dt),  
370 derived from linear regressions of POC concentrations against time through day and night  
371 intervals. In certain ocean environments, NCP<sub>POC</sub> will not equate to NCP<sub>O<sub>2</sub>/Ar</sub> as a result of  
372 additional POC sinks, including export, grazing and DOC production. Under these conditions,  
373 CR<sub>POC</sub> includes these loss terms, and therefore NCP<sub>POC</sub> more accurately reflects net POC  
374 accumulation, as will be discussed further in Sect. 4. Nonetheless, for consistency with previous  
375 studies, we use the term NCP<sub>POC</sub> to describe the quantities computed in Eq. 8.

376

$$377 NCP_{POC,D \text{ or } N} = z_{mld} \left. \frac{dPOC}{dt} \right|_{D \text{ or } N} - F_{mix(POC)} \quad (8)$$

378

$$379 GPP_{POC} = \frac{t_d(NCP_{POC,D} - NCP_{POC,N})}{t_d + t_N} \quad (9a)$$

380  $CR_{POC} = \frac{NCP_{POC,N}}{t_d + t_N}$  (9b)

381  $NCP_{POC,24hr} = \frac{t_d NCP_{POC,D} + t_N NCP_{POC,N}}{t_d + t_N}$  (9c)

382

383 The presence of significant upwelling at drifter site 1 provides additional complexity in the  
 384 estimate of NCP from optically-derived POC measurements. In particular, vertical transport of  
 385 particle-deficient seawater from below the mixed layer into the surface could dilute the  $c_p$  signal  
 386 used to derive POC concentrations (Stramska and Dickey, 1994). To address this, we applied the  
 387 vertical mixing term,  $k_{mix}$ , derived from Eq. (6) to estimate the average daily dilution effect on  
 388 mixed layer POC concentrations through drifter period 1:

389

390  $F_{mix,POC} = k_{mix} \frac{dPOC}{dz}$  (10)

391

392 A negative  $F_{mix,POC}$  indicates transfer of [POC]-deficient seawater into the mixed layer. The term  
 393  $d[POC]/dz$  represents the vertical gradient in [POC], derived from daily average POC  
 394 concentrations measured in Rosette samples at 5 m and near the base of the euphotic zone, below  
 395 the mixed layer (40–60 m) (Sect. 2.4). The  $dz$  term was calculated as the difference between the  
 396 average mixed layer depth from all CTD casts and the daily average shallowest depth of  
 397 minimum particle concentrations based on beam transmission profiles. At drifter site 2,  $F_{mix,POC}$   
 398 was considered negligible (Sect. 2.6.1) due to the high density stratification of the water column.

399 In total, three sets of 24-hour GPP, CR and NCP values were calculated during the drifter  
 400 1 deployment from the three pairs of consecutive day and night intervals, starting with the first  
 401 night interval and ending with the last day interval. We excluded the first day-time interval from  
 402 our calculations, due to the erratic salinity values observed during the first day of this drifter  
 403 deployment (Sect. 3.1; Fig. S3). Because the drifter period was terminated prior to sunset, the  
 404 last day interval was 1.6 hours shorter than the average daytime duration. For the second drifter  
 405 deployment, two sets of GPP, R and NCP values were calculated from consecutive day and night  
 406 intervals, starting with the first daytime interval and ending with the last nighttime interval. The  
 407 initiation of the drifter period occurred after sunrise, so the first day interval was 1.1 hours  
 408 shorter than the average daytime duration.

409

410 **2.6.3 Integration time scales**

411

412 The approach to calculating NCP on the basis of linear regressions utilizes the high  
413 temporal resolution of our data set. We compared our results from Sects. 2.6.1 and 2.6.2 to NCP  
414 values calculated using several of other integration time scales. Following studies that have  
415 calculated daily NCP values from “instantaneous” rates of change (e.g., hourly rates in Hamme  
416 et al. (2012) and Tortell et al. (2014) ), we divided our NCP calculations into shorter increments.  
417 Given that the average measurement interval was ~15 minutes (after removing values where the  
418 ship was not sufficiently close to the drifter; Sect. 2.1), we calculated NCP within three-hour  
419 intervals:

420

421 
$$NCP_{O_2/Ar,3hr} = \frac{3}{24} \left[ z_{mld} \left( \frac{dO_{2bio}}{dt} \right)_{3hr} + J_{ex,3hr} \right] / PQ \quad (11a)$$

422 
$$NCP_{POC,3hr} = z_{mld} \left[ \frac{3}{24} \left( \frac{dPOC}{dt} \right)_{3hr} \right] \quad (11b)$$

423

424 For each day of the drifter periods, eight consecutive three-hour NCP values were summed into a  
425 24-hour period to yield daily NCP estimates. We then applied the vertical mixing correction to  
426 these daily estimates (refer to Eqs. 5, 6, 10), since the correction was only available on a daily  
427 basis given the lower sampling resolution of [N<sub>2</sub>O] and [POC] profiles. We also calculated daily  
428 NCP using the difference between ΔO<sub>2</sub>/Ar or [POC] between two time points at the beginning  
429 and end of each 24-hour period (similar to the approach in Alkire et al. (2012); and Barnes and  
430 Antoine (2104)). Finally, we calculated a single daily NCP rate per drifter period using the linear  
431 regression of ΔO<sub>2</sub>/Ar and [POC] against time over the entire drifter deployment. For these latter  
432 two approaches, the 24-hour average and drifter-period average of relevant terms in Eqs. 1-9  
433 were used to calculate NCP, and a PQ was used to convert O<sub>2</sub> to carbon units.

434

435 **2.7 Error analysis**

436

437 Errors for all estimates of net primary productivity (CbPM-NPP, <sup>14</sup>C-NPP) and net  
438 community production (NCP<sub>O<sub>2</sub>/Ar</sub>, NCP<sub>POC</sub>) were propagated from uncertainties associated with  
439 all variables used for the computations. Error estimates for time-averaged variables were

440 generally represented by the standard deviation, as we assumed that this significantly exceeded  
441 the error of the individual measurements prior to averaging. The uncertainty in  $z_{mld}$ , derived from  
442 the standard deviation of mixed layer depths across individual CTD casts, was 2 m for drifter site  
443 1 and 5 m for drifter site 2 (Sect. 2.3). Small uncertainties in  $t_D$  and  $t_N$  were calculated as the  
444 standard deviations of all day or night lengths measured during both drifter periods (0.14 and  
445 0.10 hours, respectively). Mean relative errors of [Chl-a] and [C<sub>ph</sub>] from Burt et al. (2018), and  
446 mean relative standard deviations in MODIS-derived daily surface PAR values were propagated  
447 to calculate the error in CbPM-NPP. The standard deviations of triplicate 24-hour  $^{14}\text{C}$  uptake  
448 incubations were propagated to calculate the error in  $^{14}\text{C}$ -NPP estimates. The uncertainties in  
449  $^{14}\text{C}$ -NPP values are likely underestimated, as they do not account for bottle effects, as discussed  
450 in Sect. 4.3.

451 For calculating error in NCP, uncertainties in  $dO_{2\text{bio}}/dt$  and  $d\text{POC}/dt$  were derived from  
452 the confidence interval of the best-fit slope of linear regression of each variable against time.  
453 Standard deviations of averaged  $\Delta O_2/\text{Ar}$ ,  $k_{O_2}$ , and  $k_{N_2O}$  values, and the mean relative errors of  
454  $[\text{N}_2\text{O}]_{\text{meas}}$ ,  $[\text{N}_2\text{O}]_{\text{Eq}}$ ,  $[\text{N}_2\text{O}]_{\text{thermal}}$ , and  $\frac{dO_{2\text{bio}}}{dN_2O_{\text{bio}}}$  reported in Izett et al. (2018), were propagated into  
455 the mixing correction errors for  $\text{NCP}_{\text{O}_2/\text{Ar}}$  and  $\text{NCP}_{\text{POC}}$ . The error in  $\frac{dN_2O_{\text{bio}}}{dz}$  was calculated as the  
456 confidence interval of the best fit slope extracted from a linear regression of pooled drifter 1  
457  $[\text{N}_2\text{O}]_{\text{bio}}$  values against depth. In propagating the error associated with the  $d\text{POC}/dz$  term in Eq.  
458 10, we have included the standard deviation of the minimum transmissivity depth across daily  
459 CTD casts and the standard deviation of POC measured in multiple blank combusted filters  
460 (Sect. 2.4). Finally, to account for variability in the PQ and RQ, we assumed an uncertainty of  
461 0.1, following the range reported Laws (1991).

462

### 463 **3 Results**

464

#### 465 **3.1 Water mass properties**

466

467 Ship-board underway measurements revealed clear differences in hydrographic and  
468 biogeochemical characteristics between the water masses sampled by the two drifters. Surface  
469 water properties at drifter site 1 reflected the presence of a recently upwelled water mass that was

470 relatively cold ( $11.8 \pm 0.4$  °C), saline ( $32.6 \pm 0.04$  g/kg), and nutrient-rich (Figs. 1, S3, S4). The  
471 Pacific Fisheries Environmental Laboratory's coastal upwelling index at 45°N, 125°W was  
472 positive throughout drifter period 1. In contrast, the water mass tracked by the second drifter  
473 deployment was warmer ( $17.5 \pm 0.1$  °C) and fresher ( $31.8 \pm 0.05$  g/kg), with lower average mixed  
474 layer nutrient concentrations.

475 Examination of surface water hydrographic properties during the two drifter deployments  
476 suggest that both drifters tracked a relatively homogenous water mass, excluding a period of  
477 salinity variability during the first day of drifter deployment 1, and several transient temperature  
478 and salinity excursions after the second night of this deployment (grey patches in Fig. S3). These  
479 features indicate potential intrusion of external water masses, possibly a result of loss of the  
480 drifter drogue (Sect. 2.1). Observations during these periods were thus removed from the data set  
481 prior to analysis. Outside of these intervals, variability in salinity (drifter 1: 32.5–32.7 g/kg;  
482 drifter 2: 31.8–31.9 g/kg) was small during both drifter deployments. Variability in sea surface  
483 temperature was also limited (drifter 1: 11.2–13.0 °C, drifter 2: 17.3–17.7 °C), and largely  
484 reflected a diurnal variation of warming and cooling, which was particularly evident for drifter  
485 period 2.

