Abstract

In this study, we investigate the role of sedimentary N cycling in the Southern North Sea. We present a budget of ammonification, nitrification and sedimentary NO_3^- consumption / denitrification in contrasting sediment types of the German Bight (Southern North Sea), including novel net ammonification rates. We incubated sediment cores from four representative locations in the German Bight (permeable, semi-permeable and impermeable sediments) with labeled nitrate and ammonium to calculate benthic fluxes of nitrate and ammonium and gross rates of ammonification and nitrification. Ammonium fluxes generally suggest oxic degradation of organic matter, but elevated fluxes at one sampling site point towards the importance of bio-irrigation or short-term accumulation of organic matter. Sedimentary fluxes of dissolved inorganic nitrogen are an important source for primary producers in the water column, supporting ~7 to 59 % of the average annual primary production, depending on water depth.

We find that ammonification and oxygen penetration depth are the main drivers of sedimentary nitrification, but this nitrification is closely linked to denitrification. One third of freshly produced nitrate in impermeable sediment and two-thirds in permeable sediment were reduced to N_2 . The semi-permeable and permeable sediments are responsible for ~68 % of the total benthic N_2 production rates, which, based solely on our data, amounts to ~1030 t N d^{-1} in the southern North Sea. Thus, we conclude that semi-permeable and permeable sediments are the main sinks of reactive N, counteracting eutrophication in the southern North Sea (German Bight).

28 **1 Introduction**

29 The continental shelves and coastal margins make up for <9 % of the total area of ocean surface, but are responsible
30 for vast majority of the biogeochemical cycling both in the water column and in the sediments (Jorgensen, 1983).
31 For instance, 30 % of global marine primary production occurs in coastal, estuarine and shelf systems (LOICZ,
32 1995), and nutrient regulation in shelf sediments is a particularly valuable ecosystem service (Costanza et al.,
33 1997).

34 The German Bight is part of the southern North Sea and is bordered by densely populated and industrialized
35 countries, and receives large amounts of nutrients via river discharge (e.g., Rhine, Maas, Elbe, Weser, Ems) (Los
36 et al., 2014). This caused clear eutrophication symptoms such as phytoplankton blooms, oxygen deficiencies and
37 macrobenthos kills especially during the 1980s (Hickel et al., 1993; von Westernhagen et al., 1986) in the North
38 Sea. In the adjacent Wadden Sea intense phytoplankton blooms, a possible decrease of seagrass and massive
39 blooms of opportunistic macroalgae were attributed to eutrophication (e.g. Cadée and Hegemann, 2002). Since the
40 mid 1980s, the nitrogen (N) loads into the German Bight have been decreasing, but the entire SE North Sea is still
41 flagged as an eutrophication problem area (OSPAR, 2010).

42 Nitrogen availability increases primary production on a variety of spatial and temporal scales. At present, major
43 nitrogen sources for the Southern North Sea are agricultural and urban waste water, and to a lesser extent, a variety
44 of reactive N emission (e.g., nitrogen oxides from burning fossil) (Emeis et al., 2015).

45 Internal N cycling in sediments (e.g., assimilation, ammonification and nitrification) change the distribution and
46 speciation of fixed N, but not the overall amount of N available for primary production (Casciotti, 2016). Reduction
47 of reactive nitrogen through denitrification and anammox in anoxic conditions back to unreactive N₂, however,
48 does remove N from the biogeochemical cycle (Neumann et al., 2017).

49 Because these eliminating processes are confined to suboxic and anoxic conditions, they only occur in sediments
50 in the generally oxygenated North Sea. Due to its putative relevance as an ecosystem service, denitrification has
51 been subject to many studies, but ammonification as a source of N to primary production so far received much less
52 attention. This is in part due to the complexity created by coupled ammonification-nitrification in which different
53 N processes, such as assimilation and denitrification, interact and affect the NH₄⁺ and NO₃⁻ concentrations in pore
54 waters. To our knowledge, no ammonification rates in the North Sea have been quantified, whereas nitrification
55 rates in permeable sediments were found to be in the same order of magnitude as denitrification rates (<0.1 to ~3.0
56 mmol m⁻² d⁻¹, Tab. 1) (Marchant et al., 2016). N loss in the German Bight has been studied by several authors (e.g.
57 Deek et al., 2013) showing high spatial, temporal and seasonal variability.

58 The main N loss process in the North Sea is denitrification, whereas and anammox plays a minor role (Bale et al.,
59 2014; Marchant et al., 2016). The main drivers of denitrification are organic matter content and permeability of
60 the sediment (Neumann, 2012), and recent studies suggest that permeable sediments account for about 90
61 % of the total benthic NO_3^- consumption in the German Bight (Neumann et al., 2017).

62 Quantifying N dynamics based solely on changes in N concentrations provides limited insight into underlying
63 reactions, as only net changes can be observed. Previous authors used different methods for determination of
64 specific N rates. Lohse et al. (1993) used the acetylene block method, core flux incubations and isotope pairing in
65 the early 1990s types to determine denitrification rates in a variety of sediment types (Tab. 1). Deek and co-authors
66 (Deek et al., 2013; Deek et al., 2011) investigated N-turnover in the Wadden Sea and in the extended Elbe estuary
67 using core flux incubations and isotope pairing. Marchant et al. (Marchant et al., 2016) measured denitrification
68 rates in permeable sediments obtained from slurry incubations and percolated sediment cores. More recently,
69 Neumann et al. (2017) used pore-water NO_3^- concentration gradient profiles to determine NO_3^- consumption rates
70 in the German Bight.

71 Stable isotope techniques offer several approaches to quantify N turnover processes, and ^{15}N tracer studies have
72 been widely used to determine N transformation rates (e.g. nitrification and denitrification) (Brase et al., 2018;
73 Sanders et al., 2018). The isotope dilution method can be used to distinguish between net and gross rates and so
74 help to unravel several N-processes such as ammonification and assimilation or nitrification and denitrification.
75 ^{15}N dilution (Koike and Hattori, 1978; Nishio et al., 2001) can be used to estimate gross N transformation rates
76 by measuring the isotopic dilution of the substrate and product pools, respectively (e.g. Burger and Jackson, 2003).
77 In this study, we used the isotope dilution method with labeled NH_4^+ and NO_3^- in separate sediment cores to
78 measure gross ammonification and gross nitrification. The net rates are determined by the sediment nutrient fluxes.
79 To measure denitrification we determined the produced N_2 independently of the labelling in the core. Sediment
80 core incubation experiment setup can never reproduce the identical conditions related to the advective processes
81 in permeable sediments. Nevertheless this method has advantages over just balancing sediment-water exchanges:
82 (1) The appearance of ^{15}N in the NH_4^+ pool during the incubation allows an estimate of ammonification rates, (2)
83 the isotopic dilution of NO_3^- tracks nitrification rates,

84 This study is conducted within the project “North Sea Observation and Assessment of Habitats” (NOAH). One
85 important aspect of the project is to investigate the biogeochemical status and functions of the sea floor, especially
86 nitrogen cycling, to gauge the eutrophication mitigation potential in light of continuing high human pressures
87 (<https://www.noah-project.de>).

