60 **Abstract.** The effects of atmospheric nitrogen deposition (N_{dep}) on carbon (C) sequestration in forests have often been
assessed by relating differences in productivity to spatial variations of N_{dep} across a large geographic domain. These
correlations generally suffer from covariation of other confounding variables related to climate and other growth-limiting
factors, as well as large uncertainties in total (dry + wet) reactive nitrogen (N_r) deposition. We propose a methodology for
65 untangling the effects of N_{dep} from those of meteorological variables, soil water retention capacity and stand age, using a
mechanistic forest growth model in combination with eddy covariance CO_2 exchange fluxes from a Europe-wide network of
forest flux towers. Total N_r deposition rates were estimated from local measurements as far as possible. The forest data were
compared with data from natural or semi-natural, non-woody vegetation sites. The carbon sequestration response of forests to
nitrogen deposition (dC/dN) was estimated after accounting for the effects of the co-correlates by means of a meta-modelling
70 standardization procedure, which resulted in a reduction by a factor of about 2 of the uncorrected, apparent dC/dN value. This
model-enhanced analysis of the C and N_{dep} flux observations at the scale of the European network suggests a mean overall
 dC/dN response of forest lifetime C sequestration to N_{dep} of the order of 40–50 g (C) g^{-1} (N), which is slightly larger but not
significantly different from the range of estimates published in the most recent reviews. Importantly, patterns of gross
primary and net ecosystem productivity versus N_{dep} were non-linear, with no further responses at high N_{dep} levels ($N_{\text{dep}} > 2.5$ –
3 g (N) $\text{m}^{-2} \text{yr}^{-1}$) partly due to large ecosystem N losses by leaching and gaseous emissions. The reduced increase in
75 productivity per unit N deposited at high N_{dep} levels implies that the forecast increased N_r emissions and increased N_{dep} levels
in large areas of Asia may not positively impact the continent's forest CO_2 sink. The large level of unexplained variability in
observed carbon sequestration efficiency (CSE) across sites further adds to the uncertainty in the dC/dN response.

1 Introduction

Atmospheric reactive nitrogen (N_r) deposition (N_{dep}) has often been suggested to be a major driver of the large forest carbon
80 (C) sink observed in the Northern Hemisphere (Reay et al., 2008; Ciais et al., 2013), but this view has been challenged, both
in temperate (Nadelhoffer et al., 1999; Lovett et al., 2013) and in boreal regions (Gundale et al., 2014). In principle, there is a
general consensus that N limitation significantly reduces net primary productivity (NPP) (LeBauer and Treseder, 2008;
Zaehle and Dalmonech, 2011; Finzi et al., 2007). However, the measure of carbon sequestration is not the NPP, but the long
term net ecosystem carbon balance (NECB; Chapin et al., 2006) or the net biome productivity at a large spatial scale (NBP;
85 Schulze et al., 2010), whereby heterotrophic respiration (R_{het}) and all other C losses, including exported wood products and
other disturbances over a forest lifetime, reduce the fraction of photosynthesized C (gross primary production, GPP) that is
actually sequestered in the ecosystem.

There is considerable debate as to the magnitude of the “fertilisation” role that atmospheric N_r deposition may play on forest
carbon balance, as illustrated by the controversy over the study by Magnani et al. (2007) and subsequent comments by
90 Högberg (2007), De Schrijver et al. (2008), Sutton et al. (2008), and others. Estimates of the dC/dN response (mass C stored
in the ecosystem per mass atmospheric N deposited) vary across these studies over an order of magnitude, from 30–70 g (C)
 g^{-1} (N) (de Vries et al., 2008; Sutton et al., 2008; Högberg, 2012), to 121 (Dezi et al., 2010), to 200–725 (Magnani et al.,
2007, 2008). Recent reviews have suggested mean dC/dN responses generally well below 100 g (C) g^{-1} (N), ranging from 61–
98 for US forests (Thomas et al., 2010), 35–65 (Erisman et al., 2011; Butterbach-Bahl and Gundersen, 2011), 16–33 (Liu and
95 Greaver, 2009), 5–75 (mid-range 20–40) for European forests and heathlands (de Vries et al., 2009), and down to 13–14 in
temperate and boreal forests (aboveground woody biomass only; Schulte-Uebbing and de Vries, 2018), and 5–25 for forests
globally (de Vries et al., 2014).

A better understanding of processes controlling the dC/dN response is key to predicting the magnitude of the forest C sink
under global change in response to changing patterns of reactive nitrogen (N_r) emissions and deposition (Fowler et al., 2015).

100 The question of the allocation and fate of the deposited nitrogen appears to be crucial; N_r deposition plays a significant role in promoting the carbon sink strength only if N is stored in woody tissues with high C/N ratios (>200 – 500) and long turnover times, as opposed to soil organic matter (SOM) with C/N ratios that are an order of magnitude smaller (de Vries et al., 2008). Nadelhoffer et al. (1999) argued on the basis of a review of ^{15}N tracer experiments that soil, rather than tree biomass, was the primary sink for the added nitrogen in temperate forests; and at sites with elevated N inputs, increasingly large fractions were
105 lost as nitrate (NO_3^-) leaching. Lovett et al. (2013) found in north-eastern US forests that added N increased C and N stocks and the C/N ratio in the forest floor, but did not increase woody biomass or aboveground NPP.

Atmospheric N_r deposition is rarely the dominant source of N supply for forests and semi-natural vegetation. Ecosystem internal turnover (e.g. leaf fall and subsequent decomposition of leaf litter) and mineralization of SOM provide annually larger amounts of mineral N than N_{dep} (although ultimately, over pedogenic time scales much of the N contained in SOM is
110 of atmospheric origin). In addition, resorption mechanisms help conserve within the tree the externally acquired N (and other nutrients), whereby N is re-translocated from senescing leaves to other growing parts of the tree, prior to leaf shedding, with resorption efficiencies of potentially up to 70% and larger at N-poor sites than at N-saturated sites (Vergutz et al., 2012; Wang et al., 2013). Biological N_2 fixation can also be significant in forests (Vitousek et al., 2002). Högberg (2012) showed for eleven European forest sites that N_r deposition was a relatively small fraction (13–14% on average) of the total N supply,
115 which was dominated by SOM mineralization (up to 15 – 20 g (N) $m^{-2} yr^{-1}$). He further argued that there may be a correlation between soil fertility (of which the natural N supply by mineralization is an indicator) and N_r deposition, since historically human populations have tended to develop settlements in areas of favourable edaphic conditions, in which over time agriculture, industry and population intensified, leading to increased emissions and deposition. Thus, an apparent effect of ambient N_{dep} on current net ecosystem productivity (NEP) levels could also be related to the legacy of more than a century of
120 N_r deposition on a modified internal ecosystem cycle.

Some previous estimates of forest dC/dN response obtained by meta-analyses of NEP or NECB across a geographic gradient did not account for the major drivers of plant growth apart from nitrogen. These include climate (precipitation, temperature, photosynthetically active radiation), soil physical and chemical properties (e.g. soil drainage, depth, and water holding capacity, nutrients, pH), site history and land use. Using univariate statistics such as simple regressions of NECB as a
125 function of N_r deposition is flawed if N_r deposition is co-correlated with any of these other drivers (Fleischer et al., 2013), as is usually the case in spatial gradient survey analyses across a wide geographic domain. This is because all of the variability in ecosystem C sequestration across the physical space is only allowed to be explained by one factor, N_r deposition. For example, Sutton et al. (2008) showed (using forest ecosystem modelling) that the apparently large dC/dN slope in the dataset of Magnani et al. (2007) was reduced by a factor of 2–3 when accounting for climatic differences between sites, i.e. when co-varying limitations in (photosynthetic) energy and water were factored out.
130

Similarly, ignoring the growth stage (forest age) and the effects of management (thinning) in the analysis introduces additional uncertainty in the estimated dC/dN response. Contrasting C cycling patterns and different N use efficiencies are expected between young and mature forests. Nutrient demand is highest in the early stages of forest development (especially pole stage); a recently planted forest becomes a net C sink only after a few decades, while at maturity NPP and NEP may or
135 may not decrease, depending on a shift in the balance between autotrophic and heterotrophic respiration (R_{aut} and R_{net} , respectively) and GPP (Odum, 1969; Besnard et al., 2018). Thinning can initially increase ecosystem respiration by increasing litter and SOM stocks and reducing NPP in the short term, and some biomass can be exported (tree trunks), but the ultimate effect after a year or two is to boost forest growth as thinning indirectly increases nutrient availability at the tree level by reducing plant–plant competition. Thus, the frequency and intensity of thinning will also affect long-term or lifetime
140 NECB. Severe storms may have a similar effect.

Altogether, these complex interactions mean that it is far from a simple task to untangle the N_r deposition effect on ecosystem C sequestration from the impacts of climatic, edaphic and management factors, when analysing data from diverse monitoring sites situated over a large geographic area. This is in contrast to fertilisation experiments, where the N effect can be quantified

with all other variables being equal between manipulation plots, although their results are only valid for the conditions at the
145 specific location where the experiment has been performed (Schulte-Uebbing and de Vries, 2018). There are also potentially
large uncertainties in the C and N flux measurements or model estimates used to calculate a dC/dN response. In the
companion paper (Flechard et al., 2019), we presented – and discussed uncertainties in – plausible estimates of C and N
budgets of 40 forests and natural or semi-natural ecosystems covering the main climatic zones of Europe (from
Mediterranean to temperate to boreal, from oceanic to continental). The NEP budgets were based on multi-annual eddy
150 covariance (EC) datasets following well-established protocols, and in order to better constrain the N budgets, specific local
measurements of dry and wet N_r deposition were made. Nitrogen losses by leaching and gaseous emissions were estimated by
a combination of measurements and modelling. The data showed that observation-based GPP and NEP peaked at sites with
 N_{dep} of the order of 2–2.5 g (N) $m^{-2} yr^{-1}$, but decreased above that, and that increasingly large N_r losses occurred at larger N_{dep}
155 levels, implying that the net dC/dN response was likely non-linear, possibly due to the onset of N saturation. The data also
showed that at the scale of the European CarboEurope IP flux tower network, nitrogen deposition was not independent of
climate, but peaked in mid-range for both mean annual temperature and precipitation, which geographically corresponds to
mid-latitude Central-Western Europe, where climate is most conducive to forest productivity and growth.
In the present paper, we further the analysis of the same observational datasets through forest ecosystem modelling, with the
objective of isolating the N_r deposition impact on forest productivity and C sequestration potential from the parallel effects of
160 climate, soil water retention, and forest age and management. A mechanistic modelling framework, driven by environmental
forcings, inputs, growth limitations, internal cycling and losses, was required to untangle the relationships in measurement
data, because the observed dependence of N_r deposition on climate, combined with the large diversity but limited number of
flux observation sites, restricted the applicability and validity of multivariate statistical methods. We describe a methodology
to derive, through meta-modelling, standardization factors for observation-based forest productivity metrics, in order to factor
165 out the part of variance that was caused by influences other than N_r deposition (climate, soil, stand age). Further, we examine
patterns of C and N use efficiency both at the decadal time scale of flux towers and over the lifetime of forests.

2 Materials and methods

2.1 Carbon and nitrogen datasets from flux tower sites

Ecosystem-scale carbon fluxes and atmospheric nitrogen deposition data were estimated at 31 European forests (six
170 deciduous broadleaf forests, DBF; 18 coniferous evergreen needleleaf forests, ENF, of which seven spruce-dominated and
eleven pine-dominated; two mixed needleleaf/broadleaf forests, MF; five Mediterranean evergreen broadleaf forests, EBF)
and nine short natural or semi-natural (SN) vegetation sites (wetlands, peatlands, unimproved and upland grasslands). The
measurements were made mostly as part of the CarboEurope Integrated Project (CEIP, 2004–2008) and the parallel
NitroEurope Integrated Project (NEU, 2006–2011). In the following we often adopted the terminology «*observation-based*»
175 rather than simply «*measured*», to reflect the fact many variables such as e.g. GPP or soil carbon pools rely on various
assumptions or even empirical models for their estimation on the basis of measured data. For convenience in this paper, we
use the following sign convention for CO_2 fluxes: GPP and R_{eco} are both positive, while NEP is positive for a net sink (a C
gain from an ecosystem perspective) and negative for a net source.

