S1 Theory of random sampling

Random sampling can be covered analytically by the central limit theorem, which states that whenever independent random variables are added, their sum converges toward a normal distribution irrespective of the original distribution. Suppose that $X_1, X_2, ... X_n$ is a sequence of independent identically distributed random variables with a mean $\overline{X_n}$, finite expected value $E(X_i) = \mu$, and variance $Var(X_i) = \sigma^2$. For $n \to \infty$, the distribution function, Z_n, converges to the standardized normal distribution.

$$Z_n = \frac{\sqrt{n}(\overline{X_n} - \mu)}{\sigma}$$

The probability, P_n, that $\overline{X_n} \in [0.9 \cdot \mu, 1.1 \cdot \mu]$ can be calculated as the "sample reliability", where Φ is the probability of the normal distribution, can be calculated as follows:

$$P_n = P\left(|z_n| < 0.1\sqrt{n}\frac{\mu}{\sigma}\right) = \Phi\left(0.1\sqrt{n}\frac{\mu}{\sigma}\right) - \Phi\left(-0.1\sqrt{n}\frac{\mu}{\sigma}\right)$$
$$= 2 * \Phi\left(0.1\sqrt{n}\frac{\mu}{\sigma}\right) - 1 \quad (1)$$

The "minimum sample size", n_{min}, defines the number of samples needed under the condition that the mean of the samples does not deviate more than 10 % from the real mean biomass with a probability of at least 90 %. We determined n_{min} using Eq. (1) and the quantile of the standardized normal function, q:

$$2 \cdot \Phi\left(0.1\sqrt{n}\frac{\mu}{\sigma}\right) - 1 \geq 0.9$$

thus
$$\Phi\left(0.1\sqrt{n}\frac{\mu}{\sigma}\right) \geq \frac{1.9}{2}$$

Therefore
$$0.1\sqrt{n}\frac{\mu}{\sigma} \geq q\left(\frac{1.9}{2}\right)$$

Finally,
$$n \geq \frac{(q(0.95) \cdot \sigma)^2}{(0.1\,\mu)^2}$$

The minimum sample size here is assumed to be the minimum number of samples for which this equation is still valid.

$$n_{min} := \left\lceil \frac{(q(0.95) \cdot \sigma)^2}{(0.1\,\mu)^2} \right\rceil$$

n_{min} depends only on the mean biomass, μ, and its standard derivation, σ. In this study, this term is simplified using the coefficient of variation (CV=$\frac{\sigma}{\mu}$) as follows:

$$n_{min} = \left\lceil \frac{q(0.95)^2}{0.01} \cdot CV^2 \right\rceil \qquad (3).$$

Figure S1 Relation between the minimum sample size and the coefficient of variation (CV) of the biomass distribution. The results for random sampling of Barro Colorado Island (BCI, 50 ha), Panama (~50000 km^2 (Asner et al., 2013)), America, Africa and Asia (~7-15 Mio km^2 (Baccini et al., 2012)) are shown. The analyzed biomass maps are displayed with colored crosses (with the name and plot size shown in brackets). The analytical relationship between CV and the minimum sample size has been derived from equation 3 (red line). Please note that both axes are logarithmized.

35 **Table S1** Analyzed forest biomass maps for the tropics and their minimum sample size. Shown are the forest biomass maps for (a) South America, Africa and Southeast Asia (Baccini et al., 2012) and for (b) South America, Africa and Asia & Australia (Saatchi et al., 2011) and their random sampling performance. The minimum sample size refers to the minimum number of plots to accurately estimate the mean biomass of the forest (the mean of the samples does not deviate more than 10 % from the real mean biomass with a probability of at least 90 %). The last column shows the necessary sampling area $a_{min} = A_{plot} \cdot n_{min}$.