88 In this paper, we investigate internal N rates of ammonification, nitrification and denitrification at four stations
89 across sediment types (clay/silt, fine sand, coarse sand) in the German Bight (North Sea) during late summer
90 (August/September) 2016. To assess the internal sediment N processes and the rates of reactive N release to the
91 water column, we incubated sediment cores amended with $^{15}\text{NH}_4^+$ and $^{15}\text{NO}_3^-$. We quantify the benthic gross and
92 net nitrification and ammonification rates and evaluate the environmental controls underlying spatial variabilities.
93 We further discuss the role of ammonification as a source of reactive nitrogen for primary producers, of
94 nitrification and of denitrification in the Southern North Sea.

95 **2 Material and Methods**

96 **2.1 Study site and sampling strategy**

97 The study site is in the German Bight (Southern North Sea), an area that is strongly influenced by nutrient inputs
98 from large continental rivers. The salinity in the coastal zone of the North Sea ranges between ~30 and 35, and the
99 average flushing time is 33 days (Lenhart and Pohlmann, 1997). The sampling was performed in August and
100 September 2016 during R/V *Heincke* cruise HE-471 in the German Bight (Fig. 1).

101 The sampling sites are part of the NOAH (North Sea Assessment of Habitats) assessment scheme (Fig. 1). Samples
102 were taken from 4 site (NOAH A, C, D and E) with different water depth and sediment characteristics (Table 2).
103 The sites represent typical sediment types based on statistics of granulometric properties, organic matter content,
104 permeability, and water depth assessed during former cruises (<https://doi.org/10.1594/PANGAEA.846041>).
105 Organic matter and CN ratio data from cruises HE 383 (06/07.2012) and HE 447 (06.2015) were used.

106 **2.2 core sampling and incubation**

107 At each station (NOAH A, C,D and E) both water samples and sediment samples were taken. Water samples were
108 taken with Niskin bottles attached to a CTD with additional chlorophyll and O_2 sensors. Sediment multicores
109 equipped with acrylic tubes (PMA) with an inner diameter of 10 cm and a length of 60 cm were used. Four intact
110 sediment cores from each station (exception: Station NOAH-D, only 3 cores could successfully be retrieved) were
111 incubated in a gas tight batch-incubation setup for 24 hours (Fig. 2) in the ship's laboratory at in-situ
112 temperature (~19°C) directly after sampling. Cores were handled carefully to avoid disturbance that could alter
113 benthic fluxes. Cores were incubated in the dark and the overlying site water was gently stirred with a magnetic
114 stirrer, avoiding sediment resuspension. The overlying water column was adjusted to a height of 20 cm. Water
115 temperature and oxygen concentration of the overlying water of sediment cores were measured continuously with
116 optodes (PyroScience, Germany).

117 To measure gross ammonification, two sediment cores (Station NOAH-D 1 core only) were enriched with $^{15}\text{NH}_4^+$
118 (50 at-%), the other two cores were amended with $^{15}\text{NO}_3^-$ (50 at-%) for an assessment of gross nitrification (Fig.

119 2). NH_4^+ and NO_3^- concentrations of the added tracer solution were adjusted to bottom water concentrations based
120 on nutrient data of previous cruises of the same location and time (later confirmed by nutrient analyses of site
121 water). For label addition, site water was replaced with the respective label solution. Due to the careful adjustment
122 of concentrations, incubations were done at a tracer level, and benthic fluxes should not be altered. The label
123 addition was calculated aiming for a maximum enrichment of 5,000 ‰ in substrates.

124 Samples were taken every 6 hours. Upon sampling, incubation water was filtered with a syringe filter (cellulose
125 acetate, Sartorius, 0.45 μm pore size) and frozen in exetainers (11.8 ml, Labco, High Wycombe, UK) at -20°C for
126 later analyses of nutrients and stable isotope signatures ($\delta^{15}\text{NH}_4^+$, $\delta^{15}\text{NO}_3^-$). Additional samples for the analyses of
127 dissolved nitrogen (N_2) were taken without filtration, and were preserved in exetainers (5.9 ml, Labco, High
128 Wycombe, UK) containing 2 % of a ZnCl_2 solution (1 M). Samples were stored at 4°C under water until analysis.

129 **2.3 Analyses**

130 **N_2 measurements by MIMS**

131 N_2 production was measured by a membrane inlet mass spectrometer (MIMS, inProcess Instruments), which
132 quantifies changes in dissolved $\text{N}_2:\text{Ar}$ ratios (Kana et al., 1994) from all four cores. During the measurements, the
133 water samples were maintained in a temperature-controlled water bath (16°C). For calibration, we measured
134 equilibrated water samples at four salinities, from 0 to 35 after each 10th water sample. We measured the production
135 of ^{28}N . The internal precision of the samples was $<0.05\%$ for N_2/Ar analyses.

136 **Oxygen penetration depth**

137 The oxygen penetration depth in the sediment of each station was measured using microoptodes (50 μm tip size;
138 Presens, Germany). The optodes were moved vertically into the sediment with a micromanipulator (PyroScience,
139 Germany), in steps of 100-200 μm , depending on the oxygen concentration. Three O_2 profiles were measured in
140 one sediment core of each station. The O_2 profiles were measured directly after core retrieval, i.e. within 10 – 15
141 minutes.

142 **Sediment samples**

143 The surface sediment samples (first 1 cm) of the cruises HE 383 (06/07-2012) and HE 447 (06-2015) were
144 analyzed for total carbon and total nitrogen contents with an elemental analyzer (Carlo Erba NA 1500) The total
145 organic carbon content was analyzed after removal of inorganic carbon using 1 mol L^{-1} hydrochloric acid. The
146 standard deviation of sediment samples was better than 0.6 % for C_{org} and 0.08 % for N determination.

147 Permeability and porosity of the sediments were conducted with sediments from the cruise He-471, the methods
148 were described in detail elsewhere (Neumann, 2016).

149 **Dissolved inorganic nitrogen concentrations**

150 NO_x, NO₂⁻ and NH₄⁺ concentrations of the water column samples were determined in replicate with a continuous
151 flow analyzer (AA3, Seal Analytics, Germany) according to standard colorimetric techniques (NO_x, NO₂⁻:
152 (Grasshoff et al., 1999), NH₄⁺: (K erouel and Aminot, 1997)). NO₃⁻ concentration was calculated by difference
153 between NO_x and NO₂⁻. Based on replicate analyses, measurement precision for NO_x and NO₂⁻ was better than 0.1
154  mol L⁻¹ and better than 0.2  mol L⁻¹ for NH₄⁺.

155 Water samples from core incubations were analyzed in duplicate for concentration of NH₄⁺, NO₂⁻ and NO₃⁻ using
156 a multimode microplate reader Infinite F200 Pro and standard colorimetric techniques (Grasshoff et al., 1999) at
157 the ZMT, Bremen. The standard deviations were <1  mol L⁻¹ for NO₃⁻, <0.2  mol L⁻¹ for NO₂⁻ and <0.5  mol L⁻¹
158 for NH₄⁺.