486 Temporal differences in CTD cast profiles point to some variation in mixed layer depth  
487 ( $z_{mld}$ ) during both drifter deployments. In general, there were no multi-day trends or regular  
488 diurnal patterns in  $z_{mld}$  through both periods, suggesting that transient shifts in water column  
489 turbulence likely contributed to changes in the shape of temperature, salinity, dissolved oxygen  
490 and fluorescence profiles. Average  $z_{mld}$  values, calculated over each drifter period, had relatively  
491 low relative standard deviations (<25%) and were applied to all subsequent calculations (Sect.  
492 2.3). A sensitivity analysis, not shown, indicated that the choice of mixed layer depth using  
493 different criteria (i.e., fluorescence profiles, density profiles and the density difference criterion)  
494 and different time scales of integration (i.e., daytime/nighttime, 24 hour, and multi-day) did not  
495 significantly impact the results discussed below.

496 Average mixed layer nutrient concentrations fluctuated during both drifter deployments,  
497 but did not exhibit regular diurnal cycles (Fig. S4). At drifter site 1, concentrations ranged from  
498 0.74 to 0.85 µM phosphate, 7.8 to 9.0 µM nitrate and nitrite, and 9.2 to 11.1 µM dissolved silica,  
499 excluding day 1 of the drifter deployment and anomalously high concentrations measured during  
500 a noisy CTD cast at midnight on the last day of the deployment. Excluding these outliers, a

501 significant ( $p < 0.05$ ) linear regression of each nutrient concentration against time revealed that  
502 phosphate concentrations decreased by  $\sim 0.07 \mu\text{M}$ ,  $[\text{NO}_3^- + \text{NO}_2^-]$  decreased by  $0.9 \mu\text{M}$ , and  
503  $[\text{SiO}_2]$  decreased by  $1.2 \mu\text{M}$  over the three-day drifter period, roughly in Redfield ratio  
504 proportions (Sect. 3.4). Nutrient concentrations varied less at site 2, from  $0.08\text{--}0.10 \mu\text{M}$   $[\text{PO}_4^{3-}]$ ,  
505  $0.29\text{--}0.61 \mu\text{M}$   $[\text{NO}_3^- + \text{NO}_2^-]$ , and  $1.2\text{--}1.7 \mu\text{M}$   $[\text{SiO}_2]$ . While  $[\text{PO}_4^{3-}]$  and  $[\text{SiO}_2]$  increased  
506 significantly ( $p < 0.05$ ) by  $0.015 \mu\text{M}$  and  $0.48 \mu\text{M}$ , respectively, these changes were small  
507 compared to the nutrient drawdown observed during drifter period 1, and did not reflect Redfield  
508 ratio proportions. It is possible that intrusions of an external water mass with slightly elevated  
509 nutrient concentrations contributed to the small increase in  $[\text{PO}_4^{3-}]$  and  $[\text{SiO}_2]$  measured during  
510 these CTD casts, even though we assume that such effects on our derived productivity estimates  
511 are negligible based on inspection of underway temperature and salinity data (Fig. S3).

512

### 513 **3.2 Biogeochemical comparisons between drifter sites**

514

515 Elevated nutrient concentrations at the drifter 1 site supported high productivity and the  
516 accumulation of phytoplankton biomass, as indicated by elevated chlorophyll-a ( $[\text{Chl-a}] = 0.66\text{--}$   
517  $1.5 \mu\text{g/L}$ ), phytoplankton carbon ( $[\text{C}_{\text{ph}}] = 83\text{--}115 \mu\text{g/L}$ ) and particulate organic carbon  
518 concentrations ( $[\text{POC}] = 130\text{--}261 \mu\text{g/L}$ ) (Figs. 2a–c). We observed  $[\text{C}_{\text{ph}}]/[\text{Chl-a}]$  ratios ranging  
519 from  $68\text{--}143 \text{ g/g}$ , with a median value of  $85 \text{ g/g}$  (Fig. 2f). Using the carbon-based production  
520 model (CbPM; Sect. 2.5) and daily-averaged mixed layer PAR derived from satellite values  
521 matched to drifter location (within 5 km), these  $[\text{C}_{\text{ph}}]/[\text{Chl-a}]$  ratios translate into phytoplankton  
522 growth rates ranging from  $0.75\text{--}0.94 \text{ d}^{-1}$ . At the second drifter site, phytoplankton productivity  
523 and biomass were significantly lower in the nutrient-poor waters ( $[\text{Chl-a}] = 0.06\text{--}0.21 \mu\text{g/L}$ ,  
524  $[\text{C}_{\text{ph}}] = 11\text{--}17 \mu\text{g/L}$ , and  $[\text{POC}] = 25\text{--}38 \mu\text{g/L}$ ). Ratios of  $[\text{C}_{\text{ph}}]$  to  $[\text{Chl-a}]$  at site 2 were  
525 significantly higher ( $p < 0.05$ ) than those observed at site 1, ranging from  $69 \text{ g/g}$  to  $203 \text{ g/g}$ , with a  
526 median value of  $108 \text{ g/g}$ . The higher ratios may reflect reduced cellular  $[\text{Chl-a}]$  associated with  
527 greater nutrient limitation, higher daily-integrated PAR, and proportionally more picoplankton  
528 than microplankton at drifter site 2 (Westberry et al., 2008; Hirata et al., 2011; Graff et al., 2016;  
529 Burt et al., 2018). Median PAR levels were higher and less variable at site 2, in part contributing  
530 to lower variability in CbPM-based growth rates, which ranged from  $0.81$  to  $0.85 \text{ d}^{-1}$ .

531 Several lines of evidence suggest that the phytoplankton assemblage at drifter site 1 was  
532 enriched in large-celled phytoplankton, as compared to drifter site 2. The wavelength-dependent  
533 slope of particulate backscatter ( $b_{bp}$ ) was lower at site 1 (range: 1.4 to 1.6, median: 1.5) than at  
534 site 2 (range: 1.9–2.3, median: 2.1) (Fig. 2d), suggesting proportionally larger particle sizes  
535 (Stramska et al., 2003; Kostadinov et al., 2009). This observation is supported by size-  
536 fractionated Chl-a measurements. During the drifter 1 deployment, the  $>20\text{ }\mu\text{m}$  size fraction  
537 (Sect. 2.4), increased from 21 % to 46 % of the total Chl-a pool, indicating the enrichment of  
538 large phytoplankton in the assemblage. Pigment-based estimates of phytoplankton taxonomic  
539 composition and size class (Hirata et al., 2011; Zeng et al., 2018) suggested that relative diatom  
540 and microplankton abundances exceeded 50% on the final sampling time point. By comparison,  
541 size-fractionated [Chl-a] and HPLC analyses from drifter 2 indicated a lower proportion of large-  
542 celled phytoplankton, with 9–15% of total [Chl-a] in the  $>20\text{ }\mu\text{m}$  size fraction, and diatoms and  
543 micro-plankton estimated to account for 19–29% of the phytoplankton assemblage. The  
544 proportion of picoplankton increased through time at drifter site 2 from 31–50% of total [Chl-a],  
545 alongside a slight increase in  $b_{bp}$  slope, indicating accumulation of smaller particle sizes (Fig.  
546 S3d). Finally, median bulk refractive index values across three wavelengths (470 nm, 532 nm,  
547 650 nm) were higher at site 1 (1.08–1.11) than at site 2 (1.02–1.04) (Fig. S3e), which is  
548 consistent with a greater proportion of diatom-derived silica in the particle pool (Lide, 1997;  
549 Twardowski et al., 2001).

550

### 551 **3.3 Diurnal variability and primary production**

552

553 As shown in Fig. 3a, clear diurnal cycles in biological oxygen saturation ( $\Delta\text{O}_2/\text{Ar}$ ) were  
554 observed during both drifter deployments. Generally, values of  $\Delta\text{O}_2/\text{Ar}$  increased from dawn to  
555 dusk and decreased from dusk to dawn, yielding positive slopes of linear regressions of  $\Delta\text{O}_2/\text{Ar}$   
556 against time in the daytime, and negative slopes at night. During drifter deployment 1, this  
557 diurnal cycle was superimposed on a longer-term increase in biological O<sub>2</sub> saturation as under-  
558 saturated values returned toward atmospheric equilibrium. At least part of this increase is  
559 attributable to gas exchange, which would act to erase O<sub>2</sub> under-saturation in the mixed layer  
560 caused by recent upwelling. However, calculation of the sea-air O<sub>2</sub> flux shows that, except for  
561 the first 24-hour period, only a small amount of the daily increase in  $\Delta\text{O}_2/\text{Ar}$  can be explained by

562 gas exchange (absolute value of  $J_{ex} < 10 \text{ mmol O}_2 \text{ m}^{-2} \text{ d}^{-1}$ ) (Table 1). Thus, the temporal change  
563 in  $\Delta\text{O}_2/\text{Ar}$  can be attributed to a primarily biological source. The magnitude of this increase is  
564 further underestimated because of vertical upwelling of deep oxygen-poor waters, which would  
565 act to dampen the increase in  $\Delta\text{O}_2/\text{Ar}$  through time. After accounting for a mixing correction  
566 ranging between 22 and 97  $\text{mmol m}^{-2} \text{ d}^{-1} \text{ O}_2$  (equivalent to 16 to 70  $\text{mmol m}^{-2} \text{ d}^{-1} \text{ C}$  when  
567 assuming a photosynthetic quotient of 1.4), daily-integrated gross primary productivity  
568 ( $\text{GPP}_{\text{O}_2/\text{Ar}}$ ) ranged from 270 to 358  $\text{mmol C m}^{-2} \text{ d}^{-1}$ , and community respiration ( $\text{CR}_{\text{O}_2/\text{Ar}}$ ) rates  
569 ranged from 74 to 172  $\text{mmol C m}^{-2} \text{ d}^{-1}$  (Table 1).