Map (Resolution)	Map size [Mio. km^2]	Plot size A_{plot}[ha]	CV	Minimum sample size n_{min} [plots]	Minimum total area of samples a_{min} [ha]
a)					
South America (500 m)	15	25	61.34	102	2550
Africa (500 m)	12	25	82.54	185	4625
Southeast Asia (500 m)	7	25	69.43	131	3275
b)					
South America (1000 m)	61	100	65.83	118	118000
Africa (1000 m)	46	100	93.44	237	237000
Asia & Australia (1000 m)	73	100	82.63	185	185000

**S2** Point pattern summary functions for the clustered sampling approach

For the reconstructions of the clustered locations of the inventory plots, we use several point pattern summary functions that quantify the spatial structure of the pattern within distances of up to 100 km: (I) the probabilities $p(k, r)$ that the typical point of the pattern has k neighbors within distance interval r − bin/2, r + bin/2, where bin = 500 m is the resolution of the map and

45 $r = 0.5, 2.5, 7.5, 17.5, 25,$ and 50 km. (II) the distribution function $D(r)$ of the distances to the nearest neighbor; (III), the average number of points at distance r from the points of the pattern given by $\lambda(2\pi r)g(r)$ where λ is the density of the pattern and $g(r)$ the pair correlation function; (IV) the average number of points at a distance r from the points of the pattern given by $\lambda K(r)$, where $K(r)$ is Ripley's K; (V) $H_s(r)$ the spherical contact distribution; (VI) the distribution functions $D_k(r)$ of the k'th nearest neighbor. For further details see Wiegand, He and Hubbell, (2013).

S3 Downscaling of the South America map

To downscale the 500 m resolution map of South America to a 100 m resolution, we used statistical relationships derived from the Panama map at 100 m and the 500 m resolution. Therefore, 25 plots from the original map (100 m resolution) were aggregated to a mean value. The standard deviation of those 25 plots at a 100 m resolution sd_{100} can then be plotted against the mean value of the plots, which can be interpreted as the aggregated value at a 500 m scale AGB_{500} (see Fig. S2).

After creating classes over the AGB of 1 t/ha, each AGB value of 25 ha plot of the South American map was assigned to 25 plots of 1 ha drawing random values from a normal distribution $N(AGB_{500}, (sd_{100})^2)$. If the South American plot had an AGB value higher than the maximum value of Panama, the created plots were drawn from a normal distribution with the standard deviation of the maximum class. Negative biomass plots were set to zero.
Figure S2 Subplot heterogeneity in the Panama biomass map (500 m resolution). Shown is the aboveground biomass (AGB) at a 500 m resolution and the standard deviation (SD) of its associated 25 subplots at a 100 m resolution. Each dot represents one plot from the Panama map (~300,000 plots).

S4 Spatial clustering of the biomass

To quantify spatial correlation structures in the biomass map we used the mark variogram $\gamma_{mm}(r)$ (Illian et al. 2008; Wiegand and Moloney 2014). Each grid cell of the map has x-y coordinates and the associated biomass value is the mark. We then consider all pairs of cells that are distance r apart and determined the mean value of the test function $t_4(m_1, m_2) = (m_1 - m_2)^2/2$ where m_1 is the biomass mark of the first cell and m_2 that of the second cell. The mark variogram has small values if

the biomasses of cells that are distance *r* apart are in general similar to each other and large values if the biomasses are

dissimilar. To test for significant spatial structure we compared the observed mark variogram to that of a null model where

70   we randomly permutated the biomass values among the all forested cells.

### (a) BCI   (b) Panama   (c) South America

Figure S3 Spatial structure of the biomass maps. Shown is the observed mark variogram (green line, for details see Illian *et al.* (2008)) for maps of Barro Colorado Island (50 m resolution, 50 ha), Panama (100 m resolution, ~50000 km^2) and South America (500 m
75   resolution, 15 Mio km^2). Values of the dashed black line show the expectation under the null model of random distribution of biomass (gray color displays the 99% simulation envelopes). Values below the envelopes indicate clustering (more similar biomass values at short distances than expected by the null model), values above indicate overdispersion (more dissimilar biomass values than expected by the null model, e.g., comparable to a chessboard). For further details on the method, see Wiegand and Moloney (2014). Please note that for Panama and America, we use subsets of 10,000 plots. **(a)** No significant spatial structure was observed for the 50m resolution for Barro
80   Colorado Island (BCI). **(b-c)** In contrast to BCI, the observed biomasses for Panama and America are below simulation envelopes, indicating biomass values are within distances of 10 km and 50 km more similar to each other than expected by a random distribution of biomasses over all forested cells.