The general characteristics of the observation sites (coordinates, dominant vegetation, forest stand age and height,
180 temperature and precipitation, N_{dep} , inter-annual mean C fluxes) are provided in Table S1 of the Supplement. The sites,
measurement methods and data sources were described in more detail in the companion paper (Flechard et al., 2019); for
additional information on vegetation, soils, C and N flux results and budgets, and their variability and uncertainties across the
network, the reader is referred to that paper and the accompanying supplement. Briefly, the C datasets include multi-annual
mean estimates of NEP, GPP and R_{eco} (total ecosystem respiration) based on 10–20 Hz EC measurements, post-processing,

185 spectral and other corrections, flux partitioning and empirical gap-filling (e.g. Lee et al., 2004; Aubinet et al., 2000; Falge et
al., 2001; Reichstein et al., 2005; Lasslop et al., 2010). The fully analysed, validated, gap-filled and partitioned inter-annual
mean CO₂ fluxes (NEP, GPP, R_{eco}), as well as the meteorological data used as ecosystem model inputs (Sect. 2.2), were
retrieved from the European Fluxes Database Cluster (2012) and the NEU (2013) database. Dry deposition of reactive
nitrogen was estimated by measuring at each site ambient concentrations of the dominant gas-phase (NH₃, HNO₃, NO₂) and
190 aerosol phase (NH₄⁺, NO₃⁻) N_r concentrations (data available from the NitroEurope database; NEU, 2013), and applying four
different inferential models to the concentration and micro-meteorological data, as described in Flechard et al. (2011). Wet
deposition was measured using bulk precipitation samplers (NEU, 2013, with additional data retrieved from national
monitoring networks and from the EMEP chemical transport model (Simpson et al., 2012).

2.2 Modelling of forest C and N fluxes and pools

195 2.2.1 Calibration and implementation of the BASFOR model

The BASic FORest model (BASFOR) is a deterministic forest ecosystem model that simulates the growth (from planting)
and the biogeochemistry of temperate deciduous and coniferous even-aged stands (van Oijen et al., 2005). A description of
the model is given in BASFOR (2016) and Cameron et al. (2018), and details on model implementation and a basic
assessment of model performance in Flechard et al. (2019). Briefly, the C, N and water cycles are simulated at a daily time
200 step at the forest ecosystem scale (1-D model), in interaction with the soil and climate environments and constrained by
management (pruning and thinning). Carbon and nitrogen pools are simulated in the different ecosystem compartments (tree
stems, branches, leaves and roots, litter layers and SOM with fast and slow turnover), which are inter-connected by internal
flows and transformations (e.g. SOM mineralization, nitrogen retranslocation). Carbon, nitrogen and water enter the
ecosystem from the atmosphere (photosynthesis, N_r deposition, rainfall). Mineral nitrogen is taken up from the soil by tree
205 roots; C and N return to the litter and soil pools upon senescence of leaves, branches and roots, and also when trees are
pruned or thinned. Losses of C occur through autotrophic (root and shoot) respiration and microbial decomposition into CO₂
of litter and SOM (heterotrophic respiration); losses of N occur through nitrate leaching below the root zone and soil
emissions to the atmosphere of nitric oxide (NO) and nitrous oxide (N₂O). The water balance is constrained by incoming
rainfall, soil water holding capacity, and evapotranspiration simulated by the Penman equation. Table 1 provides a summary
210 of model state variables, inputs and outputs, as well as the descriptions of other observation-based variables used in the study.
For the purposes of this study, the model was calibrated through a multiple site Bayesian calibration (BC) procedure, applied
to three groups of plant functional types (PFT), based on C/N/H₂O flux and pool data from the CEIP/NEU databases. A total
of 22 sites were calibrated, including deciduous broadleaf forests (DB1-6), evergreen needleleaf forests ENF-spruce (EN1-7),
and ENF-pine (EN8-18) (see Cameron et al., 2018). The model parameters were calibrated generically within each PFT
215 group, i.e. they were not optimized or adjusted individually for each observation site.

As a first step, baseline BASFOR runs were produced for all 31 forest sites of the network, including even stands for which
the model was not calibrated, such as Mediterranean evergreen broadleaf (EB1 through EB5) and mixed
deciduous/coniferous (MF1, MF2), to test the predictive capacity of the model beyond its calibration range (see Fig. 6 in
Flechard et al., 2019). For the analyses and scenarios presented hereafter, these seven uncalibrated sites were removed from
220 the dataset, as were two additional sites: EN9 and EN12 (EN9 because this agrosilvopastoral ecosystem called «dehesa» has a
very low tree density (70 trees ha⁻¹; Tables S1-S2 in the Supplement to Flechard et al., 2019) and is otherwise essentially dry
grassland for much of the surface area, which BASFOR cannot simulate; EN12 because this was a very young plantation at
the time of the measurements, also with a very large fraction of measured NEP from non-woody biomass). All the
conclusions from BASFOR meta-modelling are drawn from the remaining 22 deciduous, pine and spruce stands.

225 *{Insert Table 1 here}*

2.2.2 Modelling time frames

In the companion paper (Flechard et al., 2019), C and N budgets were estimated primarily on the basis of ecosystem measurements and for the time horizon of the CEIP and NEU projects (2004–2010). In this paper, BASFOR simulations of the C and N budgets for the 22 forest sites were considered both i) over the most recent 5-year period (around the time of
230 CEIP/NEU) which did not include any thinning event and started at least 3 years after the last thinning event (referred to hereafter as «5-yr»); and ii) over the whole time span since forest establishment, referred to here as «lifetime», which ranged from 30 to 190 years across the network and reflected the age of the stand at the time of the CEIP/NEU projects. Note that the term «lifetime» in this context was not used to represent the expected age of senescence or harvest.

On the one hand, the short term (5-yr) simulations were made to evaluate cases where no disturbance by management
235 impacted fluxes and pools over a recent period, whatever the age of the stands at the time of the C and N flux measurements (ca 2000–2010). On the other hand, the lifetime simulations represent the time-integrated flux and pool history since planting, which reflects the long-term C sequestration (NECB) potential, controlled by the cumulative impact of management (thinning), increasing atmospheric CO₂ mixing ratio, and changing N_r deposition over the last few decades. Thinning modifies the canopy structure and therefore light, water and nutrient availability for the trees, reduces the LAI momentarily,
240 and in theory the left-over additional organic residues (branches and leaves) could increase heterotrophic respiration and affect the NEP. However, the impact of the disturbance on NEP and R_{eco} is expected to be small and short-lived (Granier et al., 2008), and a 3-year wait after the last thinning event appears to be reasonable for the modelling. The 5-yr data should in theory reflect the C/N flux observations, although there were a few recorded thinning events during the CEIP/NEU measurement period, and the thinning sequences used as inputs to the model were reconstructed and thus not necessarily
245 accurate (Table S2 and Fig. S5 in Supplement to Flechard et al., 2019).

2.2.3 Modelled carbon sequestration efficiency (CSE) and nitrogen use efficiency (NUE)

For both C and N, we define modelled indicators of ecosystem retention efficiency relative to a potential input level, which corresponds to the total C or N supply, calculated over both 5-yr (no thinning) and lifetime horizons to contrast short-term and long-term patterns. For C sequestration, the relevant terms are the temporal changes in carbon stocks in leaves, branches and stems (CLBS), roots (CR), soil organic matter (CSOM), and litter layers (CLITT), and the C export of woody biomass
250 (CEXP), relative to the available incoming C from gross photosynthesis (GPP). We thus define the carbon sequestration efficiency (CSE) as the ratio of either modelled 5-yr NEP, or modelled lifetime NECB, to modelled GPP in a given environment, constrained by climate, nitrogen availability and other factors included in the BASFOR model:

$$CSE_{5\text{-yr}}(\text{no thinning}) = \frac{NEP_{5\text{-yr}}}{GPP_{5\text{-yr}}} \quad (1)$$

$$255 \quad CSE_{\text{lifetime}} = \frac{NECB_{\text{lifetime}}}{GPP_{\text{lifetime}}} \quad (2)$$

$$\text{with } NECB = \frac{d(\text{CLBS} + \text{CR} + \text{CSOM} + \text{CLITT})}{dt} \quad (3)$$

$$NECB_{5\text{-yr}}(\text{no thinning}) = NEP_{5\text{-yr}} \quad (4)$$

$$NECB_{\text{lifetime}} = NEP_{\text{lifetime}} - CEXP_{\text{thinning}} \quad (5)$$

The modelled CSE_{5-yr} can be contrasted with observation based CSE_{obs} (= NEP_{obs} / GPP_{obs}) derived from flux tower data over
260 a similar, relatively short time period compared with a forest rotation (see Flechard et al., 2019). By extension, the CSE_{lifetime} indicator quantifies the efficiency of C sequestration processes by a managed forest system, reflecting not only biological and ecophysiological mechanisms, but also the long term impact of human management through thinning frequency and severity. For the N budget we define, by analogy to CSE, the N use efficiency (NUE) as the ratio of N immobilized in the forest system to the available mineral N, i.e. the ratio of tree N uptake (N_{upt}) to the total N_{supply} from internal SOM mineralization and N cycling processes (N_{miner}) and from external sources such as atmospheric N deposition (N_{dep}):
265

$$NUE = \frac{N_{upt}}{N_{supply}} \quad (6)$$

with $N_{supply} = N_{miner} + N_{dep}$ (7)

$$N_{supply} \approx N_{upt} + N_{leach} + N_{emission} \quad (8)$$

The fraction of N_{supply} not taken up in biomass and lost to the environment (N_{loss}) comprises dissolved inorganic N leaching (N_{leach}) and gaseous NO and N₂O emissions ($N_{emission}$):

$$N_{loss} = \frac{(N_{leach} + N_{emission})}{N_{supply}} \quad (9)$$

Note that i) NUE is *not* defined here as the amount of biomass produced per unit of N taken up from the soil, another commonly used N use efficiency indicator, which would be NPP/N_{upt} (e.g. Finzi et al., 2007), and ii) biological N₂ fixation, as well as N loss by total denitrification, are not accounted for in the current BASFOR version; also, leaching of dissolved organic N and C (DON, DOC) and dissolved inorganic C (DIC) is not included either, all of which potentially impact budget calculations.

2.2.4 Meta-modelling as a tool to standardize EC-based productivity data

One purpose of BASFOR modelling in this study was to gain knowledge on patterns of C and N fluxes, pools and internal cycling that were not, or could not be, evaluated solely on the basis of the available measurements (for example, SOM mineralization and soil N transfer; retranslocation processes at canopy level; patterns over the lifetime of a stand). The model results were used to complement the flux tower observations to better constrain elemental budgets and assess potential and limitations of C sequestration at the European forest sites considered here. Additionally, we used meta-modelling as an alternative to multivariate statistics (e.g. stepwise multiple regression, mixed non-linear models, residual analysis) to isolate the importance of N_r deposition from other drivers of productivity. This follows from the observations by Flechard et al. (2019) that i) N_r deposition and climate were not independent in the dataset, and that ii) due to the large diversity of sites, the limited size of the dataset, and incomplete information on other important drivers (e.g. stand age, soil type, management), regression analyses were unable to untangle these climatic and other inter-relationships from the influence of N_r deposition. BASFOR (or any other mechanistic model) is useful in this context, not so much to predict absolute fluxes and stocks, but to investigate the relative importance of drivers, which is done by assessing changes in simulated quantities when model inputs are modified. Meta-modeling involves building and using surrogate models that can approximate results from more complicated simulation models; in this case we derived simplified relationships linking forest productivity to the impact of major drivers, which were then used to harmonize observations from different sites. For example, running BASFOR for a given site using meteorological input data from another site, or indeed from all other sites of the network, provides insight into the impact of climate on GPP or NEP, all other factors (soil, vegetation structure and age, N_r deposition) being equal. Within the boundaries of the network of 22 selected sites, this sensitivity analysis provides *relative* information as to which of the 22 meteorological datasets is most, or least, favourable to growth for this particular site. This can be repeated for all sites (22*22 climate «scenario» simulations). It can also be done for soil physical properties that affect the soil water holding capacity (texture, porosity, rooting depth), in which case the result is a *relative* ranking within the network of the different soils for their capacity to sustain an adequate water supply for tree growth. The procedure for the normalization of data between sites is described hereafter.