570 Examination of the diel variability in POC and Chl-a during drifter period 1 revealed  
571 significant differences in the behavior of these variables as compared to  $\Delta\text{O}_2/\text{Ar}$  (Fig. 3b, c). In  
572 particular, while  $\Delta\text{O}_2/\text{Ar}$  increased during the first drifter deployment, [POC] and [Chl-a] values  
573 decreased. We estimated that vertical mixing ( $F_{\text{mix,POC}}$ ), accounted for 12 to 68  $\text{mmol m}^{-2} \text{ d}^{-1} \text{ C}$  of  
574 these daily changes in [POC], similar to the magnitude of the mixing correction for  $\Delta\text{O}_2/\text{Ar}$   
575 variability (Table 1). After taking mixing into account, daily-integrated  $\text{GPP}_{\text{POC}}$  decreased from  
576 242  $\text{mmol m}^{-2} \text{ d}^{-1}$  on day 1 to 98  $\text{mmol m}^{-2} \text{ d}^{-1}$  on day 3, while  $\text{CR}_{\text{POC}}$  rates ranged from 77 to  
577 147  $\text{mmol m}^{-2} \text{ d}^{-1}$ .

578 Calculated daily averaged net primary productivity (NPP) were lower than  $\text{GPP}_{\text{O}_2/\text{Ar}}$ .  
579 Rates derived from the CbPM model (Sect. 2.5), declined from 147  $\text{mmol C m}^{-2} \text{ d}^{-1}$  on day 1 of  
580 drifter deployment 1 to 112  $\text{mmol C m}^{-2} \text{ d}^{-1}$  on day 3 (Table 1), reflecting the trend in Chl-a  
581 concentrations used to derive NPP (Fig. 3c). The CbPM-derived NPP estimates were similar to  
582 that obtained in  $^{14}\text{C}$  incubations ( $150 \pm 18 \text{ mmol C m}^{-2} \text{ d}^{-1}$ ) within the first 24 hours of drifter  
583 deployment 1. However,  $^{14}\text{C}$ -based NPP estimates on the third day of the deployment ( $49 \pm 8$   
584  $\text{mmol C m}^{-2} \text{ d}^{-1}$ ) were about two-fold lower than those obtained from CbPM calculations.

585 Dissolved oxygen and POC dynamics at drifter site 2 differed significantly from those  
586 observed at site 1. Compared to the drifter site 1, diel variability in  $\Delta\text{O}_2/\text{Ar}$  and [POC] was more  
587 tightly coupled during the second drifter deployment (Fig. 3a, b). Both  $\text{O}_2/\text{Ar}$  and [POC]  
588 displayed regular diurnal variations, increasing in the daytime to a maximum around dusk and  
589 decreasing at night to a minimum around dawn. Over the full drifter deployment, concentrations  
590 of Chl-a and, to a lesser extent, POC, decreased, in contrast to  $\Delta\text{O}_2/\text{Ar}$ , which remained relatively  
591 constant across days. Daily-integrated  $\text{GPP}_{\text{O}_2/\text{Ar}}$  values ranged from 108 to 219  $\text{mmol C m}^{-2} \text{ d}^{-1}$   
592 and  $\text{CR}_{\text{O}_2/\text{Ar}}$  rates ranged from 82 to 186  $\text{m}^{-2} \text{ d}^{-1}$ . POC-derived values were considerably lower

593 and less variable, from 41 to 38 for GPP<sub>POC</sub> and 36 to 44 for CR<sub>POC</sub> (Table 1). NPP derived from  
594 CbPM calculations was 22 mmol C m<sup>-2</sup> d<sup>-1</sup> on the first day of the drifter period and 18 mmol C  
595 m<sup>-2</sup> d<sup>-1</sup> on the second day, while NPP calculated from one <sup>14</sup>C bottle incubation during the first  
596 day of the drifter 2 deployment was  $12 \pm 4$  mmol C m<sup>-2</sup> d<sup>-1</sup>, showing good agreement with the  
597 CbPM calculations.

598

### 599 **3.4 Net community production**

600

601 Daily net community production (NCP) rates were calculated using linear regressions of  
602  $\Delta O_2/Ar$  and POC over day and night intervals, corrected for gas exchange and vertical mixing  
603 (Sect. 2.6.1, 2.6.2). During drifter period 1, NCP<sub>O2/Ar</sub> and NCP<sub>POC</sub> exhibited contrasting trends, as  
604 NCP<sub>O2/Ar</sub> remained  $>100$  mmol C m<sup>-2</sup> d<sup>-1</sup> throughout, while NCP<sub>POC</sub> declined to negative values  
605 on the second and third days (Table 1; Fig. 4). The transition to negative NCP<sub>POC</sub> values over the  
606 course of the drifter 1 deployment primarily reflected diminishing daytime rates of POC  
607 accumulation (dPOC/dt term in Eq. 8). At drifter period 2, we observed closer agreement  
608 between NCP values.  $\Delta O_2/Ar$ -derived NCP ranged from -12 to 33 mmol C m<sup>-2</sup> d<sup>-1</sup> over two  
609 consecutive 24 hour periods, while NCP<sub>POC</sub> values ranged from -3 to 1 mmol C m<sup>-2</sup> d<sup>-1</sup>. These  
610 lower rates at drifter site 2 are consistent with the lower observed phytoplankton biomass and  
611 nutrient concentrations.

612 Additional constraints on NCP during drifter period 1 can be derived from examining  
613 nutrient drawdown. Because vertical upwelling of nutrient-replete waters would dampen the  
614 magnitude of observed nutrient drawdown over time (Sect. 3.1; Fig. S4), we used the derived  
615  $k_{mix}$  from Eq. 6 and a best-fit vertical gradient in nutrient concentrations between the mixed layer  
616 and 100 m (Sect. 2.4) to account for this mixing flux. This correction increases the cumulative  
617 three-day nutrient drawdown by 2.1 to 2.6 times. Over the three-day drifter deployment, surface  
618 Si, N and P concentrations declined in a ratio of 17: 13: 1, which is consistent with the  
619 stoichiometry expected for organic matter produced by a diatom-rich assemblage (Brzezinski et  
620 al., 1998; Turner et al., 1998; Brzezinski, 2004). Assuming that the observed decrease in SiO<sub>2</sub>  
621 concentrations over the three days is attributable to growth of diatoms in the mixed layer, and  
622 applying a stoichiometric ratio of 106 C: 16 Si, we estimate an average C production rate of  
623  $\sim 128$  mmol C m<sup>-2</sup> d<sup>-1</sup> for the drifter period. This value is consistent with NCP<sub>O2/Ar</sub> rates, which

624 were 137 mmol C m<sup>-2</sup> d<sup>-1</sup> on average over three days, but significantly greater than NCP<sub>POC</sub>  
625 estimates (7 mmol C m<sup>-2</sup> d<sup>-1</sup> on average) (Table 2).

626 Table 2 summarizes comparisons among NCP values calculated using day/night linear  
627 regressions of  $\Delta O_2/Ar$  and POC against time, and other approaches described in Sect. 2.6.3. In  
628 general, the different calculation methods did not significantly alter the results. NCP values  
629 derived from one linear regression over each drifter period agreed well with the average of two  
630 (drifter 2) to three (drifter 1) daily NCP values calculated via the other approaches. Small  
631 differences between linear regression-based NCP values and both NCP calculated from either 3-  
632 hour increments or two time points are likely due to the effect of lower signal to noise in  $\Delta O_2/Ar$ ,  
633  $[O_2]_{bio}$  and [POC] values utilized in these latter two approaches. The following discussion thus  
634 focuses on productivity rates derived from day/night linear regressions (i.e., Eqs. 1 and 8), which  
635 utilize all data points while minimizing uncertainty in the derived rates of change. The exception  
636 is the NCP<sub>O2/Ar</sub> value calculated for day 1 of drifter period 2 using the daytime/nighttime linear  
637 regression method. By this approach, we calculated NCP<sub>O2/Ar</sub> as 26 mmol C m<sup>-2</sup> d<sup>-1</sup>, even though  
638 the time series in Fig. 3a clearly indicates a net decrease in  $\Delta O_2/Ar$  over the 24-hour period, and  
639 all other  $\Delta O_2/Ar$ -based NCP calculations (Sect. 2.6.3) yielded negative values. For the  
640 discussion, Table 1 and Fig. 4, the NCP value derived from the integrated 3-hour increments  
641 represents net community production during this particular interval.

642

#### 643 **4 Discussion**

644

645 A number of previous studies have examined diurnal variation in upper ocean  
646 phytoplankton and organic particle dynamics across a variety of productivity regimes, from  
647 oligotrophic environments (Claustre et al., 1999, 2008; Wu et al., 2010; Gernez et al., 2011;  
648 Kheireddine and Antoine, 2014; Thyssen et al., 2014; Nicholson et al., 2015; Ribalet et al., 2015;  
649 White et al., 2017), to higher productivity waters and phytoplankton blooms (Brunet and Lizon,  
650 2003; Wu et al., 2010; Gernez et al., 2011; Alkire et al., 2012; Dugenne et al., 2014; Kheireddine  
651 and Antoine, 2014; Needham and Fuhrman, 2016; Briggs et al., 2018). In general, these studies  
652 have shown that more productive environments exhibit higher amplitude diurnal variations in  
653 beam attenuation, POC concentration, phytoplankton cell abundances, Chl-a, and metabolic  
654 rates. These prior results are consistent with the differences we observed between the two

655 distinct Northeast Pacific trophic environments represented by drifter sites 1 and 2, respectively  
656 (Sect. 3.2; Fig. 2).