159 **Nitrogen isotope analyses**

160 The nitrogen isotope ratios of NO₃⁻ were determined via the denitrifier method (Casciotti et al., 2002; Sigman et
161 al., 2001). This method is based on the mass spectrometric measurement of isotopic ratios of N₂O produced by the
162 bacterium *Pseudomonas aureofaciens*. Briefly, 20 nmoles of sample NO₃⁻ were injected in a 20 ml vial containing
163 MilliQ. Two international standards were used (IAEA-NO₃⁻  ¹⁵N = +4.7 ‰, USGS-34  ¹⁵N = -1.8 ‰) for a
164 regression-based correction of isotope values. For further quality assurance, an internal standard was measured
165 with each batch of samples. The standard deviation for  ¹⁵N was better than <0.2 ‰

166 For ammonium isotope measurements, nitrite was removed by reduction with sulfamic acid (Granger and Sigman,
167 2009) before NH₄⁺ was chemically oxidized to NO₂⁻ by hypobromite at pH ~12 and then reduced to N₂O using
168 sodium azide (Zhang et al., 2007). 10 nmol of NH₄⁺ were injected, and all samples with [NH₄⁺] >1  mol L⁻¹ were
169 analyzed. For the calibration of the ammonium isotopes, we used three international standards (IAEA-N1  ¹⁵N =
170 +0.4 ‰, USGS 25  ¹⁵N = -30.4 ‰, USGS 26  ¹⁵N = +53.7 ‰). The standard deviations were better than 1 ‰.

171 N₂O produced either by the denitrifier method or the chemical conversion of ammonium was analysed with a
172 GasBench II, coupled to an isotope ratio mass spectrometer (Delta Plus XP, Thermo Fisher Scientific).

173 **2.4. Rates and fluxes calculation for respiration, ammonification, nitrification and denitrification rates in** 174 **core incubations**

175 Benthic fluxes

176 Oxygen consumption, net ammonification, net nitrification and denitrification were calculated based on
177 concentration changes in the sediment incubations. The respective benthic fluxes were calculated as follows:

$$178 r_{\text{net}} = d(C) \cdot V / d(t) \cdot A \text{ [mmol N m}^{-2} \text{ d}^{-1}] \quad (1)$$

179 where $d(C)$ is the oxygen, nutrient or the nitrogen (N_2) concentration at the start and at the end of the experiment,
180 V is the volume of the overlying water, $d(t)$ is the incubation time and A is the surface area of the sediment..
181 Positive fluxes (outflow concentrations above inflow concentrations) imply net production in the sediment.

182 Gross rates of ammonification and nitrification

183 Gross rates of ammonification and nitrification (r_{gross}) were calculated based on ^{15}N isotope dilution (Koike and
184 Hattori, 1978; Nishio et al., 2001). For example, ammonification rates are calculated based on $^{15}\text{NH}_4^+$ additions,
185 nitrification rates are based on $^{15}\text{NO}_3^-$ additions (Fig. 2) :

$$186 \quad r_{\text{gross}} = [\ln(f^{15}\text{N}_{\text{end}}/f^{15}\text{N}_{\text{start}})]/[\ln(C_{\text{end}}/C_{\text{start}})]*(C_{\text{start}}-C_{\text{end}}/t)*(V/A*\Delta t) \quad (2)$$

187 where C_{start} is the initial NH_4^+ or NO_3^- concentration, C_{end} is the concentration at time t , and $f^{15}\text{N}_{\text{start}}$ and $f^{15}\text{N}_{\text{end}}$
188 represent ^{15}N atom% excess (Brase et al., 2018), V is the volume of the overlying water and A is the surface area
189 of the sediment. All rates are given in $\text{mmol N m}^{-2} \text{d}^{-1}$.

190 **3 Results**

191 *Ammonification*

192 We measured gross ammonification rates with the isotope dilution method using $^{15}\text{NH}_4^+$ as tracer, and measured
193 net ammonium fluxes with the flux method. The highest net ammonium flux and gross ammonification rates were
194 measured in the impermeable, organic-rich sediment at station NOAH-C ($6.6 \pm 1.4 \text{ mmol N m}^{-2} \text{d}^{-1}$ and 9.5 mmol
195 $\text{N m}^{-2} \text{d}^{-1}$ for net flux and gross ammonification, respectively).

196 The lowest net ammonium fluxes were measured in the semi-impermeable sediment at station NOAH-D ($0.5 \pm$
197 $0.1 \text{ mmol N m}^{-2} \text{d}^{-1}$). The lowest gross ammonification rate was measured at the permeable sediment station
198 NOAH-A ($2.1 \pm 0.3 \text{ mmol N m}^{-2} \text{d}^{-1}$). The impermeable sediment station NOAH-C had the highest net ammonium
199 fluxes ($6.6 \pm 1.4 \text{ mmol N m}^{-2} \text{d}^{-1}$) and gross ammonification rates ($9.5 \text{ mmol m}^{-2} \text{d}^{-1}$). Net and gross ammonification
200 rates are significantly correlated ($r^2=0.55$; see electronic supplemental).

201 *Nitrification*

202 **As for the ammonification**, we measured gross nitrification rates by means of the stable isotope dilution method
203 with $^{15}\text{NO}_3^-$ as tracer, and net nitrate fluxes employing the flux method. Net fluxes and gross nitrification rates
204 varied significantly between stations. Net nitrate fluxes were highest at station NOAH-C and at station NOAH-E
205 with $1.1 \pm 0.5 \text{ mmol N m}^{-2} \text{d}^{-1}$ and $1.2 \pm 0.5 \text{ mmol N m}^{-2} \text{d}^{-1}$, respectively (Fig. 3, Fig. 5). Gross nitrification rates
206 were highest at NOAH-C ($2.1 \pm 0.1 \text{ mmol N m}^{-2} \text{d}^{-1}$). The lowest rates of net nitrate flux ($0.3 \pm 0.3 \text{ mmol N m}^{-2} \text{d}^{-1}$)
207 and gross nitrification ($1.2 \pm 0.0 \text{ mmol m}^{-2} \text{d}^{-1}$) were observed in the permeable sediment at station NOAH-A.
208 Net and gross nitrification rates are closely correlated ($r^2=0.87$; Fig. 3) with net nitrate fluxes being systematically
209 lower than gross nitrification rates.

210 *Denitrification*

211 Unlike to ammonification and nitrification, we were not able to make use of the stable isotope tracers to evaluate
212 N_2 production rates with a stable isotope technique because the requirements for the Isotope Pairing method
213 (Rysgaard-Petersen et al., 1996) were not met because the labeled $^{15}NO_3^-$ in the overlying water is too low to
214 measure any $^{15}N-N_2$ species. Our N_2 production estimates are thus limited to the flux method. The observed
215 average denitrification rates ranged from $1.3 \pm 1.1 \text{ mmol N m}^{-2} \text{ d}^{-1}$ to $1.9 \pm 0.8 \text{ mmol N m}^{-2} \text{ d}^{-1}$ (Fig. 5)
216 and did not vary significantly between stations.

217 **Sedimentary organic matter descriptions**

218 The data show a clear correlation between sediment type and organic carbon and nitrogen content. Clay and silty
219 sediment (NOAH-C) had the highest organic carbon (0.73 %) and nitrogen (0.10 %) concentrations (Tab. 2).
220 Medium sand station (NOAH-A) had the lowest C_{org} (0.03 to 0.04 %) and total nitrogen (<0.01 to 0.01 %)
221 concentrations. This trend does probably not apply to NOAH-E since the samples for C / N analyses were retrieved
222 prior to the abrupt emergence of a large pockmark field at this station (Krämer et al. 2017) while the sediment
223 cores for the incubations were retrieved after the emergence of the pockmarks. The large scale sediment
224 resuspension event resulted in numerous newly formed depressions with increased sedimentation of organic
225 material.