Additional nitrogen affects C uptake primarily through releasing N limitations at the leaf level for photosynthesis (Wortman et al., 2012; Fleischer et al., 2013), which scales up to GPP at the ecosystem level. Other major factors affecting carbon uptake are related to climate (photosynthetically active radiation, temperature, precipitation), soil (for example water holding capacity) or growth stage (tree age). In the following section, we postulate that observation-based gross primary productivity (GPP_{obs}), which represents an actuation of all limitations in the real world, can be transformed through meta-modelling into a

standardized potential value (GPP^*) for a given set of environmental conditions (climate, soil, age), common to all sites, thereby enabling comparisons between sites. We define GPP^* as GPP_{obs} being modulated by one or several dimensionless factors (f_x):

$$GPP^* = GPP_{obs} \times f_{CLIM} \times f_{SOIL} \times f_{AGE} \quad (10)$$

310 where the standardization factors f_{CLIM} , f_{SOIL} and f_{AGE} are derived from BASFOR model simulations corresponding to the CEIP/NEU time interval around 2005–2010, as described below. The factors involved in Eq. (10) address commonly considered drivers, but not nitrogen, which is later assessed on the basis of GPP^* , rather than GPP_{obs} . Other potentially important limitations such as non-N nutrients, soil fertility, air pollution (O_3), poor ecosystem health, soil acidification, etc., are not treated in BASFOR, and cannot be quantified here. Further, the broad patterns of the GPP vs. N_{dep} relationships reported in Flechard et al. (2019) did not show any marked difference between the three forest PFT (deciduous, pine, spruce), possibly because the datasets were not large enough and fairly heterogeneous. Thus, although PFT may be expected to influence C/N interactions, we did not seek to standardize GPP with an additional f_{PFT} factor.

To determine the f_{CLIM} and f_{SOIL} factors, the model was run multiple times with all climate and soil scenarios for the n ($=22$) sites, a scenario being defined as using model input data or parameters from another site. Specifically, for f_{CLIM} , the model weather inputs at each site were substituted in turn by the climate data (daily air temperature, global radiation, rainfall, wind speed and relative humidity) from all other sites; and for f_{SOIL} , the field capacity and wilting point parameters (Φ_{FC} , Φ_{WP}) and soil depth that determine the soil water holding capacity at each site ($SWHC = (\Phi_{FC} - \Phi_{WP}) \times \text{soil depth}$), were substituted in turn by parameters from all other sites. Values of f_{CLIM} and f_{SOIL} were calculated for each site in several steps, starting with the calculation of the ratios of modelled GPP from the scenarios to the baseline value GPP_{base} such that:

$$325 \quad X(i, j) = GPP(i, j) / GPP_{base}(i) \quad (11)$$

where i ($1..n$) denotes the site being modelled and j ($1..n$) denotes the climate data set (j_{CLIM}) or soil parameter set (j_{SOIL}) used in the scenario being simulated (see Table S2 for the calculation matrices). The value of the X (i, j) ratio indicates whether the j^{th} scenario is more (> 1) or less (< 1) favourable to GPP for the i^{th} forest site.

For each site, the aim of the f_{CLIM} factor (and similar reasoning for f_{SOIL}) (Eq. (10)) is to quantify the extent to which GPP differs from a standard GPP^* value that would occur if all sites were placed under the same climatic conditions. Rather than choose the climate of one particular site to normalize to, which could bias the analysis, we normalise GPP to the equivalent of a «mean» climate, by averaging BASFOR results over all (22) climate scenarios (Eq. (14)–(15)). However, since each of the scenarios has a different mean impact across all sites ($\overline{X(j)}$, Eq. (12)), we first normalize $X(i, j)$ to $\overline{X(j)}$ value within each j^{th} scenario (Eq. (13)):

$$335 \quad \overline{X(j)} = 1/n \sum_{i=1}^n X(i, j) \quad (12)$$

$$X_{norm}(i, j) = X(i, j) / \overline{X(j)} \quad (13)$$

The normalization of X (i, j) to X_{norm} (i, j) ensures that the relative impacts of each scenario on all n sites can be compared between scenarios. The final step is the averaging for each site of X_{norm} (i, j) values from all scenarios (either j_{CLIM} or j_{SOIL}) into the overall f_{CLIM} or f_{SOIL} values:

$$340 \quad f_{CLIM}(i) = \overline{X_{norm}(i)} = 1/n \sum_{j_{CLIM}=1}^n X_{norm}(i, j_{CLIM}) \quad (14)$$

$$\text{or} \quad f_{SOIL}(i) = \overline{X_{norm}(i)} = 1/n \sum_{j_{SOIL}=1}^n X_{norm}(i, j_{SOIL}) \quad (15)$$

The factors f_{AGE} were determined by first normalizing modelled GPP (base run) to the value predicted at age 80, for every year of the simulated GPP time series at those m ($=12$) mature sites where stand age exceeded 80. The age of 80 was chosen since this was the mean stand age of the whole network. The following ratios were thus calculated:

$$345 \quad Y(k, yr) = GPP_{base}(k, yr) / GPP_{base}(k, 80) \quad (16)$$

where k ($1..m$) denotes the mature forest site being modelled. A mean temporal curve for f_{AGE} (normalized to 80 years) was calculated, to be used subsequently for all sites, after the following:

$$f_{AGE}(yr) = \left(\frac{1}{m} \sum_{k=1}^m Y(k, yr) \right)^{-1} \quad (17)$$

3 Results

3.1 Short term (5-yr) versus lifetime C and N budgets from ecosystem modelling

Modelled C and N budgets are represented schematically in Fig. 1 and Fig. 2, respectively, as «Sankey» diagrams (Matlab «drawSankey.m» function; Spelling, 2009) for three example forest sites (DB5, EN3, EN16), and in Fig. S1–S6 of the Supplement for all sites of the study. Each diagram represents the input, output and internal flows in the ecosystem, with arrow width within each diagram being proportional to flow. For carbon (Fig. 1 and S1–S3), the largest (horizontal) arrows indicate exchange fluxes with the atmosphere (GPP, R_{eco}), while the smaller (vertical) arrows indicate gains (green) or losses (red) in internal ecosystem C pools (CSOM, CBS, CR, CL, CLITT), as well as any exported wood products (CEXP, orange). NEP is the balance of the two horizontal arrows, as well as the balance of all vertical arrows.

In the 5-yr simulations with no thinning occurring (Fig. 1-left; Fig. S1), NEP is equal to NECB, which is the sum of ecosystem C pool changes over time (= C sequestration if positive). By contrast, in the lifetime (since planting) simulations (Fig. 1-center; Fig. S2), the long-term impact of thinning is shown by the additional orange lateral arrow for C exported as woody biomass (CEXP). In this case, C sequestration or NECB no longer equals NEP, the difference being CEXP, the C contained in exported stems from thinned trees. By contrast, in the model, upon thinning the C from leaves, branches and roots join the litter layers or soil pools and is ultimately respired or sequestered. To compare between sites with different productivity levels, the lifetime data are also normalized as a percentage of GPP (Fig. 1-right; Fig. S3). The clear differences between 5-yr and lifetime C-budget simulations were: i) systematically larger GPP in recent 5-yr horizon (combined effects of age as well as CO_2 and N_{dep} changes over time); ii) C storage in branches and stems (CBS) dominated in both cases, but CBS fractions were larger in the 5-yr horizon; iii) larger relative storage in soil organic matter (CSOM) when calculated over lifetime.

For clarity in the N budgets (Fig. 2 and S4–S6), the largest (horizontal) arrows indicate the modelled internal ecosystem N cycling terms (N_{miner} from SOM mineralisation, N_{upt} uptake by trees) and the secondary (vertical) arrows represent external exchange (inputs and losses) fluxes as N_{dep} , N_{leach} and $N_{emission}$ (unit: $g(N) m^{-2} yr^{-1}$). The variable NMIN describes the transient soil inorganic N pool in the soil solution and adsorbed on the soil matrix ($NMIN = NO_3^- + NH_4^+$; units $g(N) m^{-2}$). Since there is no significant long term (multi-annual) change in NMIN, the total mineral N_{supply} (defined as $N_{miner} + N_{dep}$) is basically balanced by N uptake (N_{upt}) and losses ($N_{leach} + N_{emission}$) (Eq. (8)). Modelled N budgets were calculated for a 5-yr time horizon (Fig. 2-left; Fig. S4) and for the whole time period since the forest was established (lifetime, Fig. 2-center; Fig. S5). Lifetime data were also normalized as a percentage of N_{supply} (Fig. 2-right; Fig. S6). The clear differences between 5-yr and lifetime N-budget simulations are: i) N_{loss} and especially N_{leach} were significantly larger over the stand lifetime since planting; ii) N_{upt} was a larger fraction of total N_{supply} over the recent 5-yr period.

3.2 Contrasted carbon and nitrogen use efficiencies

Collectively, the changes in the ecosystem C pools, especially the increases in stems and branches (CBS), roots (CR) and soil organic matter (CSOM) represent roughly 20–30% of GPP for both 5-yr and lifetime simulations (Fig. 1, S1–S3). By contrast, the analogous term for the N, the N_{upt} fraction of total N_{supply} , is a much more variable term, both between sites of the network and between the 5-yr and lifetime simulations (Fig. 2, S4–S6). Modelled lifetime CSE and NUE values are

compared in Fig. 3 with the 5-yr values, as a function of stand age, indicating that (i) the more mature forests of the network (age range ~80–190 yrs) tend to have larger NUE than younger forests (~30–60 yrs), and (ii) the difference in NUE between young vs. mature forests is especially clear if NUE is calculated over the whole period since planting (lifetime). These observations are plausible and consistent with current understanding of long term N cycling in planted forests, incorporated in the model structure, equations and parameters. Namely, (i) is a consequence of BASFOR predicting larger relative N_{loss} in younger stands, in which lower N demand by a smaller living biomass, combined in the early years with enhanced N_{miner} from higher soil temperature (canopy not yet closed) and with a larger drainage rate (smaller canopy interception of incident rainfall), all lead to larger NMIN losses. Observation (ii) is a mathematical consequence of high N losses during the forest's early years having a larger impact on lifetime calculations in younger than mature forests. NUE tends to reach 70–80% on average after 100 years and is smaller calculated from lifetime than from a 5-yr thinning-free period. For forests younger than 60 years, lifetime NUE is only 60%; the 5-yr thinning-free value can be larger, but thinning events are likely to be more frequent at that age.

Modelled carbon sequestration efficiency is less affected than NUE by forest age (CSE range ~15–30%) (Fig. 3). There is a tendency for 5-yr (thinning-free) CSE to decrease from ~30% to ~20% between the ages of 30 and 190 years. This means that, in the model, R_{eco} in 30 to 60-yr old stands represents a smaller fraction of GPP than in mature stands, which is a consequence of i) R_{aut} being a constant fraction of GPP in the model, ii) R_{net} being a linear function of fast and slow C pools in litter layers and SOM, and iii) soil and litter layers C pools evolving non-linearly with GPP as the forest grows older. Lifetime CSE values are slightly smaller than 5-yr values: the difference corresponds to cumulative CEXP over time, but the trend with age is weaker than for 5-yr CSE. The relatively narrow range of modelled 5-yr CSE values (20–30%) is in sharp contrast to the much wider range of observation-based CSE_{obs} values (from -9% to 61%), likely reflecting some limitations of the model and possibly also measurement uncertainties, as discussed in Flechard et al. (2019).

{Insert Fig. 3 here}

Beyond the overall capacity of the forest to retain assimilated C (as quantified by CSE), the modelled fate of sequestered C, the simulated ultimate destination of the C sink, is also a function of forest age and of the time horizon considered (Fig. 4). The fraction of NECB sequestered in above-ground biomass (CLBS) over a recent 5-yr horizon is on average around 80% (*versus* around 10% each for CR and CSOM) and not clearly linked to forest age, i.e. the model does not simulate any slowing down with age of the annual growth of above-ground biomass. Calculated over lifetimes, the dominant ultimate destination of sequestered C remains CLBS. However, this fraction is smaller (50–60%) in old-growth forests than in younger stands (60–80%), since a larger cumulative fraction of above-ground biomass (timber) will have been removed (CEXP) by a lifetime of thinnings in a mature forest, while the cumulative gain in CSOM is not repeatedly depleted, but on the contrary enhanced, by thinnings (since the model assumes bole removal only, not total tree harvest). Modelled annual C storage to the rooting system clearly declines with age and is an increasingly marginal term over time (although the absolute CR stock itself keeps increasing over time, except when thinning transfers C from roots to SOM).