657 Biogeochemical properties during the first Lagrangian survey suggested a dynamic,  
658 highly productive phytoplankton community, influenced by upwelling and elevated mixed layer  
659 nutrient concentrations (Figs. 1, S4). Several lines of evidence imply the presence of a  
660 developing diatom bloom at this site (Sect. 3.2; Figs. 2, 3). Increasing mixed layer biological  
661 oxygen saturation ( $\Delta O_2/Ar$ ) was contrasted by a general decrease in particulate organic carbon  
662 (POC) concentrations, suggesting a significant decoupling between  $O_2$  and POC dynamics. This  
663 was reflected in significant differences between  $\Delta O_2/Ar$ -derived gross primary productivity  
664 (GPP) and net community production (NCP) rates derived from  $\Delta O_2/Ar$  and POC measurements  
665 (Figs. 4, 5; Table 1). In contrast, biogeochemical properties during the second drifter deployment  
666 were indicative of a lower productivity, nutrient-limited phytoplankton assemblage, with near-  
667 zero  $\Delta O_2/Ar$  values reflecting a close balance between water column photosynthesis and  
668 respiration (Fig. 3a). Relative to the drifter 1 site, diurnal variations in  $\Delta O_2/Ar$  and POC were  
669 more closely coupled, while phytoplankton biomass ( $C_{ph}$ ) and chlorophyll-a (Chl-a)  
670 concentrations (dominated by smaller cells) varied little through time. Contrary to our  
671 expectations, even though  $NCPO_2/Ar$  and  $NCPOC$  rates agreed well, we also observed significant  
672 discrepancies between  $GPP_{O_2/Ar}$  and  $GPP_{POC}$  and between  $CR_{O_2/Ar}$  and  $CR_{POC}$  during drifter  
673 period 2. The contrasting properties between the two drifter deployments enable us to examine  
674 the coupling of  $O_2$  and POC dynamics under different ecological states, with implications for the  
675 use of  $\Delta O_2/Ar$  and POC measurements as proxies for GPP and NCP.

676

#### 677 **4.1 Decoupling of $O_2$ and POC dynamics in the mixed layer**

678

679 **4.1.1. Drifter 1.** In the absence of significant POC sinking and net loss to the dissolved  
680 organic carbon (DOC) pool, POC-based productivity rates should approximate  $\Delta O_2/Ar$ -based  
681 rates (Claustre et al., 2008; White et al., 2017). However, at drifter station 1, both  $GPP_{O_2/Ar}$  and  
682  $NCPO_2/Ar$  greatly exceeded  $GPP_{POC}$  and  $NCPOC$ , respectively (Figs. 4, 5a; Table 1). Over the  
683 three successive 24-hour periods of drifter deployment 1, the absolute difference between GPP  
684 measures increased from 41 mmol C m<sup>-2</sup> d<sup>-1</sup> to 260 mmol C m<sup>-2</sup> d<sup>-1</sup>, while the absolute difference  
685 between NCP estimates increased from 42 mmol C m<sup>-2</sup> d<sup>-1</sup> to 193 mmol C m<sup>-2</sup> d<sup>-1</sup>. This

686 discrepancy exceeded the propagated NCP uncertainties during the second and third days of the  
687 deployment, and was apparent in all approaches used to calculate NCP (Sect. 2.6.3, Table 2).

688 While mixed layer  $\Delta O_2/Ar$  primarily reflected  $O_2$  accumulation from GPP and  $O_2$  loss  
689 from CR, diurnal variability in [POC] was likely affected by several additional loss factors,  
690 which are discussed below. The variable difference between  $O_2$ -based and POC-based NCP  
691 measured over 3-hour increments (Eq. 11; Fig. S5) suggests that apparent POC loss rates were  
692 variable throughout the drifter period, and lower at night relative to day. Thus, the higher  
693  $NCP_{O_2/Ar}$  may be attributed more to differences in daytime accumulation of POC and  $O_2$  rather  
694 than differential POC and  $O_2$  losses at night. Indeed, we found that differences between  $CR_{O_2/Ar}$   
695 and  $CR_{POC}$  were smaller than differences in NCP or GPP throughout drifter period 1, and  $CR_{O_2/Ar}$   
696 exceeded  $CR_{POC}$  during two of three nights (Fig. 5b).

697 In the dynamic, high productivity upwelling environment of drifter site 1, a number of  
698 processes can account for variable POC loss rates on various time scales (Gardner et al., 1999;  
699 White et al., 2017; Briggs et al., 2018). During a diatom bloom, enhanced aggregation of large  
700 silica-rich particles and zooplankton fecal pellet production can stimulate POC export and  
701 diatom cells out of the mixed layer (Buesseler, 1998; Guidi et al., 2009; Brzezinski et al., 2015;  
702 Stukel et al., 2017), progressively decreasing  $NCP_{POC}$  relative to  $NCP_{O_2/Ar}$ . The discrepancy we  
703 observed between  $NCP_{POC}$  and  $NCP_{O_2/Ar}$  (up to 193 mmol C m<sup>-2</sup> d<sup>-1</sup>) is in the upper range of  
704 prior export estimates from various oceanic regions, including the Southern Ocean (~83 mmol C  
705 m<sup>-2</sup> d<sup>-1</sup>), North Atlantic spring bloom (96 mmol C m<sup>-2</sup> d<sup>-1</sup>) and Southern California Current  
706 system (~36 mmol C m<sup>-2</sup> d<sup>-1</sup>) (Henson et al., 2012; Alkire et al., 2012; Stukel et al., 2017),  
707 suggesting that POC export fluxes could comprise a significant fraction of the inferred POC loss  
708 at drifter site 1. At the same time, sub-daily changes in particle sinking velocities and size  
709 distributions could cause daytime export to exceed nighttime export (DuRand and Olson, 1998;  
710 Waite and Nodder, 2001; Oubelkheir and Sciandra, 2008; Khierrediene and Antoine, 2014;  
711 Ribalet et al., 2015; Briggs et al., 2018), leading to greater differences between  $GPP_{O_2/Ar}$  and  
712  $GPP_{POC}$  than between  $CR_{O_2/Ar}$  and  $CR_{POC}$ , as we observed.

713 Another likely POC loss is DOC production through cellular exudation, viral lysis and/or  
714 grazing (Karl et al., 1998; Lochte et al., 1993; Claustre et al., 2008; Dall'Olmo et al., 2011;  
715 Briggs et al., 2018). On daily time scales, this loss term would lower  $NCP_{POC}$  relative to  
716  $NCP_{O_2/Ar}$ , provided that DOC production exceeds DOC respiration. Further, higher daytime net

717 DOC production would cause  $\text{GPP}_{\text{O}_2/\text{Ar}}$  to increase more than  $\text{GPP}_{\text{POC}}$  in the daytime, while a  
718 decrease at night would cause  $\text{CR}_{\text{O}_2/\text{Ar}}$  to exceed  $\text{CR}_{\text{POC}}$  (Karl et al., 1998). Light- and  
719 productivity-dependent increases in DOC production in the daytime, could result, for example,  
720 from the effects of photo-respiration and other mechanisms of dissipating excess light energy  
721 (Schuback and Tortell, 2019). While we did not conduct direct measurements of DOC  
722 concentrations during the cruise, previous work in a variety of ocean environments has shown  
723 that DOC production can account for 3-37% of NCP in the Ross Sea, up to 10-40% in the  
724 equatorial Pacific Ocean, up to 66% in the Sargasso Sea during the seasonal phytoplankton  
725 bloom, and 22-40% during the North Atlantic bloom (Hansell and Carlson, 1998; Alkire et al.,  
726 2012). In the eastern Subarctic Pacific, Bif and Hansell (2019) estimated springtime  $\Delta\text{DOC}/\text{NCP}$   
727 ratios of 0.05 – 0.54 and summertime ratios of 0 – 0.28 along the Line P transect (130 – 152  
728 °W).

729 In addition, assuming that DOC exudation from phytoplankton cells is positively related  
730 to growth in heterotrophic biomass (Fuhrman et al., 1985; Kuipers et al., 2000; Church et al.,  
731 2004), variations in total bacterial biomass may have impacted  $c_p$  measurements at drifter site 1  
732 (Oubelkheir and Sciandra, 2008; Gernez et al., 2011; Barnes and Antoine, 2014). If detected by  
733 the ac-s sensor, bacteria could potentially account for some of the discrepancy between diel POC  
734 and  $\text{O}_2$ -derived variability. In particular,  $c_p$  decreases from phytoplankton exudation would  
735 counter  $c_p$  increases from heterotrophic growth. At night, this would decrease CR rates derived  
736 from  $c_p$ -based [POC], relative to  $\text{O}_2$ -derived CR rates.

737 A final consideration involves diurnal variation of zooplankton abundances and grazing  
738 rates, which could enhance POC loss without depleting  $\Delta\text{O}_2/\text{Ar}$  (Dall'Olmo et al., 2011; White et  
739 al., 2017; Briggs et al., 2018), assuming that biomass accumulation rates from grazing surpass  
740 grazer respiration rates (Dagg et al., 1982). Further, once POC is assimilated into the body of a  
741 grazer, it joins a larger particle size class that likely exceeds the size-dependent detection limits  
742 of the beam attenuation coefficient (Stramski and Kiefer, 1991; Marra, 2002; Claustre et al.,  
743 2008;), decreasing the  $c_p$  signal used to derive POC. During our expedition, we observed a strong  
744 signature of diel migrating zooplankton based on increased nighttime signal spikes in surface  
745 optical backscatter measurements (Burt and Tortell, 2018). These effects would enhance  $\text{CR}_{\text{POC}}$   
746 relative to  $\text{CR}_{\text{O}_2/\text{Ar}}$ , contrary to what we observed. We thus assume that grazing at drifter site 1 is  
747 minimal relative to the effects of particle export and DOC production on GPP, CR and NCP.

748

749       **4.1.2 Drifter 2.** Relative to the drifter 1 site, drifter site 2 exhibited similar discrepancies  
750 between  $\text{GPP}_{\text{O}_2/\text{Ar}}$  and  $\text{GPP}_{\text{POC}}$ , and greater discrepancies between  $\text{CR}_{\text{O}_2/\text{Ar}}$  and  $\text{CR}_{\text{POC}}$  (Fig. 5a-b;  
751 Table 1). Irrespective of the time of day, the rate of  $\Delta\text{O}_2/\text{Ar}$  change computed over 3-hour  
752 intervals (Eq. 11) consistently exceeded POC-derived changes throughout the drifter period (Fig.  
753 S5). The strong, positive relationship between these two 3-hour measures ( $p<0.05$ ,  $r^2=0.64$ ),  
754 compared to the weaker correlation at drifter site 1 ( $p<0.05$ ,  $r^2=0.39$ ) (Figs. 5c-d), suggests that  
755 despite large differences in the magnitude of  $\Delta\text{O}_2/\text{Ar}$ -derived and POC-derived GPP and CR  
756 rates, POC-based changes were a good relative indicator of  $\text{O}_2$ -derived productivity rates at  
757 drifter site 2.