226

227 **4 Discussion**

228 **4.1 Magnitude and relevance of ammonification**

229 A principal goal of this study was to assess the role of ammonification in the nitrogen cycle of the German Bight.
230 Ammonification releases NH_4^+ during the decomposition of organic matter and resupplies the water-column
231 inventory of reactive nitrogen. The quantification of ammonification rates is challenging, because ammonium is
232 readily assimilated by primary producers or is rapidly nitrified, causing low ammonium concentrations and
233 necessitating to use the isotope dilution method.

234 This study represents direct measured gross ammonification rates across typical sediment types of the North Sea,
235 covering a large range from 1.9 to 9.5 $\text{mmol N m}^{-2} \text{ d}^{-1}$: Ammonification rates were mainly governed by sediment
236 texture and organic matter content. The impermeable muddy sediment at station NOAH-C with high C_{org} and TN
237 content (0.73 % and 0.10 %, respectively, Tab. 2) had highest gross and net ammonification rates. This is line with
238 other studies showing enhanced ammonium release in muddy coastal sediments (e.g. Caffrey, 1995).

239 The sandy sediments at sites NOAH-A, NOAH-D and NOAH-E exhibited significantly lower gross
240 ammonification rates. This reflects the lower sediment organic matter content in these sandy sediments expressed
241 in C_{org} (0.03 – 0.04 %) and N (0.01 – <0.01 %) concentrations (Caffrey, 1995), Tab. 2).

242 It is striking, though, that net and gross ammonification in the sandy sediment at station NOAH-E was clearly
243 elevated compared to the other sandy stations NOAH-A and NOAH-D. There are two possible explanations for
244 this enhanced ammonium production: (1) enhanced supply of organic matter to the sediment surface or (2) effects
245 bioirrigation and bioturbation.

246 Station NOAH-E is located inside a pockmark field that had developed relatively recently, between July and
247 November 2015 (Krämer et al., 2017). Our assessment of C and N content is based on samples that were taken
248 prior to the pockmark formation in 2012 and 2015 (<https://doi.org/10.1594/PANGAEA.883199>). The sediment
249 samples during the cruise (He-471) in 2016 were taken from the depression inside an individual pockmark, which
250 was about ~0.2 deeper than the surrounding sediment (Krämer et al., 2017). We assume that organic matter from
251 the water column accumulated in these transient structures, and that the organic carbon and nitrogen content thus
252 was elevated. A transient change in surface sediment composition, which is not captured by our compositional
253 data, may thus have caused the enhanced ammonification rate.

254 An alternative explanation is an elevation of ammonium fluxes from the sediment due to sediment reworking. In
255 the sediment incubations, we found a high benthic activity of *Spiophanes bombyx* and *Phoronis sp.*. Both benthic
256 organisms can increase the nutrient fluxes from the sediment to the bottom water, the oxygen penetration depth,
257 and, in turn, organic matter degradation in the oxic zone (Aller, 1988).

258 Under completely oxic conditions, the ratio of NH_4^+ release and O_2 consumption in the entire study area should
259 approximate Redfield ratios of about 1:8.6 (Thibodeau et al., 2010). Such ratios were observed at the semi-
260 permeable station NOAH-D, the permeable station NOAH-A (Fig. 2), and at station NOAH-E, suggesting that in
261 these cores most of the organic matter was degraded under oxic conditions. At station NOAH-C, however, the
262 N: O_2 ratio was clearly elevated above the Redfield ratio. While this finding is based on an individual assessment,
263 it appears plausible: We presume that the enhanced production of ammonium relative to O_2 consumption reflects
264 the importance of anoxic ammonium generation, i.e., during methanogenesis or sulfate reduction (e.g. Jorgensen,
265 1982). This is quite likely at station NOAH-C, where oxygen penetration depth in the impermeable, organic-rich
266 sediment is lowest, and where increasing NH_4^+ concentrations with depth indicate decomposition or organic matter
267 in the absence of free oxygen (Hartmann et al., 1973).

268 **4.2 Ammonification coupled to denitrification by nitrification**

269 Based on the interpolation of gross rates of ammonification, it is evident that ammonification contributes
270 significantly to nutrient regeneration in the German Bight. However, there is a clear difference between gross and
271 net ammonification rates, suggesting that ammonium is taken up, either by assimilation or nitrification. In dark
272 sediments, where phototrophic organisms are light limited, we presume that nitrification is likely the more
273 important process (Dähnke et al., 2012).

274 Nitrification produces NO_3^- , which represents the largest DIN pool in the water column of the North Sea and is the
275 substrate for denitrification, and thus the link to an ultimate removal of fixed nitrogen from the water column.

276 We observed gross nitrification rates at all four stations ranging from $1.2 \pm 0.0 \text{ mmol N m}^{-2} \text{ d}^{-1}$ at the sandy station
277 NOAH-A, to $1.3 \text{ mmol N m}^{-2} \text{ d}^{-1}$ in the moderately permeable sediment at NOAH-D and to $2.1 \pm 0.1 \text{ mmol N m}^{-2}$
278 d^{-1} in the impermeable sediment at station NOAH-C (Fig. 3, Fig. 5). Gross nitrification at the impermeable
279 sediment station NOAH-C accounted for around 22.2 % (± 0.7 %), around 38.5 % at the semi-permeable station
280 (NOAH-D) and around 50.6 % (± 15.8 %) at the permeable sediment stations of total DIN flux to the bottom water.

281 Overall, nitrification is in the same range as reported by Marchant et al. (2016) in sandy sediment near Helgoland
282 (0.2 to $3.0 \text{ mmol m}^{-2} \text{ d}^{-1}$; Tab. 1). Highest nitrate fluxes from the sediment and gross nitrification rates were
283 observed at the impermeable station NOAH-C and at station NOAH-E, where pockmark structure and organic
284 matter accumulation might have affected benthic nutrient fluxes (see section 4.1).

285 Lowest gross nitrification rates and nitrate fluxes are found at the permeable station NOAH-A, but apart from this,
286 we do not see a clear correlation of nitrification and permeability in our study. Nonetheless, nitrification rates are
287 lowest at Station NOAH-A, where oxygen penetration depth is highest, and the sediment has low organic matter
288 content (Tab. 2). A high oxygen penetration depth can support nitrification, but it is in this case obviously substrate
289 limited due to low organic matter content, which limits ammonification. Oxygen penetration can enhance
290 nitrification at greater depth, but can, on the other hand, also increase diffusion limitation (Alkhatib et al., 2012).

291 Due to this dual control of nitrification by OPD on the one hand and substrate availability on the other, the
292 individual correlations between C_{org} or TN and nitrification are relatively weak. Generally, organic matter
293 deposition in the sediment supports higher ammonification rates, which in turn enhance nitrification under oxic
294 conditions (Henriksen and Kemp, 1988; Rysgaard et al., 1996). Consequently, nitrification is affected by the NH_4^+
295 pool in the sediment, temperature, salinity and O_2 (e.g. Sanders, 2018).