3.3 Standardization of observation-based GPP through meta-modelling

The purpose of meta-modelling was to standardize observation-based GPP_{obs} into GPP^* through model-derived factors that separate out the effects of climate, soil and age between monitoring sites (Eq. (10)), so that the importance of N_i can be isolated. The sensitivity of modelled GPP to climate and soil physical properties was tested through various model input and parameter scenarios, allowing standardization factors f_{CLIM} and f_{SOIL} to be calculated as described in Methods (Eq. (11)–(15)) and Table S2 in the Supplement. The resulting distributions of all simulations for all sites were represented in Fig. 5 as «violin» plots (Matlab «*distributionPlot.m*» function; Dorn, 2008) for the climate-only and soil-only scenarios ($n^2 = 484$ simulations each), and also combined climate*soil scenarios ($n^3 = 10648$ simulations). For each site, the scenarios explore the modelled response of ecosystem C dynamics to a range of climate and soil forcings different from their own. The size and

430 position of the violin distribution indicate, respectively, the degrees of sensitivity to- and limitation by- climate, soil, or both;
a site is especially limited by either factor (relative to the other sites of the network) when the baseline/default run (GPP_{base}) is
located in the lower part of the distribution.

Similarly, to account for the effect of tree age, the f_{AGE} factor was calculated following Eq. (17), whereby the time series for
the ratio of modelled $GPP_{base}(yr)$ to $GPP_{base}(80)$ (Eq. (16)) followed broadly similar patterns for the different sites (Fig. 6),
with values mostly in the range 0.6–0.8 at around age 40, crossing unity at 80 and levelling off around 1.2–1.4 after a century.
435 Some of the older sites (e.g. EN2, EN6, EN15) showed a peak followed by a slight decrease in modelled GPP, but not at the
same age. This was due to a peak in N_{dep} in the early 1980's in Europe (see Fig. S4 in the Supplement to Flechard et al.,
2019), with the N_{dep} peak occurring at different ontogenetic stages in the differently aged stands. By calculating a mean f_{AGE}
factor across sites the peak N_{dep} effect was smoothed out (Fig. 6). Thus, for a younger forest, the multiplication of GPP_{obs} by
 f_{AGE} (>1) simulated the larger GPP^* that one could expect for the same site at 80 yr; conversely, the GPP^* a mature forest
440 (>100 yr) would be reduced compared with GPP_{obs} .

{Insert Fig. 5 here}

{Insert Fig. 6 here}

The combined modelled effects of climate, soil, and stand age on GPP are summarized in Fig. 7. Values for both f_{CLIM} and
 f_{SOIL} are mostly in the range 0.7–1.5, and are predictably negatively correlated to mean annual temperature (MAT) and soil
445 water holding capacity (SWHC), respectively (Fig. 7A). A value well above 1 implies that GPP_{obs} for one site lies below the
value one might have observed if climate or SWHC had been similar to the average of all other sites of the network. In other
words this particular site was significantly limited by climate, SWHC, or both, relative to the other sites. Conversely, a value
below 1 means that GPP at the site was particularly favoured by weather and soil. Climate or soil conditions at some sites
have therefore the potential to restrict GPP by around one third, while other climates or soil conditions may enhance GPP by
450 around one third, compared with the average conditions of the whole network. Applying the f_{CLIM} , f_{SOIL} and f_{AGE} multipliers
to GPP_{obs} (Eq. (10)) provides a level playing field (GPP^*) for later comparing sites with respect to N_r deposition, but also
increases the scatter and noise in the relationship of GPP^* to N_{dep} , particularly with the introduction of f_{AGE} (Fig. 7B).

{Insert Fig. 7 here}

3.4 Response of gross primary productivity to N_r deposition

455 The standardized forest GPP^* values, i.e. $GPP^*(f_{CLIM})$, $GPP^*(f_{CLIM} \times f_{SOIL})$ and $GPP^*(f_{CLIM} \times f_{SOIL} \times f_{AGE})$, show in the N_{dep}
range 0–1 $g(N) m^{-2} yr^{-1}$ a much less steep relationship to N_{dep} than the original GPP_{obs} (Fig. 7B). This supports the
hypothesis that GPP at low N_{dep} sites is also limited by climate and/or soil water availability. In Fig. 7B, 2nd-order
polynomials are fitted to the data to reflect the strong non-linearity present in GPP_{obs} , driven especially by the 4 highest N_{dep}
sites ($>2.5 g(N) m^{-2} yr^{-1}$ at EN2, EN8, EN15 and EN16). The non-linearity (magnitude of the 2nd-order coefficient) is reduced
460 by the introduction of f_{CLIM} and f_{SOIL} , while f_{AGE} has a small residual impact on the shape of the regression. Due to this non-
linear behaviour, the $dGPP/dN_{dep}$ responses decrease with N_{dep} for the observation-based GPP, but less so for the standardized
 GPP^* estimates (Fig. 7C). Values of $dGPP_{obs}/dN_{dep}$ (calculated for each N_{dep} level by the slope of the tangent line to the
quadratic fits of Fig. 7B) range from around 800 $g(C) g^{-1}(N)$ at the lowest N_{dep} level down to negative values at the highest
 N_{dep} sites; for the standardized GPP^* accounting for all climate, soil and age effects, this range is much narrower, from
465 around 350 down to near 0 $g(C) g^{-1}(N)$.

Average $dGPP/dN_{dep}$ figures that are representative of this set of forest sites are given in the upper part of Table 2, either
calculated over the whole range of 22 sites, or for a subset of 18 sites that excludes the four highest deposition sites ($>2.5 g(N) m^{-2} yr^{-1}$).
If all modelled sites are considered, the mean $dGPP/dN_{dep}$ regression slopes are smaller (190–260 $g(C) g^{-1}(N)$), being influenced by the reductions in GPP at very high N_{dep} levels, possibly induced by the negative side effects of N
saturation. If these four sites are excluded, the mean $dGPP/dN_{dep}$ is larger (234–425 $g(C) g^{-1}(N)$), reflecting the fact that
470 healthier, N-limited forests are more responsive to N additions. In this subset of 18 sites, the effects of climate, soil and stand

age account for approximately half of GPP (the mean $dGPP/dN_{dep}$ response changes from 425 to 234 $g(C) g^{-1}(N)$). For comparison, Table 2 also provides the values of $dGPP_{obs}/dN_{dep}$ obtained directly through simple linear regression for all forest sites and for the semi-natural vegetation sites, with values of the same order (432 and 504 $g(C) g^{-1}(N)$, respectively) if the high N deposition sites ($N_{dep} > 2.5 g(N) m^{-2} yr^{-1}$) are removed.

As a further comparison, an additional BASFOR modelling experiment is shown in Fig. 8A, in which GPP at all sites is simulated in a range of N_{dep} scenarios (0, 0.1, 0.2, 0.5, 1, 1.5, 2, 2.5, 3, 3.5, 4 and 4.5 $g(N) m^{-2} yr^{-1}$, constant over lifetime) to substitute for the actual N_{dep} levels of each site. Around half the sites show a steadily increasing (modelled) GPP as N_{dep} increases over the whole range 0–4.5 $g(N) m^{-2} yr^{-1}$, with broadly similar slopes between sites; while the other half levels off and reaches a plateau at various N_{dep} thresholds, indicating that beyond a certain level N_{dep} is no longer limiting, according to the model. For comparison with the dC/dN responses calculated previously for GPP_{obs} and GPP^* in Fig. 7B–C and Table 2, we derive a mean modelled $dGPP/dN_{dep}$ response from a linear regression of Fig. 8A data over the range 0–2.5 $g(N) m^{-2} yr^{-1}$ (i.e. excluding the highest deposition levels). This yields a mean $dGPP/dN_{dep}$ slope across all sites of 297 (273–322) $g(C) g^{-1}(N)$ for the N_{dep} model experiment, only marginally larger than the three GPP^* average slopes of Table 2. Note that in Fig. 7B, the response of GPP^* to N_{dep} is calculated *between sites* of the network, while in Fig. 8A the GPP to N_{dep} response is calculated *within each site* from the model scenarios, then averaged across all sites.

{Insert Fig. 8 here}

3.5 Response of net ecosystem productivity to N_r deposition

Similarly to GPP, the NEP and NECB responses to N_{dep} cannot be reliably inferred directly from EC-flux network data given the large variability between sites in climate, soil type, age and other constraints to photosynthesis and ecosystem respiration. However, plausible estimates can be obtained by applying a range of mean CSE indicators (as defined previously) to project the normalized GPP^* responses to N_{dep} (Table 2). Carbon sequestration efficiencies for forests are confined to a narrow range (17–31% of GPP, average $\mu=22\%$, standard deviation $\sigma=4\%$) in model simulations over 5-yr (no thinning) time horizons (Fig. 3); they vary considerably more in EC-based observations (range -9 to 61%, $\sigma=17\%$), but with a similar mean ($\mu=25\%$). CSE metrics express the GPP fraction not being respired (R_{eco}) or exported (CEXP) out of the ecosystem. Multiplied by the $dGPP/dN_{dep}$ slope they provide estimates of the net ecosystem C gain per unit N deposited (Table 2).

Short-term (5-yr) mean estimates for NEP responses, based on average CSE from both observations (CSE_{obs}) and modelling (CSE_{5-yr}), and accounting for GPP climate/soil/age normalization, range from 41 to 47 $g(C) g^{-1}(N)$, averaged over all sites, or 51 to 57 $g(C) g^{-1}(N)$ removing the four highest N_{dep} sites (middle part of Table 2). Predictably, lifetime estimates for $dNECB/dN_{dep}$ responses are about 20% smaller, on the order of 34–42 $g(C) g^{-1}(N)$. For comparison, the mean 5-yr $dNEP/dN_{dep}$ obtained directly by BASFOR modelling of N_{dep} scenarios for all sites (Fig. 8B) was larger ($76 \pm 7 g(C) g^{-1}(N)$) than the measurement-based, model-corrected estimates of Table 2.

If the forest NEP response to N_{dep} is calculated directly through simple linear or quadratic regression of NEP_{obs} vs. N_{dep} (bottom part of Table 2), therefore not including any standardization of the data, the dC/dN slope is much larger (178–224 $g(C) g^{-1}(N)$) within the N_{dep} range 0–2.5 $g(N) m^{-2} yr^{-1}$. If all forest sites are considered (including N-saturated sites with N_{dep} up to 4.3 $g(N) m^{-2} yr^{-1}$), the dC/dN slope is much smaller (71–108 $g(C) g^{-1}(N)$), but this only reflects the reduced NEP observed at those elevated N_{dep} sites (see Fig. 4C in Flechard et al., 2019), with altogether very large scatter and very small R^2 . Equivalent figures for (not standardized) semi-natural NEP vs. N_{dep} appear to be significantly smaller (34–89 $g(C) g^{-1}(N)$) than in forests.

If the meta-modelling standardization procedure for climate, soil and age is attempted (for comparison only) directly on NEP, as opposed to the preferred procedure using GPP (Eq. (10)–(17)), the simulated f_{CLIM} , f_{SOIL} and f_{AGE} reduce the NEP response to N_{dep} by only 18%, from 178 down to 146 $g(C) g^{-1}(N)$ (bottom part of Table 2), while the equivalent reduction for GPP was 45%. The resulting figure (112–146 $g(C) g^{-1}(N)$) is likely much over-estimated, around factor of 2–3 larger than those

obtained through the stepwise method using $CSE * dGPP/dN_{dep}$. Standardization factors derived from BASFOR meta-
515 modelling are more reliable for GPP than for NEP, since model performance is significantly better for GPP than for R_{eco} and
hence NEP (Fig. 6 in Flechard et al., 2019).