758       Because daytime increases in both  $\Delta\text{O}_2/\text{Ar}$  and [POC] were balanced by nighttime  
759 decreases, absolute differences in  $\text{NCP}_{\text{O}_2/\text{Ar}}$  and  $\text{NCP}_{\text{POC}}$  were smaller than at drifter site 1. This  
760 result suggests a closer coupling between primary production and heterotrophic consumption, as  
761 expected for this more oligotrophic ecosystem (Claustre et al., 2008; White et al., 2017). While  
762 the NCP discrepancy was negligible over the first 24-hour period, it increased to 32 mmol C m-  
763  $2\text{d}^{-1}$  over the 24-hour period (Table 1; Fig. 4), exceeding the uncertainty of both NCP  
764 calculations. This suggests low, but non-negligible, rates of particle export, grazing and/or net  
765 DOC production at drifter site 2. Although we lack direct DOC measurements, this result is  
766 consistent with several previous observations of low net DOC production in oligotrophic waters  
767 (Bif et al., 2018; Hansell and Carlson, 1998), with values approaching ~30% of NCP in low  
768 productivity offshore waters of the Subarctic Pacific (Bif and Hansell, 2019). Low particle  
769 sinking rates could also explain the smaller absolute discrepancy between  $\text{NCP}_{\text{O}_2/\text{Ar}}$  and  $\text{NCP}_{\text{POC}}$   
770 at drifter site 2. Low particle export is generally expected from phytoplankton assemblages  
771 dominated by small particle sizes  $<20\mu\text{m}$ , as evident in higher  $b_{\text{bp}}$  slope values and Chl-a size  
772 fractionation measurements at drifter site 2 (Sect. 3.2; Fig. 2) (Fowler and Knauer, 1986; Guidi  
773 et al., 2008).

774       Prior studies have observed that the amplitude of diurnal variability in  $\Delta\text{O}_2/\text{Ar}$  exceeds  
775 the amplitude of diurnal variability in  $c_{\text{p}}$ -based [POC], as we observed at drifter site 2 (Kinkade  
776 et al., 1999; Hamme et al., 2012; Briggs et al., 2018). For example, Briggs et al. (2018) observed  
777 higher amplitude variations in  $\text{O}_2$  relative to  $c_{\text{p}}$ -derived [POC] during the North Atlantic bloom,  
778 leading to higher absolute  $\text{O}_2$ -derived respiration and gross oxygen production (GOP) rates

779 compared to  $c_p$ -derived rates. In the Southern Ocean, Hamme et al. (2012) also observed high  
780 ratios of underway  $\Delta O_2/Ar$ -derived gross oxygen production to gross carbon production (i.e.,  
781 GPP) based on photosynthesis-irradiance incubations. As discussed above for drifter site 1, these  
782 offsets between  $\Delta O_2/Ar$  and POC-based measures might result from the effects of bacteria on  $c_p$   
783 measurements, especially at a relatively low productivity site like drifter site 2 (Table 1; Fig. 2)  
784 (Claustre et al. 2008; Oubelkheir and Sciandra, 2008; Barnes and Antoine, 2014). Bacterial  $c_p$   
785 variability would act to counter phytoplankton  $c_p$  variability, decreasing the magnitude of CR<sub>POC</sub>  
786 relative to the magnitude of CR<sub>O<sub>2</sub>/Ar</sub>. Indeed, the positive CR<sub>O<sub>2</sub>/Ar</sub> - CR<sub>POC</sub> discrepancy at drifter  
787 site 2 contributed to 58-82% of the differences between  $\Delta O_2/Ar$  and POC-derived GPP rates. The  
788 remaining difference may be attributed to greater daytime POC losses to the DOC pool and  
789 through particle export.

790

## 791 **4.2 Other factors driving variability in NCP**

792

793 In interpreting our results, it is important to consider a number of methodological caveats  
794 that could contribute to the apparent difference between NCP<sub>O<sub>2</sub>/Ar</sub> and NCP<sub>POC</sub>. One important  
795 variable in all of our comparisons of productivity rates is the O<sub>2</sub>-to-POC conversion factor,  
796 represented by the photosynthetic (PQ) and respiratory quotient (RQ). Given the relatively  
797 narrow range of possible PQ values applicable to our study sites (~1.1-1.4) (Laws 1991),  
798 variability in this term cannot account for the total discrepancy observed between  $\Delta O_2/Ar$  and  
799 POC-derived GPP, CR and NCP rates. By contrast, RQ values in the ocean are more variable  
800 than PQ (Robinson and Williams, 1999; Robinson et al., 1999; Hedges et al., 2002). Therefore,  
801 variability in RQ values at both drifter sites could introduce considerable uncertainty into  
802 GPP<sub>O<sub>2</sub>/Ar</sub>, CR<sub>O<sub>2</sub>/Ar</sub> and NCP<sub>O<sub>2</sub>/Ar</sub> calculations unaccounted for in our error propagations (Sect.  
803 2.7). However, we found that use of RQ values ranging between 1.0 – 1.4 (Anderson and  
804 Sarmiento, 1994; Robinson and Williams, 1999; Hedges et al., 2002; Daneri et al., 2012) did not  
805 greatly change calculated GPP<sub>O<sub>2</sub>/Ar</sub>, CR<sub>O<sub>2</sub>/Ar</sub>, and NCP<sub>O<sub>2</sub>/Ar</sub> relative to GPP<sub>POC</sub>, CR<sub>POC</sub>, and  
806 NCP<sub>POC</sub>. Therefore, it is unlikely that our selected RQ values, 1.4 and 1.1 for drifter sites 1 and  
807 2, respectively, biased our main interpretations.

808 In our analysis, we interpret variations in particulate backscatter ( $b_{bp}$ ) and beam  
809 attenuation ( $c_p$ ) in terms of phytoplankton and total particulate organic carbon concentrations,

810 assuming a negligible influence of inorganic suspended minerals from various sources, including  
811 sediment resuspension and transport by the Columbia River plume (Thomas and Weatherbee,  
812 2006). This assumption is supported by the salinity of waters we sampled at both drifter sites,  
813 which was significantly higher than that expected for river-influenced regions, (below 30 g/kg;  
814 Hickey et al., 1998). At the same time, the observed bulk refractive index of particles ( $\eta_p$ ) at  
815 drifter site 1 do not preclude the presence of mixing between POC and a small fraction of shelf-  
816 derived inorganic particles. Estimates of  $\eta_p$  were generally below 1.12 for this near-shore site  
817 (Sect. 2.2; Fig. S3e), as compared to values as high as 1.26 for inorganic minerals in seawater  
818 (Lide, 1997; Twardowski et al., 2001). By comparison, calculated  $\eta_p$  values during the drifter 2  
819 deployment were below 1.08, which is much closer to values expected for water-containing  
820 predominantly non-diatom phytoplankton organic carbon.

821 Additional uncertainty in our analysis derives from the algorithms used to estimate POC  
822 and phytoplankton carbon  $C_{ph}$  from optical measurements (Sect. 2.2). Because of particle size  
823 limitations in the optical measurements, they may not fully capture all significant size classes of  
824 the particulate pool, such as larger microplankton and zooplankton. Such a size bias in the  $c_p$   
825 signal at 660 nm, used to derive [POC], would cause an underestimate of larger POC particles  
826 measured by beam attenuation (Claustre et al., 2008; Marra, 2002; Stramski and Kiefer, 1991),  
827 and thereby contribute to the apparent discrepancy between diel changes in [POC] and diel  
828 changes in  $\Delta O_2/Ar$ . Despite these potential caveats, recent work (Graff et al., 2016; Briggs et al.,  
829 2018; Burt et al., 2018) has demonstrated that  $c_p$  and  $b_{bp}$ -based derivations of [POC] and [ $C_{ph}$ ]  
830 can indeed be robust in high biomass ocean regions, where productivity and the proportion of  
831 large-celled phytoplankton is significant.

832 Equally important, changes in the  $c_p$ -to-[POC] relationship through time could also drive  
833 apparent variability in optical [POC] estimates. The linear regression of [POC] against  $c_p$  at 660  
834 nm measured across diverse marine environments is defined over a range of POC concentrations  
835 from  $\sim 5$  to  $\sim 175$   $\mu g/L$  (Graff et al. 2015). At drifter site 2, POC concentrations fell within the  
836 range of this fit, and particle properties that may influence POC/ $c_p$  values (i.e.,  $b_{bp}$  slope values,  
837 phytoplankton community composition, particle size and bulk refractive index) were relatively  
838 constant through time (Figs. S3d, e). By comparison, POC concentrations at drifter station 1  
839 were 25% higher than the empirical limits of the  $c_p$ -based algorithm in Graff et al. (2015),  
840 requiring extrapolation of the POC/ $c_p$  relationship beyond its calibration range. In a limited

841 comparison with discrete POC samples, we found a POC– $c_p$  slope that was similar to that of  
842 Graff et al. (albeit with a different y intercept) (Fig. S1). Nonetheless, we cannot rule out changes  
843 in the  $c_{p660}$ –[POC] relationship due to shifts in cell size and, to a lesser extent, bulk refractive  
844 index resulting from diatom accumulation (Kheireddine and Antoine, 2014; Stramski and  
845 Reynolds, 1993) (Fig. S3d–e). Indeed, Briggs et al. (2018) observed that the ratio of [POC] to  $c_p$   
846 decreased by ~20% during the rise of the North Atlantic bloom, while values increased by ~60%  
847 during the bloom decline. If we assume a 20% decrease in POC/ $c_{p660}$  values (from ~420 to ~340  
848 mg m<sup>-2</sup>) associated with diatom growth (Briggs et al., 2018), our daily NCP<sub>POC</sub> estimates would  
849 be less positive during day 1 and less negative during days 2–3. This, in turn, would increase the  
850 apparent decoupling between NCP<sub>POC</sub> and NCP<sub>O<sub>2</sub>/Ar</sub> on days one (~27%) and three (~1%), and  
851 bring the values slightly closer on day two (~8%). Overall, the value of these potential changes is  
852 small relative to the differences we observed between NCP<sub>O<sub>2</sub>/Ar</sub> and NCP<sub>POC</sub>, and we thus  
853 conclude that variable POC/ $c_{p660}$  ratios cannot explain the observed decoupling between POC,  
854 C<sub>ph</sub> and dissolved O<sub>2</sub> dynamics at the drifter 1 site.