296 This interplay of factors is mirrored in a clear and statistically significant ($\alpha=0.05$) correlation of gross nitrification
297 and gross ammonification rates ($r^2 = 0.92$). Overall, the gross NO_3^- production (1.2 to $2.1 \text{ mmol m}^{-2} \text{ d}^{-1}$) was small
298 relative to ammonification rates (1.9 to $9.5 \text{ mmol N m}^{-2} \text{ d}^{-1}$). We find that nitrification is governed by a complex
299 interplay of variables such as ammonification rate, permeability, organic matter availability and oxygen

300 penetration depth, and is likely difficult to predict based on one of these factors alone. Generally, organic matter
301 deposition in the sediment supports higher ammonification rates, which in turn enhance nitrification under oxic
302 conditions (Henriksen and Kemp, 1988; Rysgaard et al., 1996). In our setting, this is reflected in a clear correlation
303 of gross rates of ammonification and nitrification.

304 **4.3 Denitrification**

305 Denitrification, the reduction of NO_3^- to gaseous N_2 , reduces the pool of bioavailable N, and is therefore very
306 relevant in eutrophic coastal areas such as the southern North Sea. In our study, the measured denitrification rates
307 ranged from 1.3 to 1.9 $\text{mmol N m}^{-2} \text{d}^{-1}$ (Fig. 5). This estimate is on the higher end of previous measurements from
308 sites in the German Bight (Deek et al., 2013; Marchant et al., 2016) (Tab. 1), but generally fits with previous
309 observations. We assume that the rates in our study are elevated because sampling took place after the spring
310 phytoplankton bloom, and not all organic matter that had been deposited at the sediment surface had been
311 remineralized. Such a decoupling of water column production and sedimentary denitrification has been observed
312 before in stratified water masses of the Baltic Sea (Hellemann et al., 2017). Even though our study was designed
313 to cover diverse sediment types, and thus allow for an improved extrapolation of rates to the total German Bight
314 area, this highlights the heterogeneity of sediments, and points out that the sampling season can have a marked
315 effect on measured rates. Therefore, follow-up experiments should try to cover the seasonality as much as possible
316 to improve estimates of denitrification in the German Bight area.

317 Important seasonal effects on denitrification can be attributed to variations in oxygen supply, changing bottom
318 water NO_3^- concentration and organic carbon content in the sediment (Deek et al., 2013). In our study, the bottom
319 water nitrate concentration is too low (<0.5 to $4.5 \mu\text{mol L}^{-1}$) to sustain the observed denitrification rates, and thus
320 the major nitrate source fueling the observed denitrification must be coupled nitrification-denitrification fueled by
321 mineralization of sedimentary organic material. This is reflected in a strong correlation between gross nitrification
322 and denitrification rates ($r^2 = 0.85$).

323 In our study, we find that this coupled nitrification-denitrification determines the total N flux. Denitrification
324 essentially removes, within the given uncertainties (Fig. 5) all nitrate produced by nitrification at study sites
325 NOAH-A and NOAH-D. At stations NOAH-C and NOAH-E, where we assume a (possibly transient in case of
326 NOAH-E) accumulation of organic matter, nitrification rates are enhanced, and a substantial amount of freshly
327 produced nitrate is released to the water column.

328 In comparison to the supply of mineralized N (i.e., gross ammonification) denitrification accounts for ~20 % (1.9
329 $\text{mmol N m}^{-2} \text{d}^{-1} / 9.5 \text{mmol N m}^{-2} \text{d}^{-1}$) at the impermeable sediment station NOAH-C, ~39 % (1.3 $\text{mmol N m}^{-2} \text{d}^{-1}$
330 / 3.3 $\text{mmol N m}^{-2} \text{d}^{-1}$) at the semi-permeable sediment station NOAH-D and ~ 62 % (1.3 $\text{mmol N m}^{-2} \text{d}^{-1} / 2.1$

331 mmol N m⁻² d⁻¹) at permeable sediment stations (NOAH-A). As discussed above, this trend does not hold for the
332 less representative station NOAH-E due to the transient formation of numerous pockmarks.

333 **4.4 Significance of benthic N-recycling**

334 Our study covers the most sediment types across the German Bight, but is based on core incubations and therefore
335 potentially underestimates advective processes. In a recent study by Neumann et al. (2017), the authors used NO₃⁻
336 pore water profiles to calculate the NO₃⁻ consumption rates across a similar range of North Sea sediments. They
337 extrapolated their nitrate consumption rates to the entire area of the German Bight based on a permeability
338 classification of sediments. They propose that ~24 % of sediments in the southern North Sea (German Bight) are
339 impermeable sediments (12,200 km²), ~39 % are moderately permeable sediments (19,600 km²) and ~37 %
340 (18,800 km²) are permeable sediments. They estimated that permeable sediment were the most efficient NO₃⁻ sink
341 accounting for up to 90 % of the total benthic NO₃⁻ consumption. In our assessment, which better represents the
342 role of nitrification, we arrive at a somewhat lower contribution of ~68 % of total denitrification occurring in
343 moderately permeable and permeable sediments. Based solely on our data, we estimate a total nitrogen removal
344 of ~1030 t N d⁻¹ in our study area, which corresponds to an average N₂ flux of approximately 1.5 mmol N m⁻² d⁻¹.
345 This daily N₂ production during late summer equals the total N discharge (~1.000 t N d⁻¹) by the main rivers Maas,
346 Rhine, North-Sea Canal, Ems, Weser and Elbe (Pätsch and Lenhart, 2004), and, as such, underscores the role of
347 coastal sediments to counteract the eutrophication in the North Sea.

348 Our assessment, however, does reflect the impact of only diffusive transport and faunal activity while not
349 accounting for advective fluxes. Based on the same data set of permeability for classification of different sediment
350 types that Neumann et al. (2017) used, we will merge our dataset with the results of Neumann et al. (in preparation)
351 to arrive at an improved estimate of sediment denitrification that includes benthic nitrification as a nitrate source.
352 In the following, we aim to put our estimates of N-transition rates into perspective by setting an upper limit of N
353 turnover based on primary production since N cycling is linked to organic carbon availability, which is ultimately
354 provided by pelagic primary production. For the freshwater influenced regions of the German Bight, Capuzzo et
355 al. (2018) assume a C fixation of 1.05 g C m⁻² d⁻¹. For an estimate of the maximum N transition rate we assume
356 that 10 % of the fixed C is processed in the sediment (Heip et al., 1995) and that all carbon is remineralized in the
357 sediment in pace with N turnover. Based on Redfield stoichiometry (~12 g / mol C, ~14 g / mol N), average C
358 fixation translates to [1.05 g * 10 % / 12 C * 14N =] 0.123 mg N that is removed per m⁻² and day, or 9 mmol N m⁻²
359 d⁻¹, respectively. This sets an upper limit to the N turnover rate and compares well with the observed
360 ammonification rate in impermeable sediment at NOAH-C (9.5 mmol NH₄⁺ m⁻² d⁻¹, Figure 5). The ammonification
361 rates at the sandy stations are substantially lower, which certainly reflects that sandy sediments are frequently