{Insert Table 2 here}

4 Discussion

4.1 A moderate non-linear response of forest productivity to N_{dep} deposition

520 The C sequestration response to N_{dep} in European forests was derived using a combination of flux tower-based C and N
exchange data and process-based modelling, while a number of previous studies have been based on forest inventory methods
and stem growth rates (e.g. de Vries et al.2009; Etzold et al., 2014). The main differences with previous meta-analyses that
were also based on EC-flux datasets (e.g. Magnani et al., 2007; Fleischer et al., 2013; Fernández-Martínez et al., 2014, 2017),
525 were that i) we derived total N_{dep} from local measurements of the wet and dry fractions as opposed to regional/global CTM
outputs; ii) we untangled the N_{dep} effect from climatic, soil and other influences by means of a mechanistic model, not
through statistical methods; and iii) in Flechard et al. (2019) we estimated ecosystem-level N, C and GHG budgets calculated
through a combination of local measurements, mechanistic and empirical models, and database and literature data mining.

Our most plausible estimates of the dC/dN response of net productivity over the lifetime of a forest are of the order of 40–50
 $g(C) g^{-1}(N)$ on average over the network of sites included in the study (Table 2). Such values are broadly in line with the
530 recent reviews by Erisman et al. (2011) and by Butterbach-Bahl et al. (2011) (range 35–65 $g(C) g^{-1}(N)$), but slightly larger
than estimates given in a number of other studies (e.g. Liu and Greaver, 2009; de Vries et al., 2009, 2014). Given the
considerable uncertainty attached to these numbers (Table 2), they cannot be considered significantly different from any of
those earlier studies. The meta-modelling-based approach we describe for normalizing forest productivity data to account for
differences in climate, soil and age among sites, reduces the net productivity response to N_{dep} by roughly 50%, which is of the
535 same order as the results (factor of 2–3 reduction) of a similar climate normalization exercise by Sutton et al. (2008). This
means that not accounting for inter-site differences would have led to an over-estimation of the dC/dN slope by a factor of 2.

Observations and model simulations both indicate that the N_{loss} fraction of N_{supply} increases with N_{dep} ; thus, at many sites but
especially those with $N_{dep} > 1.5\text{--}2 g(N) m^{-2} yr^{-1}$, N availability is not limiting forest growth. In such cases it becomes
meaningless to try to quantify a N fertilisation effect. Indeed, despite large uncertainties in measured data and in model-
540 derived normalization factors, the non-linear trend is robust, with dC/dN values tending to zero in N-saturated forests ($>2.5\text{--}3$
 $g(N) m^{-2} yr^{-1}$). In their review paper De Vries et al. (2014) gave a range of N_{dep} levels varying between 1.5–3 $g(N) m^{-2} yr^{-1}$
beyond which growth and C sequestration were not further increased or even reversed. These findings suggest that in areas of
the world where N_{dep} levels are larger than 2.5–3 $g(N) m^{-2} yr^{-1}$, which now occur increasingly in Asia, specifically in parts of
China, Japan, Indonesia, and India (Schwede et al., 2018), the forecast increased N_r emissions and increased N_{dep} levels may
545 thus not have a positive impact on the continent's land based CO_2 sink. Data treatment and selection in our dataset (e.g.
removal of N-saturated forests) strongly impacted the plausible range of dC/dN responses (Table 2) derived from the original
data. The non-linearity of ecosystem productivity relationships to N_{dep} (Butterbach-Bahl and Gundersen, 2011; Etzold et al.,
2014) limits the usefulness and significance of simple linear approaches. These data suggest that there is no single dC/dN
figure applicable to all ecosystems, that the highly non-linear response depends on current and historical N_{dep} exposure levels,
550 and on the degree of N saturation, although other factors than N, discussed later, may also be involved.

For the short semi-natural vegetation sites, included in the study as a non-fertilised, non-woody contrast to forests, the
apparent impact of N_{dep} on GPP_{obs} was of the same order as in forests, but likely much smaller than in forests when
considering NEP_{obs} (Table 2). This is in principle consistent with the hypothesis (de Vries et al., 2009) that the ecosystem
 dC/dN response may be larger in forests due to the large C/N ratio (200–500) of above-ground biomass (stems and branches),

555 where much of the C storage occurs (up to 60–80% according to BASFOR, Fig. 4); whereas in semi-natural ecosystems C
storage in SOM dominates, with a much lower C/N ratio (10–40). However, this comparison of semi-natural *versus* forests is
based on NEP_{obs} that was not normalized for inter-site climatic and edaphic differences, since no single model was available
to carry out a meta-modelling standardization for all the different semi-natural ecosystem types (peatland, moorland, fen,
grassland), and therefore these values must be regarded as highly uncertain.

560 4.2 Limitations and uncertainties in the approach for quantifying the dC/dN response

Monitoring atmospheric gas-phase and aerosol N_r contributed to reducing the large uncertainty in total N_r deposition at
individual sites, because dry deposition dominates over wet deposition in most forests (Flechard et al., 2019), except at sites a
long way from sources of atmospheric pollution, and because the uncertainty in dry deposition and its modelling is much
larger (Flechard et al., 2011; Simpson et al., 2014). However, despite the considerable effort involved in coordinating the
565 continental-scale measurement network (Tang et al., 2009), the number of forest sites in this study (31) was relatively small
compared with other studies based on ICP (de Vries et al., 2009; ICP, 2019) or other forest growth databases, or global-scale
FLUXNET data (hundreds of sites worldwide; see Burba, 2019). Thus, the gain in precision of N_{dep} estimates from local
measurements was offset by the smaller population sample size. Nonetheless this study does show the added value of the N_r
concentration monitoring exercise and the need to repeat and extend such initiatives.

570 Understanding, quantifying and reducing all uncertainties leading up to dC/dN estimates are key issues to explore. Apart from
measurement uncertainties in N_r deposition and losses, and in the C balance based on EC measurements, analysed in the
companion paper, the major difficulties that arose when assessing the response to N_{dep} of forest productivity included:

- 575 i) The heterogeneity of the population of forests, climates and soils in the network, and the large number of
potential drivers relative to the limited number of sites, hindered the use of a straightforward, regression-based
analysis of observational data without a preliminary (model-based) harmonization;
- ii) The model-based normalization procedure for GPP, used to factor out differences in climate, soil and age
among sites, significantly amplified the noise in C/N relationships, an indication that the generalized modelled
effects may not apply to all individual sites and that other important ecological determinants affecting forest
productivity are missing in the BASFOR model;
- 580 iii) The EC measurement-based ratio of R_{eco} to GPP (=1-CSE) was very variable among forests and this high
variability cannot be explained or simulated by the ecosystem model we used, i.e. more complex model
parameterizations of R_{aut} and R_{het} may be required to better represent the diversity of situations and processes;
- iv) Nitrogen deposition likely contributes a minor fraction (on average 20% according to the model) of total
ecosystem N supply (heavily dominated by soil organic N mineralization), except for the very high deposition
585 sites (up to 40%). Thus, in many cases the N_{dep} fertilisation effect may be marginal and difficult to detect,
because it may be smaller than typical measurement uncertainties and noise in C and N budgets.

The EC-based flux data suggest that the N_{dep} response of forest productivity is clearer at the gross photosynthesis level, in
patterns of (normalized) GPP differences among sites, than at the NEP level, where very large differences in CSE among sites
lead to a de-coupling of N_{dep} and NEP. The response of GPP to N_{dep} appeared to be reasonably well constrained by both EC
590 flux measurements and BASFOR modelling, which is why we chose to normalize GPP, not NEP. The significantly better
model performance obtained for GPP than for R_{eco} and NEP (Fig. 6 in Flechard et al., 2019) likely reveals a relatively poor
understanding and mathematical representation of R_{eco} (especially for the soil heterotrophic and autotrophic components),
and the factors controlling their variability among sites. The large unexplained variability in CSE and C sequestration
potentials may also involve other limiting factors that could not be accounted for in our measurement/model analysis, since
595 they are not treated in BASFOR. Such factors may be related to soil fertility, ecosystem health, tree mortality, insect or wind
damages in the previous decade, incorrect assumptions on historical forest thinning, all affecting general productivity
patterns.

4.3 What drives the large variability in carbon sequestration efficiency?

Carbon sequestration efficiency metrics are directly and negatively related to the ratio of R_{eco} to GPP, expressing the likelihood that one C atom fixed by photosynthesis will be sequestered in the ecosystem. Earlier FLUXNET-based statistical meta-analyses have demonstrated that although R_{eco} is strongly dependent on temperature on synoptic or seasonal scales (Mahecha et al., 2010; Migliavacca et al., 2011), GPP is the key determinant of spatial variations in R_{eco} (Janssens et al., 2001; Migliavacca et al., 2011; Chen et al., 2015), and further, that the fraction of GPP that is respired by the ecosystem is highly variable (Fernández-Martínez et al., 2014), and more variable than in current model representations. We have used three different CSE indicators, averaged across all sites, to derive a $\text{NEP}/N_{\text{dep}}$ response from model-standardized GPP* data (Table 2). Values of CSE_{obs} varied over a large range among sites (-9 to 61%, Fig. 9). Some of the variability might be due to measurement errors, but small (<10%) or large (>40%) CSE_{obs} values could also genuinely reflect the influence or the absence of ecological limitations related to nutrient availability or vegetation health.

4.3.1 From nutrient limitation to nitrogen saturation

Can nutrient limitation (nitrogen or otherwise) impact ecosystem carbon sequestration efficiency? Soil fertility has been suggested to be a strong driver at least of the forest biomass production efficiency (BPE), defined by Vicca et al. (2012) as the ratio of biomass production to GPP, with BPE increasing in their global dataset of 49 forests from 42% to 58% in soils with low- to high-nutrient availability, respectively. The study by Fernández-Martínez et al. (2014) of 92 forest sites around the globe reported a large variability in CSE (=NEP/GPP calculated from FLUXNET flux data), which they suggest is strongly driven by ecosystem nutrient availability (ENA), with CSE levels below 10% in nutrient-poor forests and above 30% in nutrient-rich forests. The range of CSE values derived from flux measurements in our study (CSE_{obs} in Table 2) was similarly large, even though all of our sites were European and our dataset size was one third of theirs ($N=31$, of which 26 sites in common with Fernández-Martínez et al., 2014). We did not attempt in this study to characterize a general indicator of ENA beyond total N_f deposition; but if we use the high, medium or low (H, M, L) scores of ENA attributed to each site through factor analysis of nutrient indicators by Fernández-Martínez et al. (2014), we find that the H group (7 sites) has a mean CSE_{obs} of 32% (range 16–48%), the M group is slightly higher (7 sites, mean 39%, range 21–61%), while the L group has indeed a significantly smaller mean CSE_{obs} of 14% (12 sites, range -9 to 38 %). Interestingly, the mean N_{dep} levels for each group are $H = 1.5$ (range 0.5–2.3) $\text{g (N) m}^{-2} \text{ yr}^{-1}$, $M = 2.1$ (range 1.1–4.2) $\text{g (N) m}^{-2} \text{ yr}^{-1}$ and $L = 1.3$ (range 0.3–4.1) $\text{g (N) m}^{-2} \text{ yr}^{-1}$, i.e. the highest mean CSE_{obs} of the three groups is found in the group with the highest mean N_{dep} (M).

The nutrients and other indicators of fertility considered by Fernández-Martínez et al. (2014) included, in addition to N, P, soil pH, C/N ratios and cation exchange capacity, as well as soil texture and soil type. However, very few sites were fully documented (see their Supplement Table S1), data were often qualitative, and other key nutrients were not included in the analysis (K, Mg and other cations; S also has been suggested to have become a limiting factor for forest growth following emission reductions, see Fernández-Martínez et al., 2017). The extent to which the overall fertility indicator quantified by ENA was driven by nitrogen in the Fernández-Martínez et al. (2014) factor analysis is not evident. At sites where other nutrients are limiting, the response to N additions would be small or negligible regardless of whether N itself is limiting. This places severe constraints on the interpretation of productivity data in response to N_{dep} , since most current models, which do not account for other nutrient limitations, cannot be called upon to normalize for differences between sites.