855 There are a number of other potential caveats in our analysis of phytoplankton carbon  
856 from  $b_{bp}$  and particle size distribution from  $b_{bp}$  slope. Previous studies have reported that daily  
857 variations in  $b_{bp}$  do not always track daily variations in  $c_p$ , suggesting that  $b_{bp}$  dynamics do not  
858 reflect phytoplankton carbon dynamics on diel time scales (Kheireddine and Antoine, 2014;  
859 Briggs et al., 2018). We observed a similar decoupling between  $b_{bp}$  and  $c_p$  in this study; for  
860 example, while  $c_p$  values at 660 nm steadily declined in the last 24 hours of drifter period 1,  $b_{bp}$   
861 at 470 nm stayed relatively constant. Nonetheless, [C<sub>ph</sub>] estimates from  $b_{bp}$  (Fig. 2) remain useful  
862 for comparisons between drifter sites, and differences in apparent phytoplankton biomass  
863 concentration were consistent with a number of the other biogeochemical differences measured  
864 between the two trophic regimes. Similarly, the relationship between  $b_{bp}$  slope and particle size  
865 distribution has been challenged in previous literature (e.g., Zeng et al., 2018). While this limits  
866 our interpretation of daily  $b_{bp}$  slope dynamics, we did find independent evidence for larger  
867 particle sizes at drifter site 1 (as predicted by the  $b_{bp}$  slope), from size fractionated [Chl-a]  
868 measurements and pigment analysis showing a greater fraction of microplankton (Sect. 3.2).  
869

870 **4.3 Reconciling NCP and NPP**

871

872 During both drifter surveys, we estimated daily-integrated net primary productivity  
873 (NPP) values using carbon-based production model (CbPM) calculations and  $^{14}\text{C}$  bottle  
874 incubations (Sect. 2.5). On several days, these two estimates of NPP were consistently lower  
875 than  $\text{NCPo}_2/\text{Ar}$  integrated over the same time scales and mixed layer depths (Table 1). Similarly,  
876 Briggs et al. (2018) and Alkire et al. (2012) also reported NCP values that were equal to or  
877 greater than NPP values obtained from different methodologies during their Lagrangian study of  
878 the North Atlantic Bloom.

879 In theory, NCP cannot exceed NPP, as NCP includes additional respiration terms not  
880 included in NPP, and must always be equal to or (more realistically) lower than NPP. Recent  
881 work in the Northeast Pacific Ocean, has reported mean NCP/NPP ratios, based on  $\Delta\text{O}_2/\text{Ar}$   
882 measurements and CbPM calculations, ranging from 0.16 to 0.26 in offshore and coastal waters  
883 (Burt et al., 2018). These values, determined from continuous observations along a moving ship-  
884 track, are consistent with theoretical expectations. The observed high ( $>1$ ) apparent NCP/NPP  
885 values observed in our study and that of Briggs et al. (2018) and Alkire et al. (2012) highlight a  
886 number of methodological limitations that could depress NPP estimates.

887 One possibility, which has been discussed at length by various authors (Gieskes et al.,  
888 1979; Fogg and Calvário-Martinez, 1989; Marra, 2009), is that bottle containment effects limit  
889 accurate estimates of  $^{14}\text{C}$  uptake. This effect would have caused underestimates of  $^{14}\text{C}$ -NPP  
890 during both drifter surveys, relative to CbPM-NPP and  $\text{NCPo}_2/\text{Ar}$ , which do not require discrete  
891 sample incubations. In addition, during the last  $^{14}\text{C}$ -uptake experiment of drifter survey 2, the  
892 incubator warmed (as the ship passed through warm SST water used to cool the tanks),  
893 potentially creating heat stress on phytoplankton and depressing  $^{14}\text{C}$ -NPP values.

894 A number of factors may also influence CbPM-based NPP estimates. While the model  
895 applies a satellite-based relationship between  $[\text{Chl-a}]/[\text{C}_{\text{ph}}]$  and daily mixed layer irradiance ( $E_g$ )  
896 to calculate growth rate, these  $E_g$  values may not fully parametrize phytoplankton physiology for  
897 mixed assemblages in the ocean (Westberry et al., 2008). Indeed, phytoplankton  
898 photophysiology varies with other environmental conditions and phytoplankton composition  
899 (Cloern et al., 1995; Geider et al., 1998; MacIntyre et al., 2002; Westberry et al., 2008). In  
900 addition, the CbPM does not allow calculated growth rates to exceed 2 d<sup>-1</sup>, which may not apply  
901 to all ocean environments (Graff et al., 2016). These uncertainties could potentially impact the  
902 applicability of the CbPM parameters to the specific ocean conditions at drifter sites 1 and 2. In

903 addition, a vertical mixing correction for ac-s and backscatter-derived [Chl-a] and [C<sub>ph</sub>],  
904 respectively, not feasible in the present data set, may improve CbPM-based estimates of NPP.

905

## 906 **5 Conclusions**

907

908 In the current study, biological oxygen saturation ( $\Delta O_2/Ar$ ) and optically-derived  
909 particulate organic carbon (POC) were measured continuously and simultaneously during two  
910 Lagrangian drifter deployments. This dual measurement approach facilitated direct comparison  
911 of  $O_2/Ar$  and POC-derived measures of gross primary productivity (GPP), community respiration  
912 (CR), and net community production (NCP), from a mesotrophic upwelling-influenced system  
913 and a more oligotrophic system further offshore. As hypothesized, the results show that  $O_2$  and  
914 POC-based measures of GPP and NCP diverge in mid-to-high productivity phytoplankton  
915 communities, where daily fluctuations in  $\Delta O_2/Ar$  are decoupled from POC cycling. Interestingly,  
916 oxygen-based GPP and CR also exceeded POC-based GPP and CR rates at the lower  
917 productivity site, though we found that net changes in POC scaled with  $\Delta O_2/Ar$ -based  
918 productivity estimates, suggesting a tighter coupling between  $O_2$  and POC cycles.

919 These findings are generally consistent with current understanding of productivity  
920 dynamics and mixed layer POC cycling in these two coastal Pacific environments, and  
921 complement only one prior comparison of daily GPP and NCP estimates from simultaneous,  
922 autonomous measurements of  $c_p$  and  $O_2$  in the North Atlantic mixed layer (Alkire et al., 2012;  
923 Briggs et al., 2018). Importantly, however, our results differ from earlier studies by providing  
924 two examples of significant disagreement between  $GPP_{O_2/Ar}$  and  $GPP_{POC}$ , and  $CR_{O_2/Ar}$  and  
925  $CR_{POC}$ , likely resulting from sub-daily variations in particle export, net DOC production, and  
926 bacterial growth over respiration. In such cases, assuming constant daily respiration rates by  
927 extrapolating nighttime rates of change may pose challenges for comparing  $\Delta O_2/Ar$  and POC-  
928 based GPP and CR. We have further shown that for upwelling regions like drifter site 1, it is  
929 important to account for vertical mixing of sub-surface waters into the mixed layer, and its effect  
930 on not only  $NCP_{O_2/Ar}$  calculations (Izett et al., 2018), but also on  $NCP_{POC}$  estimates through  
931 dilution of the surface POC signature. Our study thus illustrates an application of the vertical  
932 mixing coefficient,  $k_{mix}$ , derived from  $[N_2O]$  profiles to more accurately estimate net changes in  
933 POC and nutrient concentration in such environments.

Moving forward, the disparity between POC and O<sub>2</sub>-based NCP estimates offers an opportunity to continuously track cumulative POC losses in the mixed layer using autonomous ship-board or in situ sensors. As it is labor intensive to measure POC export on short time scales with sediment traps and the <sup>234</sup>Th-<sup>238</sup>U disequilibrium method (Buesseler et al., 2006; Savoye et al., 2006), simultaneous underway measurements of dissolved O<sub>2</sub>, particulate beam attenuation and CDOM absorption and spectral slope over a range of wavelengths <400 nm (Del Vecchio and Blough, 2004; Grunert et al., 2018) may provide a valuable, first-order approximation of POC partitioning among living phytoplankton biomass, particle export and dissolved organic carbon (DOC) in the surface ocean on short time scales. At drifter site 1, for example, taking an upper bound of 40% of NCP as DOC production (close to the fraction estimated Alkire et al. (2012) during the North Atlantic spring bloom) yields a 3-day average DOC flux of 55 mmol C m<sup>-2</sup> d<sup>-1</sup> and residual export flux of 76 mmol C m<sup>-2</sup> d<sup>-1</sup>. Being able to estimate such quantities with this approach is especially important in the California coastal upwelling regime and other similar ecosystems with high NCP and significant potential for carbon transfer to higher trophic levels.

For future work, we recommend a number of approaches to facilitate estimation of POC export from coupled O<sub>2</sub>, POC, and DOC dynamics. First, it will be valuable to constrain particle size, and partitioning of POC into detrital and living (phytoplankton and heterotrophic bacteria) components to properly assess the size range captured by optically-derived POC and C<sub>ph</sub> measurements. Second, independent estimates of POC export and DOC concentrations during each drifter deployment could validate POC export fluxes derived from coupled O<sub>2</sub> and POC measurements. Relatedly, depth-resolved backscatter profiles (Briggs et al., 2013, 2018) could be used as another autonomous approach to calculating export fluxes, as an independent check on surface-based estimates. Going forward, there is significant future potential to exploit coupled O<sub>2</sub> and c<sub>p</sub> measurements on autonomous platforms, including various ocean moorings (e.g., the Optical Dynamics Experiment, the Biowatt II program, and the Bermuda Testbed Mooring program), and biogeochemical floats and gliders to resolve opportunistic, high-resolution POC export time series (Stramska and Dickey, 1992; Kinkade et al., 1999; Dickey and Chang, 2002). Deployment of such autonomous measurement systems across a range of oceanic regions will help to constrain POC and productivity dynamics on global scales.