362 resuspended and organic particles are resuspended and degraded in the water column. For a second line of
363 argument, we consider the annual nitrate budget of the southern North Sea (Hydes et al. 1999, van Beusekom et
364 al. 1999) with an annual average denitrification rate of $0.7 \text{ mmol N m}^{-2} \text{ d}^{-1}$. This value agrees well with the average
365 gap of $0.5 \text{ mmol N m}^{-2} \text{ d}^{-1}$ between gross nitrification and actual nitrate flux (Figure 4), which we attribute to
366 denitrification. Both rates, the budget-based estimate and the nitrification gap are in the lower range of our
367 measured N_2 fluxes of 0.3 to $2.9 \text{ mmol N m}^{-1} \text{ d}^{-1}$ (Tab. 1, Fig. 5). For a third line of argument, we employ the
368 approach of Seitzinger and Giblin (1996) to link benthic respiration and denitrification directly to the pelagic
369 primary production. By employing their formulas and using the primary production rates by Capuzzo et al. (2018),
370 the annual average of the sediment oxygen demand would be $14.3 \text{ mmol O}_2 \text{ m}^{-2} \text{ d}^{-1}$ ($1.05 \text{ g C d}^{-1} \text{ m}^{-2} = 87.5 \text{ mmol}$
371 $\text{C d}^{-1} \text{ m}^{-2}$), which corresponds to a benthic denitrification rate of $3.3 \text{ mmol N m}^{-2} \text{ d}^{-1}$. Since the annual average of
372 actually measured oxygen fluxes are close to this estimate ($15.4 \pm 12.9 \text{ mmol O}_2 \text{ m}^{-2} \text{ d}^{-1}$, $N=175$) (Neumann et al.,
373 in preparation), we are confident that our denitrification estimates of up to $2.9 \text{ mmol N m}^{-2} \text{ d}^{-1}$ are reasonable.
374 However, with the multitude of our approaches yielding quite a span of plausible denitrification estimates the
375 question emerges which of the figures in the range of 0.5 to $3.3 \text{ mmol N m}^{-1} \text{ d}^{-1}$ is actually the true value for the
376 average denitrification rate. One major reason for this level of uncertainty is the fact that the local sediment
377 properties with regard to macrofauna composition and organic matter content varied considerably within each
378 station, which is reflected e.g. in the variability of oxygen consumption rates (see electronic supplemental). Since
379 we were restricted to 4 cores per station in total, and just 2 cores for labelling with $^{15}\text{NH}_4^+$ and $^{15}\text{NO}_3^-$, respectively,
380 the inevitable spatial heterogeneity introduced a substantial degree of random error. Additionally, the preceding
381 results we used above to evaluate our observations are certainly likewise based on imperfect data, which results in
382 uncertainty on that side. In summary, our limited set of new observations is not sufficiently large to favor one of
383 the preceding denitrification estimates. At least, the average of all our N_2 measurements of $1.5 \pm 0.9 \text{ mmol N m}^{-2}$
384 d^{-1} ($N=13$) falls right in the center of the interval of 0.5 to 3.3 mm and might represent our best estimate for an
385 average denitrification rate in late summer. The remaining fraction of the initial ammonification is recycled back
386 into the water column as DIN, which accounts for $69 \pm 18 \%$ ($N=12$) of the total benthic N flux ($\text{N}_2 + \text{DIN}$).
387 Since benthic N recycling substantially restocks the pelagic N inventory, we further assessed the contribution of
388 benthic N recycling by comparing the benthic DIN (ammonium + nitrite + nitrate) fluxes with the inventory of
389 DIN below the thermocline. Assuming steady state, we find a rapid turnover of sediment-derived DIN at NOAH-
390 C and NOAH-E, in the range of 1-3 days (Tab. 3). This implies that even below the thermocline, DIN derived by
391 the sediment is rapidly assimilated by phytoplankton. Previous publications showed that primary production below
392 the thermocline contributes $\sim 37 \%$ to total primary production in the North Sea (van Leeuwen et al., 2013).

393 Assuming Redfield stoichiometry and an average primary production of $1.05 \text{ g C m}^{-2} \text{ d}^{-1}$, benthic DIN fluxes in
394 our measurements can support a primary production of about 6.2 to $51.4 \text{ mmol C m}^{-2} \text{ d}^{-1}$ or $74 - 617 \text{ mg C m}^{-2}$
395 day^{-1} . This is within the range of previously observed and modeled primary production rates in the North Sea
396 during summer (e.g. van Leeuwen et al., 2013). We further estimate that depending on the thickness of the bottom
397 water layer below the thermocline, benthic N fluxes during the sampling time supported between $7.1 \pm 2.6 \%$ (38
398 m bottom water layer) and $58.7 \pm 10.6 \%$ (10 m bottom water layer) of the annual average of primary production
399 (Tab. 3). This dependence of relative sediment contribution on water depth has been observed previously for
400 respiration processes (Heip et al., 1995). Our data also match the calculation of Blackburn and Henriksen (1983)
401 for Danish sediments, where N fluxes could support 30 to 83 % of the nitrogen requirement of the planktonic
402 primary producers (Blackburn and Henriksen, 1983).

403

404 **5 Summary and concluding remarks**

405 We evaluated a range of sedimentary nitrogen turnover pathways and found that ammonification in sediments is
406 an important N-source for primary production in the water column of the southeastern North Sea during summer.
407 Depending on water depth, 7.1 to 58.7 % of the estimated water column primary production is fueled by
408 sedimentary N release. Nitrification act as the main sinks of NH_4^+ mineralized from sedimentary organic matter.
409 Ultimately, the main factors governing nitrification are organic matter content / ammonification and oxygen
410 penetration depth in the sediment. The share of newly produced NO_3^- reduced to N_2 amounts to two thirds of NO_3^-
411 in permeable sediments, to nearly one half in moderately permeable sediment, and to one third in impermeable
412 sediments. We further showed that moderately permeable and permeable sediments account for up to ~80 % of
413 the total benthic N_2 production ($\sim 1030 \text{ t N d}^{-1}$) in the southern North Sea (German Bight) during the peak of benthic
414 activity in late summer. Only then, benthic N_2 production can compensate the annually averaged daily N input by
415 the main rivers (e.g. Elbe, Ems, Rhine, Weser) discharging into the southern North Sea ($\sim 1.000 \text{ t N d}^{-1}$). Thus
416 impermeable sediments act as an important N source for primary producers, whereas moderately permeable and
417 permeable sediments comprise a main reactive N sink counteracting eutrophication in the North Sea. Seasonal and
418 spatial variabilities, especially from nearshore to offshore, should be evaluated in future studies.

419

420 **Acknowledgements**

421 We thank the captain and the crew of *R/V Heinke* for their support during the sampling campaigns. M. Birkicht
422 from the Leibniz Centre for Tropical Marine Research (ZMT) in Bremen is gratefully acknowledged for his

423 assistance with nutrient measurements. We further thank E. Logemann for the analysis of macrobenthos. We also
424 gratefully thank the two anonymous reviewers for comments that helped to greatly improve this manuscript.