The impact of the fertility classification on CSE of the sites included in Fernández-Martínez et al. (2014) was questioned by Kutsch and Kolari (2015) on the basis of unequal quality of the EC-flux datasets found in FLUXNET and other databases. By excluding complex terrain sites (and young forests) from the Fernández-Martínez et al. (2014) dataset, Kutsch and Kolari (2015) calculated a much reduced variability in CSE, with a «reasonable» mean value of 15% (range 0–30%), and suggesting a much lower influence of nutrient status than claimed by Fernández-Martínez et al. (2014). In their reply, Fernández-Martínez et al. (2015) re-analyzed the same subset of sites selected by Kutsch and Kolari (2015), but using the same

640 generalized linear model as used in their original analysis of the whole dataset, as opposed to the linear model used by Kutsch
and Kolarí (2015). Fernández-Martínez et al. (2015) then maintained that the findings of the original study were still valid for
the restricted dataset, i.e. that the nutrient status had a significant influence on CSE.

The smaller European dataset of our study poses a similar dilemma. The much wider variation in CSE_{obs} than modelled CSE_{5-yr}
may both point to possible measurement issues if CSE_{obs} values (especially the larger ones) are considered ecologically
645 implausible, and/or inform on important ecological processes that are not accounted for in the model. Among the forests in
our study that seemed particularly inefficient ($CSE_{obs} < 10\%$) at retaining photosynthesized carbon (EN4, EN6, EN8, EN11,
EN17, EB5), all were classified as L (low ENA) in Fernández-Martínez et al. (2014) and two (EN6, EN11) were even net C
sources ($R_{eco} > GPP$). The EN4, EN6, EN17 sites had the three largest soil organic contents (SOC, Fig. 9A), which may have
induced larger rates of heterotrophic respiration, but EN4 has also been reported as having unrealistically large ecosystem
650 respiration rates (Anthoni et al., 2004). The EN8 site (mature pine-dominated forest in Belgium) was very unlikely to be N-
or S-limited, having been under the high deposition footprint of Antwerp petrochemical harbour and local intensive
agriculture for decades, even if emissions have declined over the last 20 years (Neiryneck et al., 2007, 2011). However, the
comparatively low LAI, GPP and CSE (Fig. 4 in Flechard et al., 2019) at this site are likely not independent of the historical,
N- and S-induced soil acidification, which has worsened the already low P and Mg availabilities (Janssens et al., 1999), and
655 from which the forest is only slowly recovering (Neiryneck et al., 2002; Holmberg et al., 2018). This site is actually an
excellent example to illustrate the complex web of biogeochemical and ecological interactions, which further complicate the
quantification of the (single-factor) N_{dep} impact on C fluxes. By not accounting for the low Mg and P availabilities and the
poor ecosystem health, the BASFOR model massively over-estimated GPP, R_{eco} and NEP at EN8 (Fig. 6 in Flechard et al.,
2019). In fact, based on prior knowledge of this site's acidification history, and since such mechanisms and impacts are not
660 mathematically represented in BASFOR, EN8 was from the start discarded from the calibration dataset for the Bayesian
procedure (Cameron et al., 2018). The four lowest CSE_{obs} values were found at sites with topsoil $pH < 4$ (Fig. 9C), although
other forests growing on acidic soils had reasonably large CSE_{obs} ratios.

The large variability in CSE_{obs} cannot be explained by any single edaphic factor (Fig. 9A-C), more likely by a combination of
many factors that may include N_{dep} (Fig. 9E). As noted previously, C flux measurements at all four forest sites with $N_{dep} > 2.5$
665 $g(N) m^{-2} yr^{-1}$ (EN2, EN8, EN15, EN16) indicated lower productivity estimates than those in the intermediate N_{dep} range, or at
least smaller than might have been expected from a linear N fertilisation effect (Fig. 4 in Flechard et al., 2019). EN2 (spruce
forest in southern Germany) is also well-documented as an N-saturated spruce forest with large total N losses ($\sim 3 g(N) m^{-2}$
 yr^{-1}) as NO , N_2O and NO_3^- (Kreutzer et al., 2009), but its productivity and CSE are not affected to the same extent as EN8.
Not all the difference is necessarily attributable to the deleterious impacts of excess N_f deposition, as suggested by the GPP
670 normalization exercise (Fig. 7). For example, EN15 and EN16, planted on sandy soils, appear from meta-modelling to suffer
from water stress comparatively more than the average of all sites (Fig. 5-Soil), if indicators of soil water retention based on
estimates of soil depth, field capacity and wilting point can be considered reliable.

4.3.2 Forest age

Forest age is expected to affect photosynthesis (GPP), growth (NPP), carbon sequestration (NEP) and CSE for many reasons.
675 A traditional view of the effect of stand age on forest NPP (Odum, 1969) postulated that R_{aut} increases with age and
eventually nearly balances a stabilized GPP, such that NPP approaches zero upon reaching a dynamic steady state. Revisiting
the paradigm, Tang et al. (2014) found that NPP did decrease with age (> 100 yr) in boreal and temperate forests, but the
reason was that both GPP and R_{aut} declined, with the reduction in forest growth being primarily driven by GPP, which
decreased more rapidly with age than R_{aut} after 100 years. However, the ratio NPP/GPP remained approximately constant
680 within each biome.

The effect of age on NEP and CSE is even more complex since this involves not only changing successional patterns of GPP
and R_{aut} , but also of R_{net} over a stand rotation of typically one century or more, which is much longer than the longest

available flux datasets. Therefore age effects are often studied by comparing differently aged forest sites across the world, which introduces many additional factors of variation, including differences in water availability, soil fertility, or even tree species, genera, or PFTs. Forest and tree ages should in theory be normalized to account for species-specific ontogeny patterns, i.e. the age of 80 years may be relatively young for some species, and quite old for others, and therefore population dynamics may be very different for the same age. Nevertheless, forest age has been suggested to be a dominant factor controlling the spatial and temporal variability in forest NEP at the global scale, compared with abiotic factors such as climate, soil characteristics and nutrient availability (Besnard et al., 2018). In that study, the multivariate statistical model of NEP, using data from 126 forest eddy-covariance flux sites worldwide, postulated a non-linear empirical relationship of NEP to age, adapted from Amiro et al. (2010), whereby NEP was negative (a net C source) for only a few years after forest establishment, then increased sharply above 0 (a net C sink), stabilized after around 30 years and remained at that level thereafter for mature forests (> 100 years). This model, therefore, did not assume any significant reduction in forest net productivity after maturity, up to 300 years, consistent with several synthesis studies that have reported significant NEP of centuries-old forest stands (Buchmann and Schulze, 1999; Kolari et al., 2004; Luysaert et al., 2008).

By analogy, our approach for accounting for the age effect was based on the modelled time course of GPP (Eq. (16)-(17)), which in the BASFOR model tended to stabilize after 100 years, and subsequently using a mean CSE that did not depend on stand age. However, the variability in CSE_{obs} appeared to be much larger in mature forests (>80 years) than in the younger stands (Fig. 9D). For the younger forests (<60 years, all sites probably still in an aggrading phase), the CSE_{obs} values were in a narrow band of 15–30% and were well represented by model simulations, with the exceptions of EN1, EB3 at around 50% and of EN4 being near 0% (all three locations being high elevation sites with complex terrain and potential EC measurement issues, see Flechard et al., 2019). By contrast, values for mature forests were either below 15% or above 30%. For some cold sites such as EN6 and EN11, growing in low nutrient environments (e.g. peat at EN6) with high SOC (Fig. 9A) and/or high soil C/N ratio (Fig. 9B) and low soil pH (Fig. 9C), or for the N-saturated and acidified EN8 site, the low CSE is not necessarily linked to age. Aging, senescence and acidification may at some point curb sequestration efficiency in older forests, but even excluding the complex terrain sites, there remain a good number of productive mature sites with CSE_{obs} in the range 30–40%, which questions the Odum (1969) paradigm of declining net productivity and C equilibrium in old forests.

{Insert Fig. 9 here}

4.3.3 Does nitrogen deposition impact soil respiration?

The overall net effect of N_i deposition on carbon sequestration must include not only productivity gains, but also indirect, positive or negative impacts on soil C losses, which all affect CSE. Carbon sequestration efficiency reflects the combined magnitudes of soil heterotrophic (R_{het}) and autotrophic (R_{aut} , both below- and above-ground) respiration components, relative to GPP. We postulated that the primary effect of N_{dep} and N_{supply} is on GPP, but potential side effects of N_{dep} or N additions on ecosystem and soil carbon cycling have been postulated. The traditional theory of the role of N on microbial decomposition of SOM was that, above a certain C/N threshold value, the lack of N inhibits microbial activity compared with lower C/N ratios. However, the review by Fog (1988) found that microbial activity was often unaffected, or even negatively affected, by the addition of N to low-N decomposing organic material. The negative effects were mostly found for recalcitrant organic matter (high lignin content) with a high C/N ratio (e.g. wood or straw); while N addition to easily degradable organic matter with a low C/N ratio (e.g. leaf litter with low lignin content) actually boosted microbial activity. The meta-analysis by Janssens et al. (2010) of N manipulation experiments in forests suggests that excess N_i deposition reduces soil – especially heterotrophic – respiration in many temperate forests. They argue that the mechanisms include i) a decrease in below-ground C allocation and the resulting root respiration, permitted by a lesser need to develop the rooting system when more N is available (see also Alberti et al., 2015); ii) a reduction in the activity, diversity and biomass of rhizospheric mycorrhizal communities (see also Treseder, 2008); iii) a reduction in the priming effect, the stimulation of SOM decomposition by saprotrophic organisms through root and mycorrhizal release of energy-rich organic compounds; iv) N-induced shifts in

saprotrophic microbial communities, leading to reduced saprotrophic respiration; and v) increased chemical stabilization of SOM into more recalcitrant compounds. The authors point out that in N-saturated forests different processes and adverse effects are at play (e.g. base cation leaching and soil acidification).

730 An important implication of the negative impact of N_r on soil respiration is that the nitrogen fertilisation effect on gross photosynthesis would be roughly doubled, in terms of C sequestration, by the concomitant decrease in soil respiration. In their meta-analyses of N addition experiments in forests and comparison of sites exposed to low vs elevated N_{dep} , Janssens et al. (2010) show that both R_{het} and soil carbon efflux (SCE), a proxy for total R_{soil} ($= R_{het} + R_{aut,soil}$), tend to decline with N addition, be it through fertilisation or atmospheric deposition, although the effect is far from universal. The negative N_{dep} response of R_{het} was much more pronounced for SOM than for leaf litter, and stronger at highly productive sites than at less
735 productive sites. The negative impact on SCE was mostly found at sites where N was not limiting for photosynthesis. When N is strongly limiting, and in young forests, N_r deposition may well favour SOM decomposition.

To examine the potential impact of N_{dep} on R_{soil} , we compiled the soil respiration data available from the literature and databases for the collection of forest sites in our study, which covers the whole N limitation to N saturation spectrum. Sites ranged from highly N-limited boreal systems, where an N addition might trigger enhanced tree growth, increased microbial
740 biomass and heterotrophic respiration, to N-saturated, acidified systems (EN2, EN8, possibly also EN15, EN16), in which poor ecosystem and soil health may lead to different ecological responses than those of the below-ground carbon cycling scheme in Janssens et al. (2010).

Since the below-ground autotrophic (root and rhizosphere) respiration component is regulated by photosynthetic activity (Collalti and Prentice, 2019) and contributes a large part of R_{soil} on an annual basis (Korhonen et al., 2009), the relationship of
745 R_{soil} to N_{dep} is examined by first normalizing to GPP (Fig. 10A), yielding a soil respiration metric that is comparable between sites (for R_{soil} data, see Table S7 in the Supplement to Flechard et al., 2019). Similarly, the ratio R_{soil}/R_{eco} shows the relative contribution of below-ground to total (ecosystem) respiration (Fig. 10C). Note that caution is needed when considering both R_{soil}/GPP and R_{soil}/R_{eco} ratios, since significant uncertainty may arise from i) methodological flaws in comparing chamber
750 *versus* eddy covariance measurements (e.g. considerations over tower footprint, spatial heterogeneity and representativeness of soil collars), ii) uncertainty in deriving GPP and R_{eco} estimates from EC-NEE measurements, and iii) different time spans for the EC and soil chamber measurements, affected by inter-annual flux variability. Thus, values of R_{soil}/R_{eco} above unity (Fig. 10C), although physically non-sensical, do not necessarily imply large measurement errors, but possibly also that there may be no spatial or temporal coherence in EC and chamber data (Luyssaert et al., 2009).