1311  
1312

1313 **Table 1:** Daily-integrated mixed layer net primary production (NPP) and net community  
 1314 production (NCP), including all components used to calculate NCP from  $\Delta\text{O}_2/\text{Ar}$  or POC time  
 1315 series, as indicated: gross primary productivity (GPP), respiration (CR), vertical mixing (Mix),  
 1316 and gas exchange ( $J_{\text{ex}}$ ). All units here are in mmol C m<sup>-2</sup> d<sup>-1</sup>. Note that CbPM is the Carbon-  
 1317 Based Production Model (Behrenfeld et al., 2005; Westberry et al., 2008; Graff et al., 2016)  
 1318 (Sect. 2.5).

1319

	Drifter 1:			Drifter 2:	
	Day 1	Day 2	Day 3	Day 1	Day 2
<b>NPP (CbPM)</b>	147 ± 61	137 ± 51	112 ± 40	22 ± 9	18 ± 7
<b>NPP (<sup>14</sup>C)</b>	150 ± 18	-	49 ± 8	12 ± 4	-
<b>GPP (<math>\Delta\text{O}_2/\text{Ar}</math>)</b>	284 ± 75	270 ± 178	358 ± 198	108 ± 101	219 ± 211
<b>GPP (POC)</b>	242 ± 51	106 ± 26	98 ± 35	41 ± 8	38 ± 7
<b>R (<math>\Delta\text{O}_2/\text{Ar}</math>)</b>	-73 ± 65	-150 ± 88	-172 ± 56	-83 ± 35	-186 ± 64

1320

1321 \*Calculated using summed three-hour increments of NCP<sub>O2/Ar</sub> (refer to Table 2 and Sect. 2.6.3).  
 1322 All other NCP values reported here were computed using day/night linear regressions of [POC]  
 1323 and [O<sub>2</sub>]<sub>bio</sub> against time (Sects. 2.6.1, 2.6.2).

1324

1325

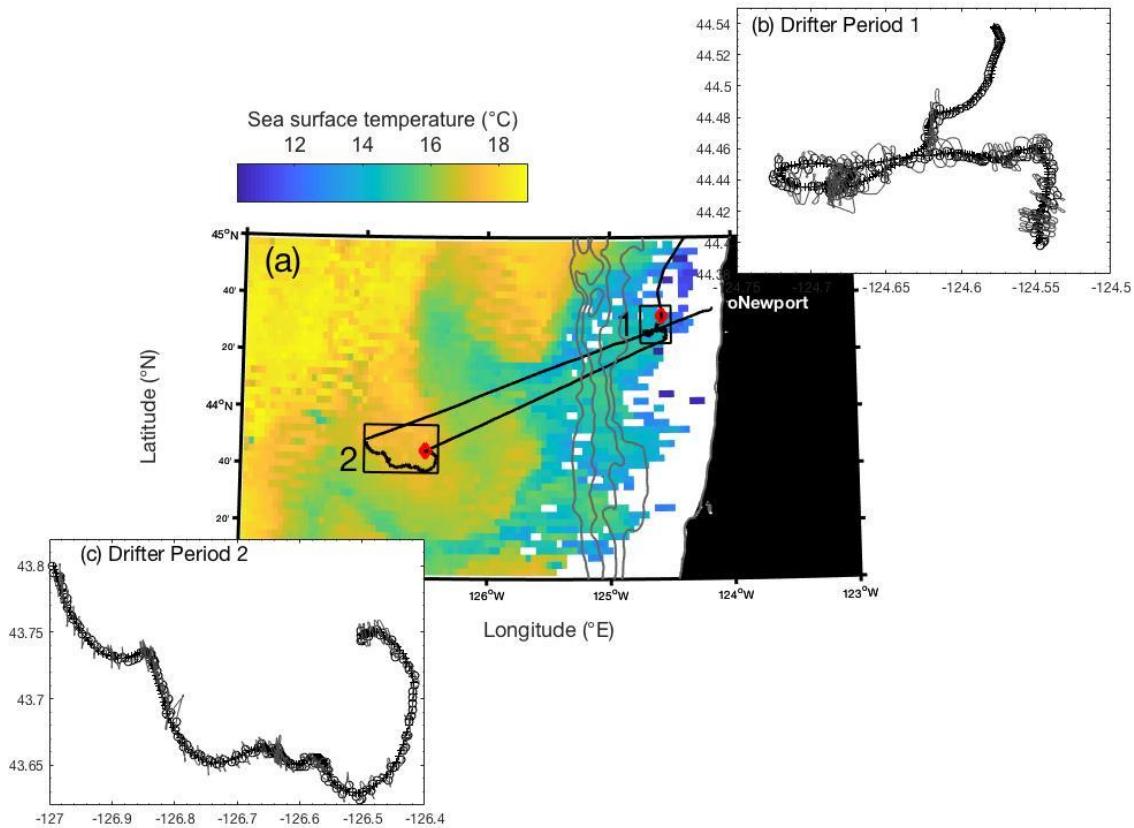

1326

1327 **Table 2:** Comparisons of NCP calculated using four different time scales of integration: (rows 1-  
1328 2) day/night linear regressions, (rows 3-4) summed linear regressions over 3-hour increments,  
1329 (rows 5-6) the difference between two time points every 24 hours, and (rows 7-8) a single linear  
1330 regression over the entire drifter period. Refer to Sect. 2.6.3 for further details. For every  
1331 calculation approach, “Export + DOC” is the average difference between  $\text{NCP}_{\text{O}_2/\text{Ar}}$  and  $\text{NCP}_{\text{POC}}$   
1332 values  $\pm 1$  S.D. or  $\pm$  the propagated error. All units here are in  $\text{mmol C m}^{-2} \text{ d}^{-1}$ .

1333

	Drifter 1:				Export + DOC	Drifter 2:			
	Day 1	Day 2	Day 3	Mean $\pm$ S.D.		Day 1	Day 2	Mean $\pm$ S.D.	Export + DOC
$\text{NCP}_{\text{O}_2/\text{Ar}}$	140 $\pm$ 45	104 $\pm$ 84	167 $\pm$ 52	137 $\pm$ 32		26 $\pm$ 18	33 $\pm$ 20	29 $\pm$ 5

1334

1335  
1336

1337 **Figure 1:** (a) Map of AQUA MODIS-derived 8-day composite sea surface temperature (11 $\mu$ m,  
1338 nighttime) from 21-28 August 2017, overlapping with the duration of both drifter deployments.  
1339 The two hollow boxes on the map denote location of drifter tracks, with the red diamonds  
1340 indicating the location of the initial release. Gray bathymetry contours represent 0, 500, 1000,  
1341 1500 and 2000 m depths. Panels (b and c) show a detailed view of the two drifter tracks (cross  
1342 symbol), with the ship's track shown in a light grey line and open circles denoting times when  
1343 the ship was <1.5 km away from the drifter position. Only measurements taken at these cross-  
1344 over locations were used for analysis.

1345

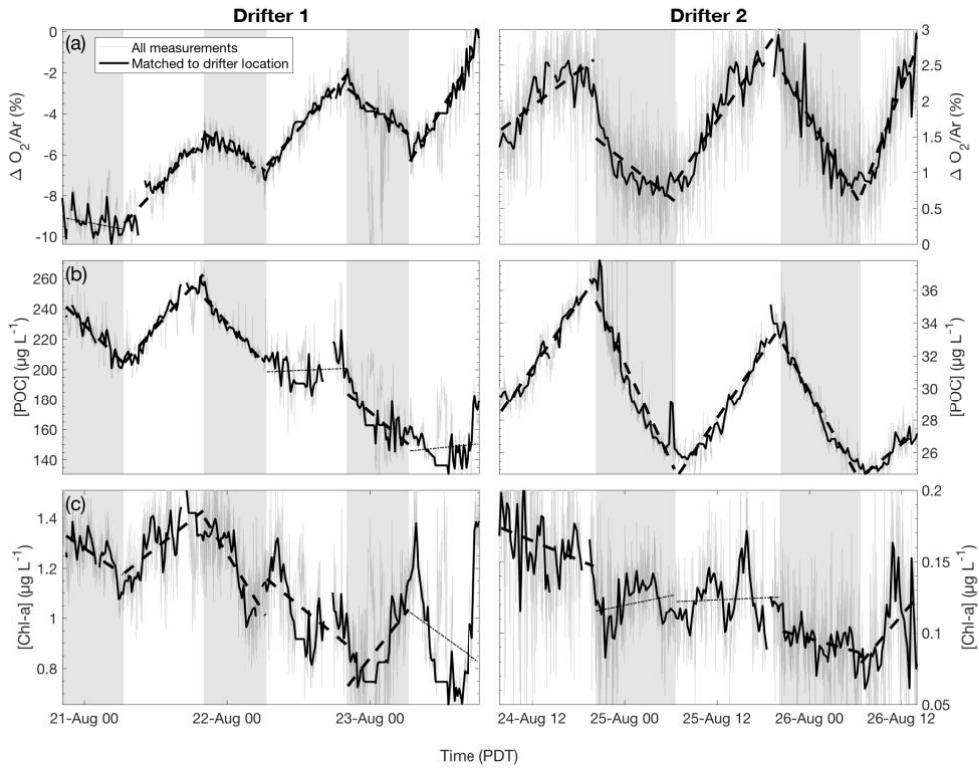

1346

1347 **Figure 2:** Comparison of average surface water properties between the two drifter deployments:

1348 (a) chlorophyll-a concentration (Chl-a), (b) phytoplankton carbon concentration (C<sub>ph</sub>), (c)  
 1349 particulate organic carbon (POC) concentration, (d) the wavelength-dependent slope of  
 1350 particulate backscatter ( $b_{\text{bp}}$ ), (e) biological oxygen saturation anomaly ( $\Delta\text{O}_2/\text{Ar}$ ), and (f) the  
 1351 [C<sub>ph</sub>]/[Chl-a] ratio. Boxes represent the median (center line) and 25 and 75 percentiles (box  
 1352 edges). Outliers are indicated as black “+” marks.