Table 3: Rates of benthic net NO₃⁻ and benthic net NH₄⁺ fluxes per area, water depth below thermocline (average value of all sediment cores per station) and concentration of dissolved inorganic nitrogen (DIN) in the thermocline. Bottom water concentration of nitrate (cNO₃⁻), nitrite (cNO₂⁻) and ammonium (cNH₄⁺). The concentration of DIN per area was calculated by the multiplication of the water depth below the thermocline with the concentration of DIN. Turnover rates of nitrogen were calculated by the division of DIN per area with the rates of NH₄⁺_{net} and NO₃⁻_{net} and the effect of sedimentary N release on the reactive nitrogen available for primary production in the water column.

Station	rNH ₄ ⁺ _{net} + rNO ₃ ⁻ _{net}	Water depth below thermocline	cNO ₃ ⁻	cNO ₂ ⁻	cNH ₄ ⁺	DIN per area	N turnover	sedimentary N support for primary production
[-]	[mmol m ⁻² d ⁻¹]	[m]	[μmol L ⁻¹]			[mmol m ⁻²]	[days]	[%]
NOAH-A	1.6 ± 0.4	29.5	0.1	< 0.1	0.6 ± 0.2	20.7	10.8 ± 0.3	14.1 ± 4.7
NOAH-C	6.6 ± 1.4	10.0	< 0.1	0.7	2.0 ± 0.2	30.0	3.4 ± 0.1	58.7 ± 10.6
NOAH-D	0.5 ± 0.1	38.0	0.1 ± 0.1	0.1	0.8 ± 0.6	26.6	28.5 ± 0.6	7.1 ± 2.6
NOAH-E	3.2 ± 0.6	10.0	< 0.1	< 0.1	0.3 ± 0.1	3.0	0.9 ± 0.1	26.5 ± 14.3

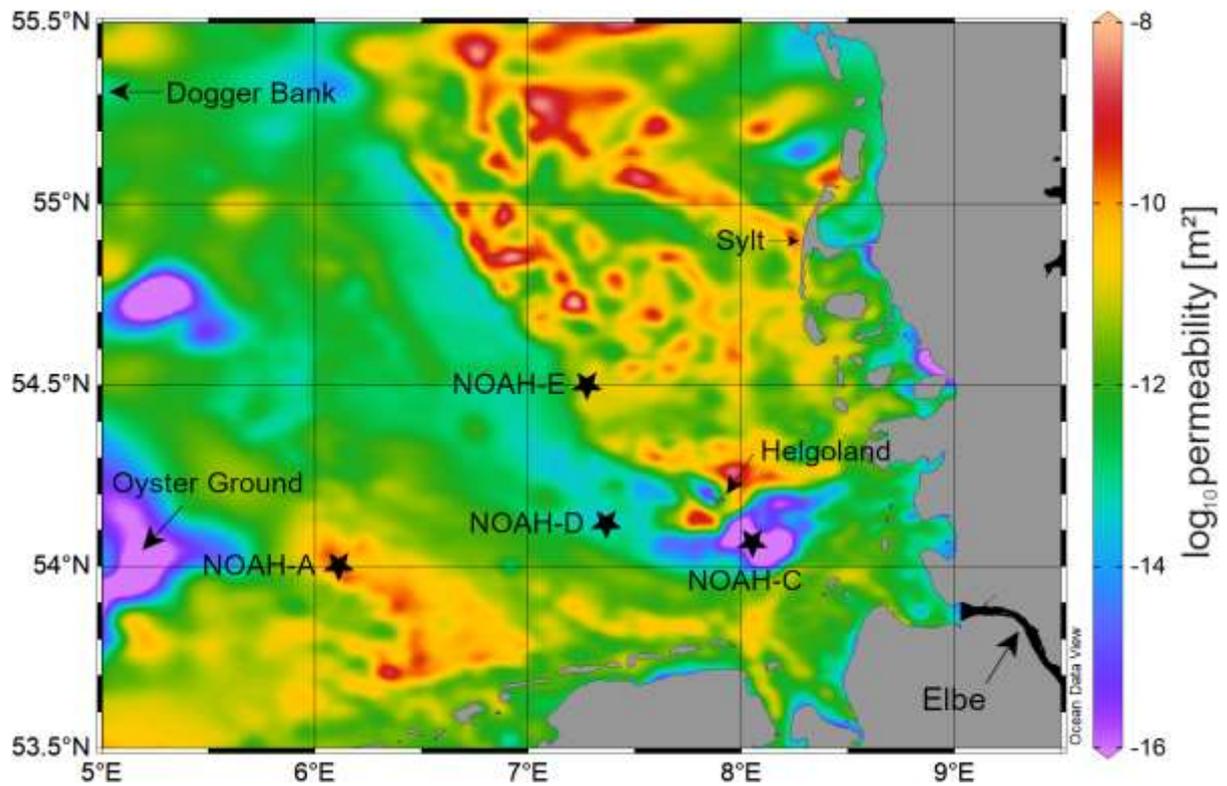

Figure 1: Map showing the sampling stations NOAH-A, NOAH-C, NOAH-D and NOAH-E in the German Bight in the North Sea. Colored areas show the spatial variability of surface sediment permeability (<https://doi.org/10.1594/PANGAEA.872712>).

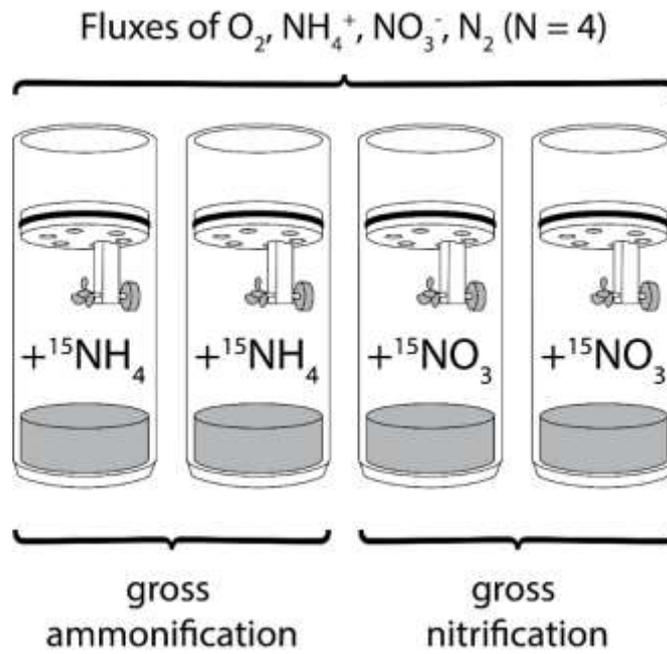

Figure 2: Schematic illustration of the experimental setup. Four sediment cores were incubated to measure benthic fluxes of oxygen, ammonium, nitrate, and N_2 . Two of these flux cores were amended with either $^{15}NH_4^+$ or $^{15}NO_3^-$ for the measurement of gross rates of ammonification and nitrification, respectively.