Either ignoring such outliers, or judging that a measurement bias by soil chambers affects all sites the same way (e.g.
755 systematic over-estimation of soil respiration in low turbulence conditions when using static chambers, Brændholt et al., 2017), we may argue that the apparent decrease of both chamber/EC ratios R_{soil}/GPP and R_{soil}/R_{eco} with N_{dep} (Fig. 10A, 10C) has some reality, even if their absolute values are biased. Soil CO_2 efflux tends to be a larger fraction of GPP (>0.5) at the smaller N_{dep} rates (<1.5 g (N) m^{-2} yr^{-1}) than at sites with larger N_{dep} , where this fraction is more often in the range 0.4–0.5. It is also noteworthy that the largest R_{soil}/GPP ratios (EN5, EN17) are found at sites with very large SOC compared with the
760 other sites (Fig. 10B). The R_{het}/R_{soil} ratio also tends to decrease with N_{dep} (Fig. 10E), and although measured by different methods at the different sites, this is arguably a more robust metric than chamber/EC respiration ratios, because the differential respiration measurements on control and treatment plots (root exclusion, trenching, girdling) are made on the same spatial and temporal scales.

Many other factors that impact soil respiration (age, soil pH, microbial abundance and diversity, etc.) are not considered here
765 and beyond the scope of this paper. In view of these uncertainties, if the assessment within this restricted dataset does not provide a full and incontrovertible proof of the negative impact of N_r deposition on soil respiration, it at least is not in open contradiction to the prevailing paradigm that both below-ground autotrophic and heterotrophic respiration are expected to decrease as N_r deposition increases. However, the decreasing trends observed in Fig. 10A, 10C, 10E are largely driven by

770 these few high N_{dep} sites ($>3\text{g (N) m}^{-2} \text{yr}^{-1}$) in which the negative effects of N saturation and acidification very likely outweigh the benefits of reduced soil respiration in terms of C sequestration.

{Insert Fig. 10 here}

5 Conclusion

775 The magnitude of the mean N_r deposition-induced fertilisation effect on forest C sequestration, derived here from eddy covariance flux data from a diverse range of European forest sites, is of the order of $40\text{--}50 \text{g (C) g}^{-1} \text{(N)}$, and comparable with the lower end of estimates obtained from inventory data and deposition rates from continental-scale deposition modelling used in the most recent studies and reviews. The range of dC/dN values is a consequence of where in the ecosystem the N_r -induced carbon sequestration takes place, whether there are N_r losses and how other environmental conditions affect growth. However, this mean dC/dN response should be taken with caution for several reasons. First, uncertainties in our dC/dN estimates are large, partly because of the relatively small number of sites (31) and their large diversity in terms of age, species, climate, soils, and possibly fertility and nutrient availability. Second, adopting a mean overall dC/dN response universally and regardless of the context may be misleading due to the clear non-linearity in the relationship between forest productivity and the level of N_r deposition, i.e. the magnitude of the response changes with the N status of the ecosystem. Beyond a N_r deposition threshold of $1\text{--}2 \text{g (N) m}^{-2} \text{yr}^{-1}$ the productivity gain per unit N_r deposited from the atmosphere starts to decrease significantly. Above $2.5 \text{g (N) m}^{-2} \text{yr}^{-1}$, productivity actually decreases with further N_r deposition additions, and this is accompanied by increasingly large ecosystem N_r losses, especially as NO_3^- leaching.

780 Ecosystem meta-modelling was required to factor out the effects of climate, soil water retention and age on forest productivity, a necessary step before estimating a generalised response of C storage to N_r deposition. Neglecting these effects would lead to a large over-estimation (factor of 2) of the dC/dN effect in this European dataset and possibly also in other datasets worldwide. After factoring out the effects of climate, soil water retention and forest age in the present dataset, only part of the non-linearity was removed and there was still a decline in the dC/dN response with increasing N_{dep} . One possible interpretation is that the remaining non-linearity may be regarded as an indicator of the impact of increasing severity of N saturation on ecosystem functioning and forest growth. However, the results also show that the large inter-site variability in carbon sequestration efficiency, here defined at the ecosystem scale and observed in flux data, cannot be entirely explained by the processes represented in model we used. This is likely due in part to an incomplete understanding and over-simplified model representation of plant carbon relations, soil heterotrophic and autotrophic respiration, the response to nitrogen deposition of physiological processes such as stomatal conductance and water-use efficiency, and possibly also because other nutrient limitations were insufficiently documented at the monitoring sites and not accounted for in the model.

Code and data availability

800 The data used in this study are publicly available from online databases and from the literature as described in the Materials and Methods section.

The codes of models and other software used in this study are publicly available online as described in the Materials and Methods section.

Author Contributions

805 CRF, MvO, DRC, WdV, MAS, AI conceived the paper; CRF performed the data analyses, ran model simulations and wrote the text; MvO, DRC wrote and provided the BASFOR model code and performed Bayesian calibration; MAS, EN, UMS, KBB, WdV conceived or designed the NEU study; AI, NB, IAJ, JN, LM, AV, DL, ALeg, KZ, MAub, MAur, BHC, JD, WE,

RJ, WLK, ALoh, BL, GM, VM, JO, MJS, TV, CV, KBB, UMS provided eddy covariance and/or other field data, or contributed to data collection from external databases and literature; MvO, DRC, WdV, AI, MAS, NB, NBD, IAJ, JN, LM, AV, DL, ALeg, KZ, AJF, RJ, AN, EN, UMS contributed substantially to discussions and revisions.

1080 Figures and Tables

1085

Figure 1. Modelled (BASFOR) partitioning of C fluxes at three example forest sites (DB5: 45-yr old *Fagus sylvatica*; EN3: 120-yr old *Picea abies*; EN16: 51-yr old *Pseudotsuga menziesii*), and associated modelled changes in C pools in soil organic matter (CSOM), roots (CR), litter layers (CLITT), branches and stems (CBS) and leaves (CL) (units: g (C) m⁻² yr⁻¹ left and center; normalized to % lifetime GPP on the right). Simulations were run either over the most recent 5-year period which did not include any thinning event («5-yr» in the text), or over the whole time period since the forest was established («lifetime»). Green indicates ecosystem C gain (photosynthesis and C pool increase); red denotes ecosystem C loss (respiration and C pool decrease); the orange arrows indicate C export through thinning. The NECB percentage value (right) corresponds to the lifetime carbon sequestration efficiency (CSE). The sizes of the Sankey plots are not proportional to the C fluxes of the different study sites.

1090

1095 Figure 2. Modelled (BASFOR) nitrogen budgets at three example forest sites (DB5: 45-yr old *Fagus sylvatica*; EN3: 120-yr old
 1100 *Picea abies*; EN16: 51-yr old *Pseudotsuga menziesii*). Simulations were run either over the most recent 5-year period which did not
 include any thinning event («5-yr» in the text), or over the whole time period since the forest was established («lifetime»). The data
 show ecosystem SOM mineralisation (N_{miner}) and atmospheric N_r deposition (N_{dep}), balanced by vegetation uptake (N_{upt}) and the
 sum of losses as dissolved N (N_{leach}) and gaseous $\text{NO} + \text{N}_2\text{O}$ (N_{emission}) (units: $\text{g (N) m}^{-2} \text{ yr}^{-1}$ left and center; $\% \text{ of lifetime } N_{\text{supply}}$
 on the right, with N_{supply} defined as $N_{\text{miner}} + N_{\text{dep}}$). NMIN indicates the mean size of the soil inorganic N pool (g (N) m^{-2}) over the
 modelling period. The N uptake percentage value (right) corresponds to the lifetime nitrogen use efficiency (NUE). The sizes of the
 Sankey plots are not proportional to the N fluxes of the different study sites.

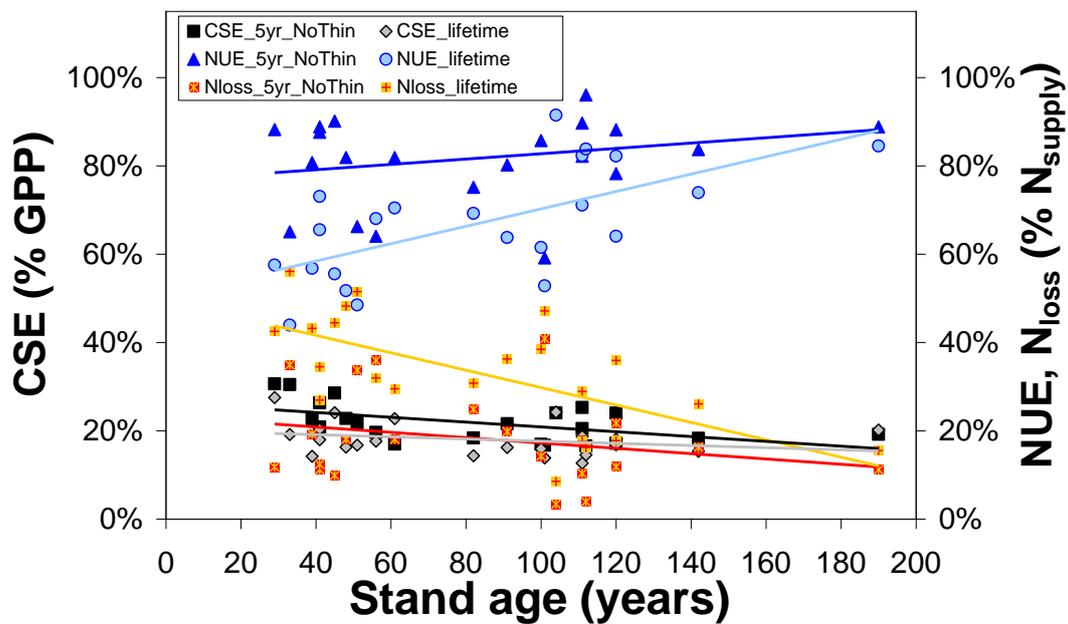

Figure 3. Influence of forest stand age on modelled (BASFOR) C sequestration efficiency (CSE, expressed as % GPP), N use efficiency (NUE) and the N_{loss} fraction ($\% N_{\text{supply}}$). Each data point represents one of 22 modelled forest sites. CSE and NUE are calculated either i) over the most recent 5-year period including no thinning event around the time frame of the CEIP/NEU projects, or ii) over the whole lifetime of the stands (including all thinning events). See Eq. (1)-(9) for definitions and calculations of the indicators.

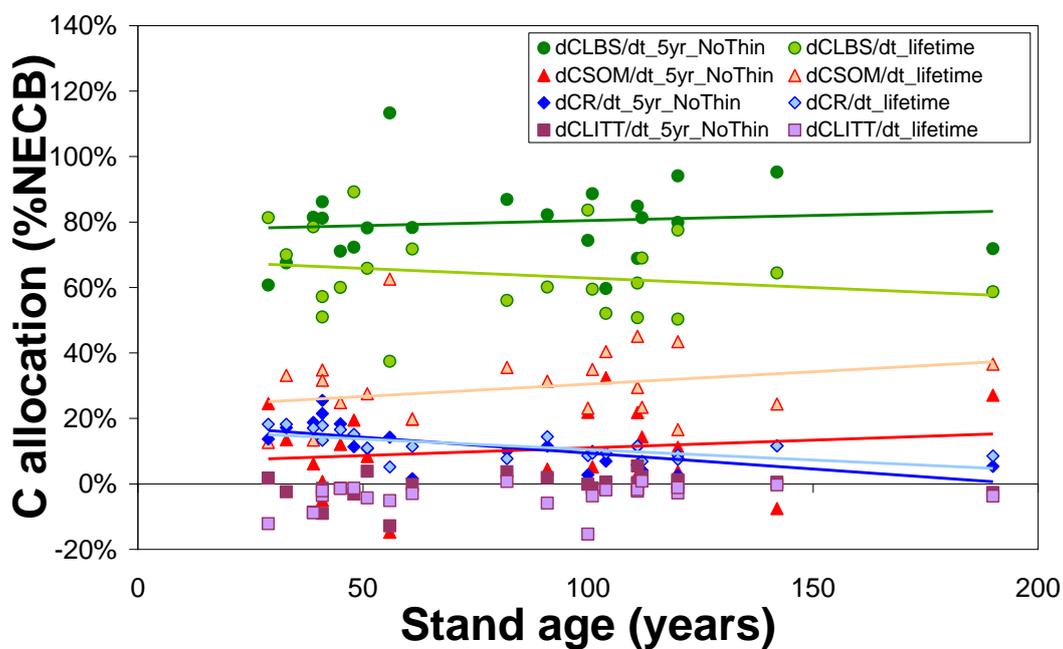

Figure 4. Modelled (BASFOR) ultimate allocation of sequestered C (as % NECB) into pools in soil organic matter (CSOM), roots (CR), litter layers (CLITT), leaves, branches and stems (CLBS). Each data point represents one of 22 modelled forest sites, plotted as a function of stand age.