1353

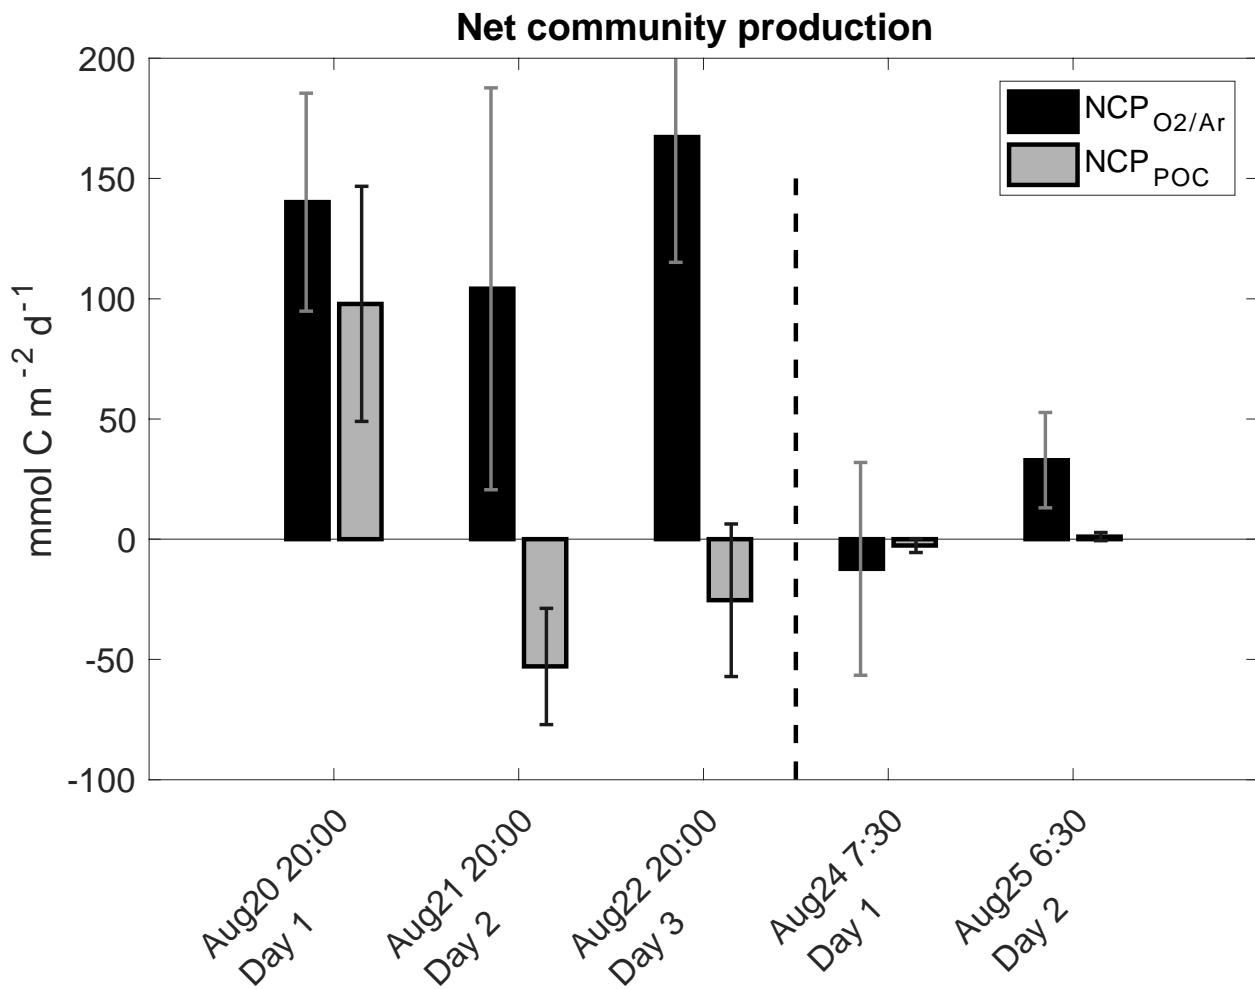

1354

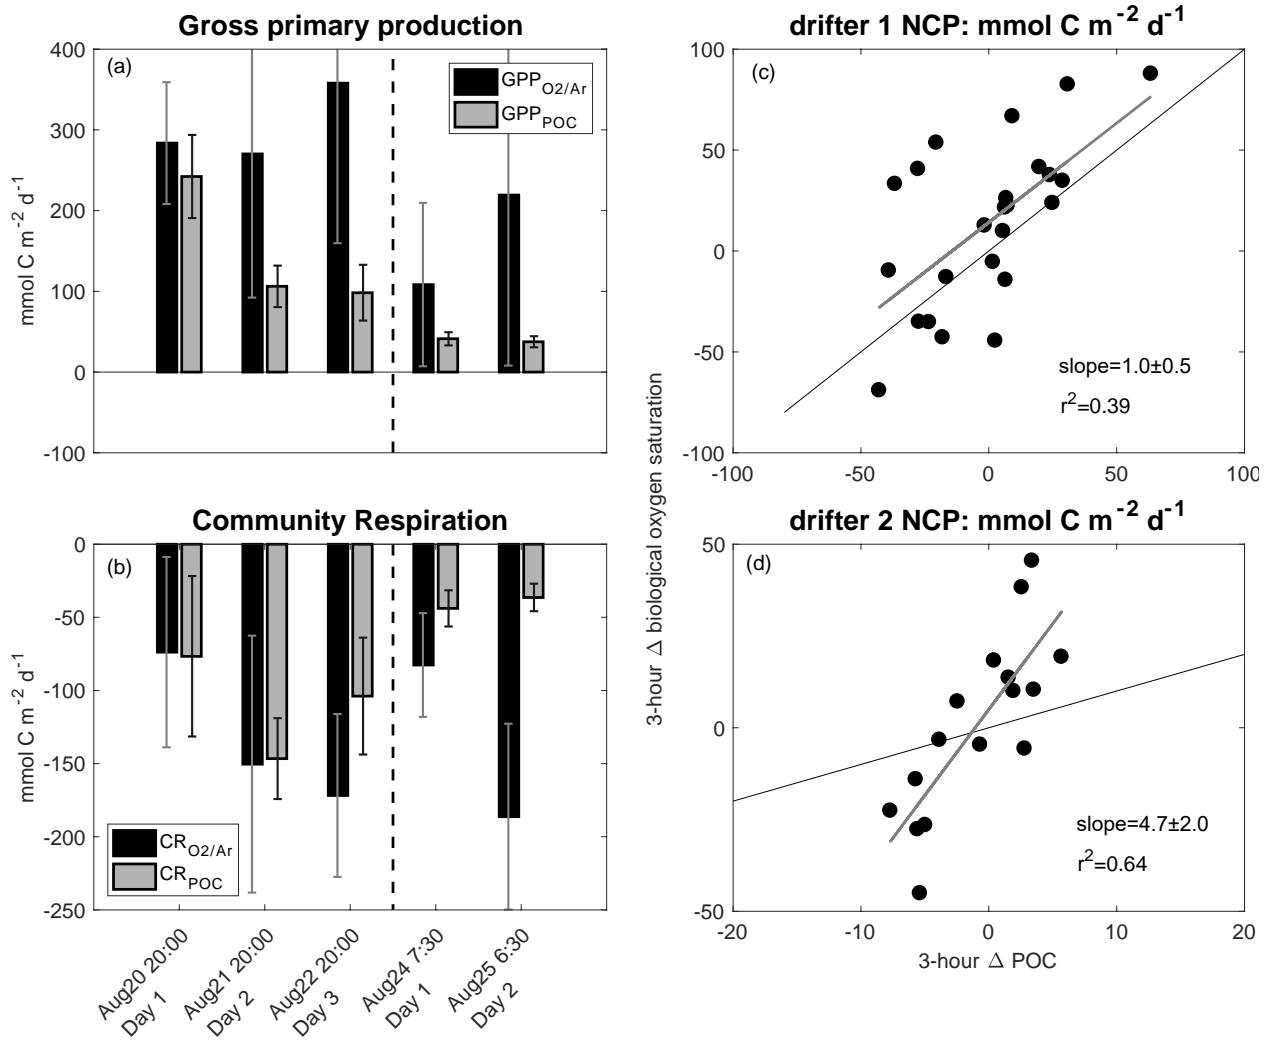

1355

1356 **Figure 3:** Time-series of (a) biological oxygen saturation ( $\Delta O_2/Ar$ ), (b) particulate organic  
 1357 carbon (POC) concentration, and (c) chlorophyll-a (Chl-a) concentration during the two drifter  
 1358 deployments (left and right panels, respectively). For each daytime (non-shaded) and nighttime  
 1359 (shaded) interval, the best fit linear regression line is plotted. Significant regressions ( $p < 0.05$ ) are  
 1360 plotted as thick dashed lines, while non-significant regressions ( $p \geq 0.05$ ) are plotted as thin dotted  
 1361 lines. Grey lines show all measurements while thicker black line shows observations collected  
 1362 when the ship was within 1.5 km of the drifter location.

1363

1364  
1365  
1366 **Figure 4:** Daily net community production (NCP) during successive days of the two drifter  
1367 deployments derived from diurnal variations of biological oxygen saturation ( $\Delta O_2/Ar$ ) and  
1368 particulate organic carbon (POC) concentration. Each set of bars is for one 24-hour period, with  
1369 approximate starting times on the x-axis. Note that the negative NCP $O_2/Ar$  value for the first day  
1370 of drifter period 2 was computed by integrating NCP $O_2/Ar$  values over eight consecutive three-  
1371 hour increments (refer to Table 2).

**Figure 5:** The left panels show comparisons between  $\Delta\text{O}_2/\text{Ar}$ -derived and POC-derived (a) GPP and (b) CR over the five days of both drifter deployments. The right panels show  $\Delta\text{O}_2/\text{Ar}$ -derived NCP ( $\text{NCP}_{\text{O}_2/\text{Ar}}$ ) as a function of POC-derived NCP ( $\text{NCP}_{\text{POC}}$ ) over three-hour increments during (c) drifter period 1 and (d) drifter period 2. The vertical dashed lines in (a) and (b) indicate the break between drifter periods 1 and 2. Thin black lines in (c) and (d) represent the 1:1 line, while thicker grey lines are the best-fit from linear regressions and correspond to the indicated slope and  $r^2$  values.