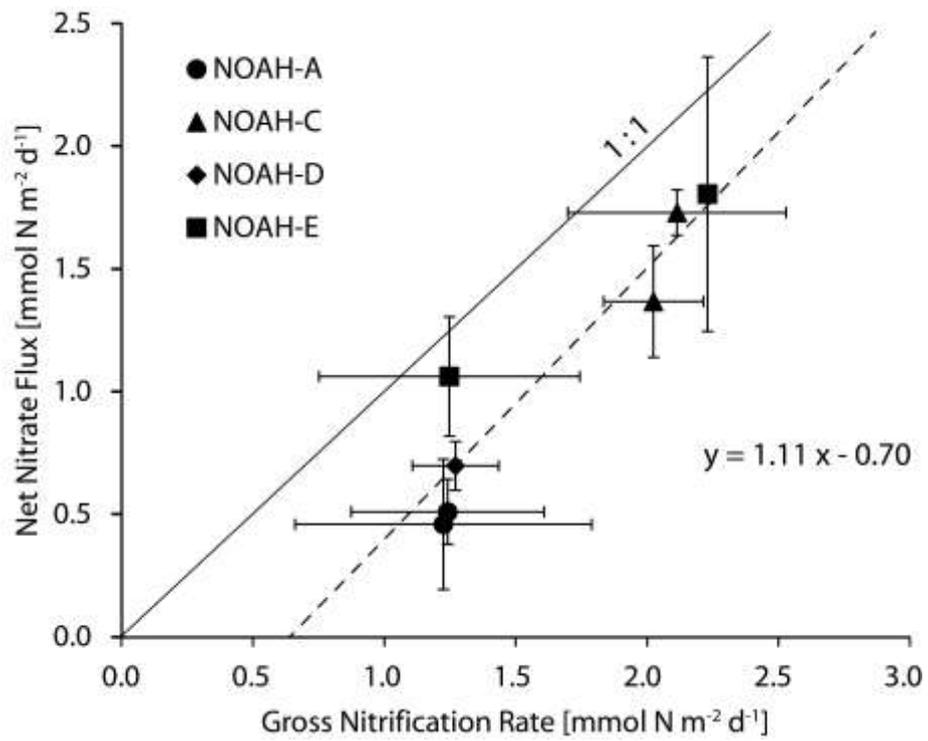

Figure 3: Correlation of gross nitrification rates and actual nitrate fluxes. The solid line indicates the 1:1 ratio, the dashed line indicates the linear regression. The error bars indicate the regression error of individual rates at the 0.95 confidence level.

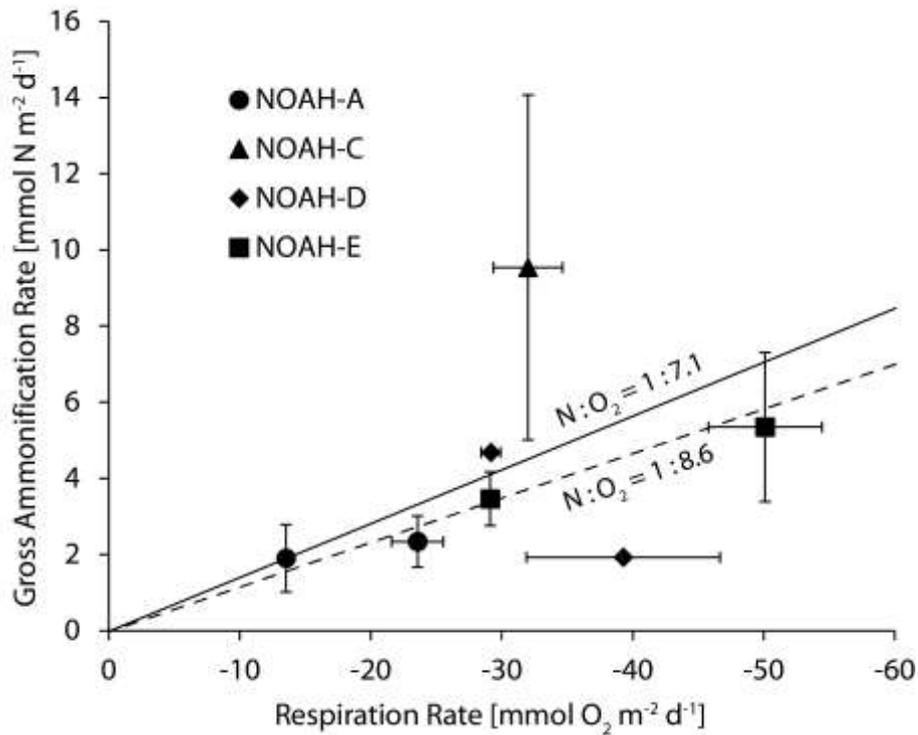

Figure 4: Benthic O₂ fluxes and gross ammonification rates of the sampled stations. The dashed line indicates the Redfield ratio of oxygen and nitrogen (N:O₂ 1:8.625) (Redfield, 1958), and the solid lines indicates the ratio of oxygen and nitrogen determined by the C/N ratio in the North Sea (N:O₂ 1:7.1). The error bars indicate the regression error of individual rates at the 0.95 confidence level.

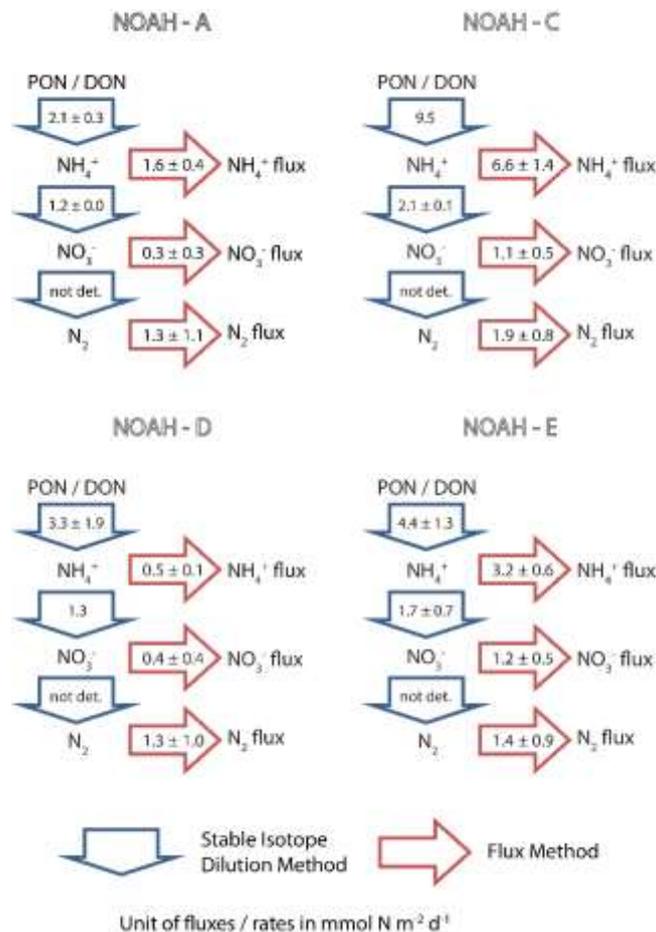

Figure 5: Benthic N-transformation rates (in $\text{mmol N m}^{-2} \text{d}^{-1}$) of ammonification (NH_4^+) and nitrification (NO_3^-) as measured by means of stable isotope methods (blue arrows). Simultaneously measured fluxes of ammonium (NH_4^+ flux), nitrate (NO_3^- flux), and N_2 (in $\text{mmol N m}^{-2} \text{d}^{-1}$) as measured by the flux method (red arrows).