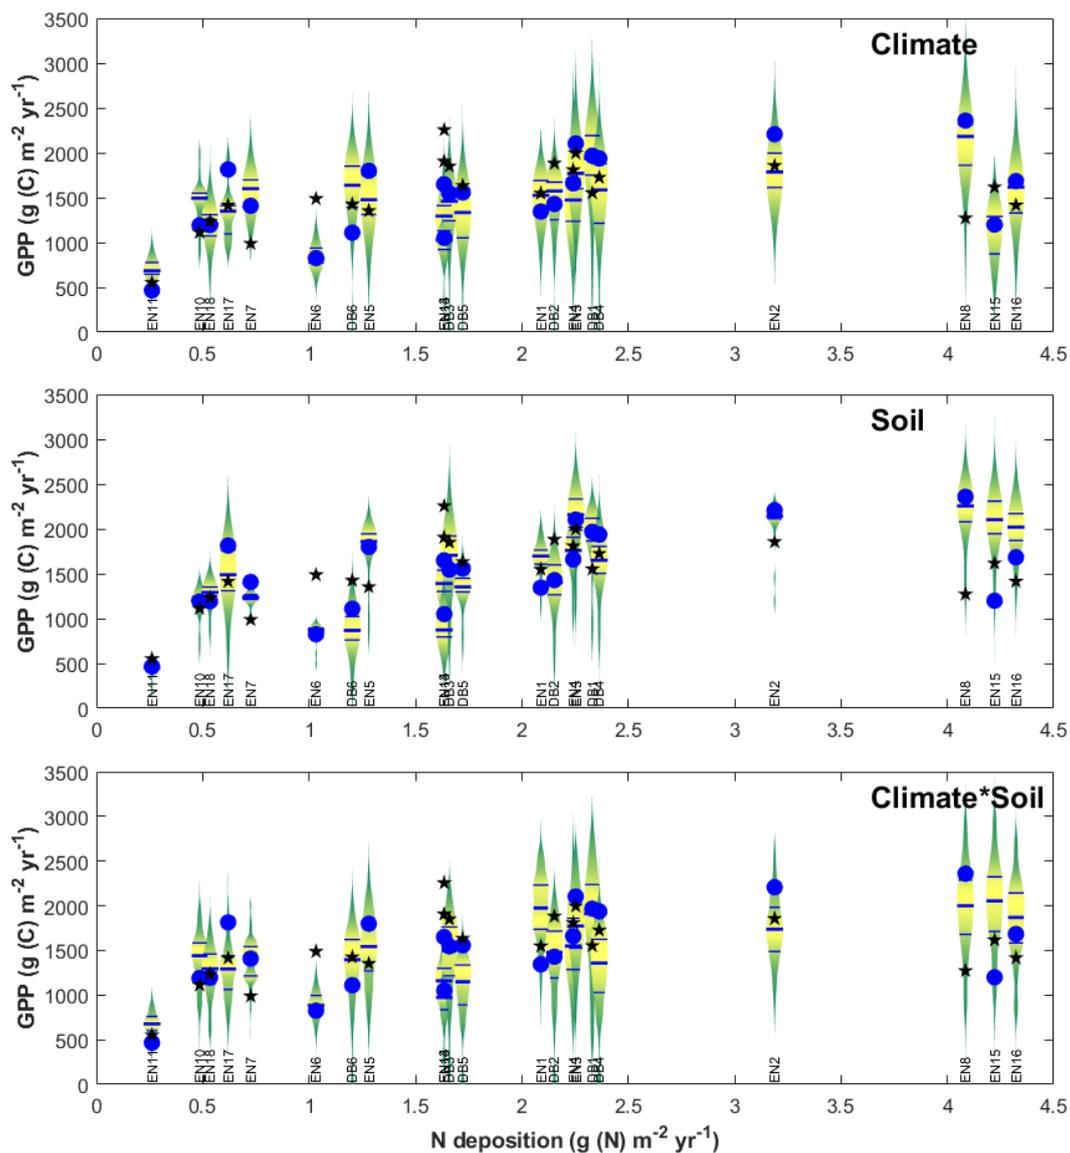

Figure 5. Comparison of distributions of gross primary productivity (GPP) at each forest monitoring site for modelled soil/climate scenarios (vertical «violin» plots), versus model base runs GPP_{base} (blue circles) and EC-derived GPP_{obs} (black stars). The data are displayed as a function of N_e deposition over the CEIP-NEU measurement periods, for $n=22$ deciduous broadleaf and coniferous evergreen needleleaf forest ecosystems. See text for details.

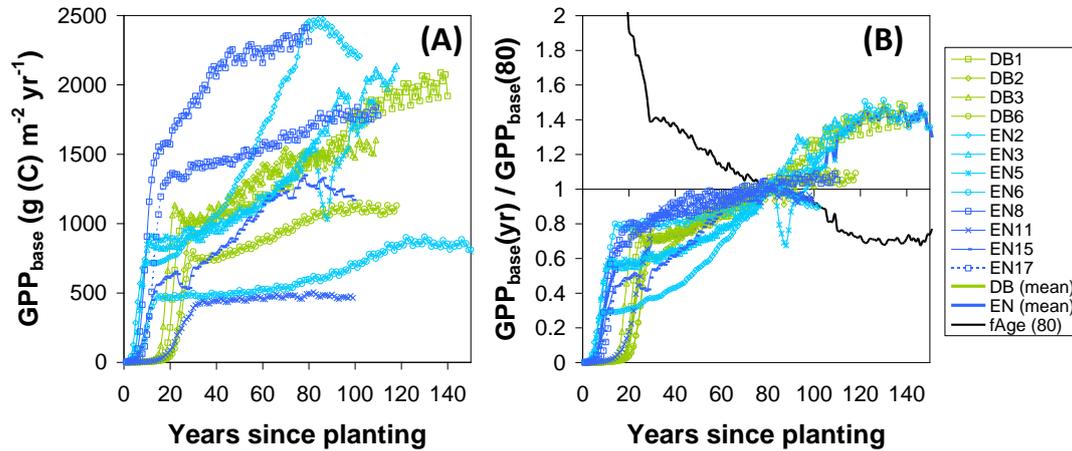

Figure 6. Calculation of f_{AGE} (normalized to 80 yr) from modelled BASFOR growth curves for mature forests (12 sites older than 80 yr). (A) Modelled (baseline) gross primary productivity (GPP_{base}); (B) Each site's GPP_{base} curve is normalized to the value at 80 yr. A single f_{AGE} curve is then calculated as the mean of all sites after normalization to $GPP_{base}(80)$ (see Eq. (16)-(17)). DB: deciduous broadleaf; EN: coniferous evergreen needleleaf.

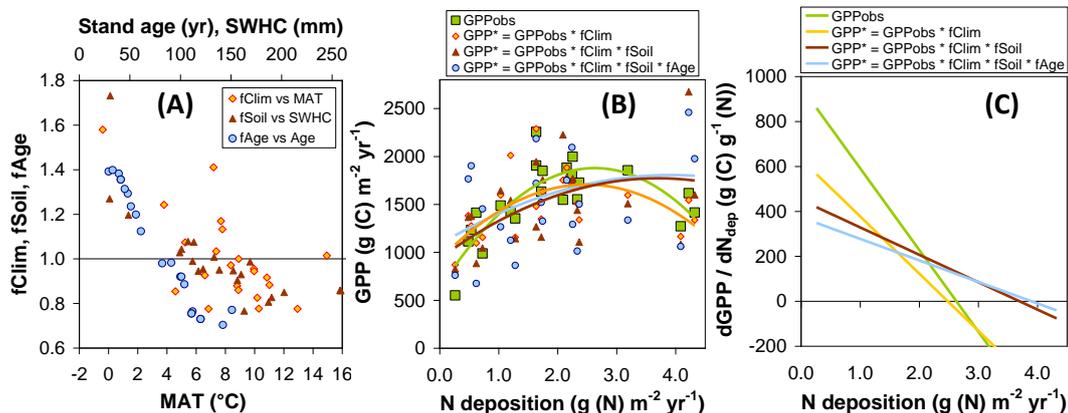

Figure 7. Model-based assessment of the sensitivity of gross primary productivity (GPP) to climate, soil, age and N_{dep}. (A) GPP standardization factors for observational (EC-based) data as a function of the dominant climatic and soil drivers (MAT: mean annual temperature; SWHC: soil water holding capacity; see text for details); (B) the resulting standardized GPP* compared with the original GPP_{obs} as a function of N_{dep} (one data point for each of 22 sites), with 2nd-order polynomial fits; (C) estimates of the GPP response to N_{dep} , calculated as the slope of the tangent line to the quadratic fits and plotted as a function of N_{dep} .

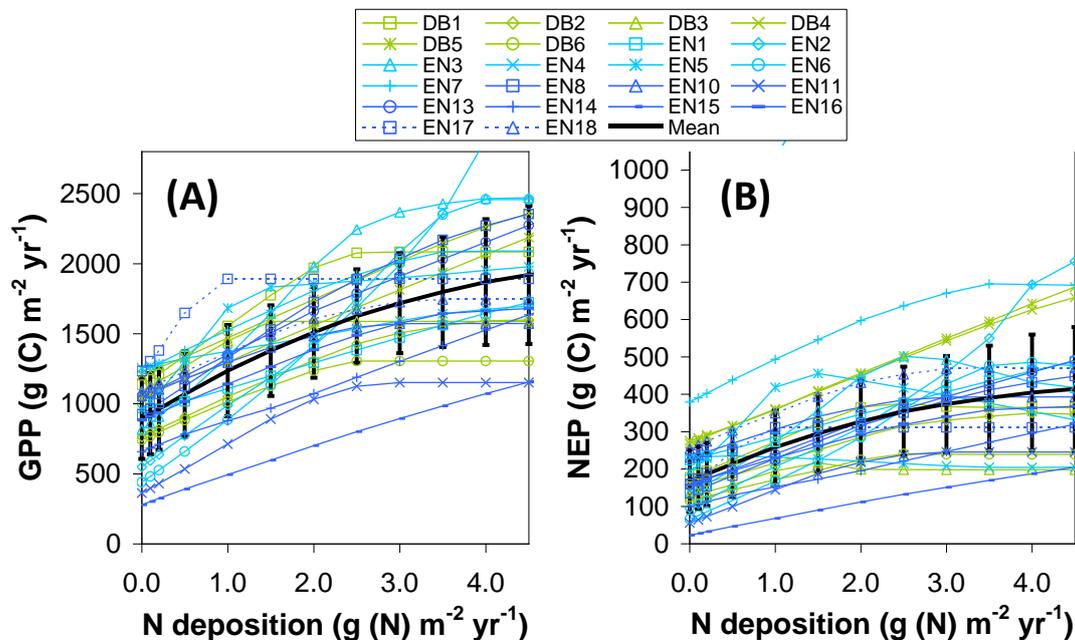

Figure 8. Modelling (BASFOR) sensitivity scenarios for (A) gross primary productivity (GPP) and (B) net ecosystem productivity (NEP) for 22 forest sites (with mean \pm standard deviation), in which each site was modelled using a range of N_{dep} values from 0 to $4.5 \text{ g (N) m}^{-2} \text{ yr}^{-1}$ (constant N_{dep} over the lifetime of the stands).

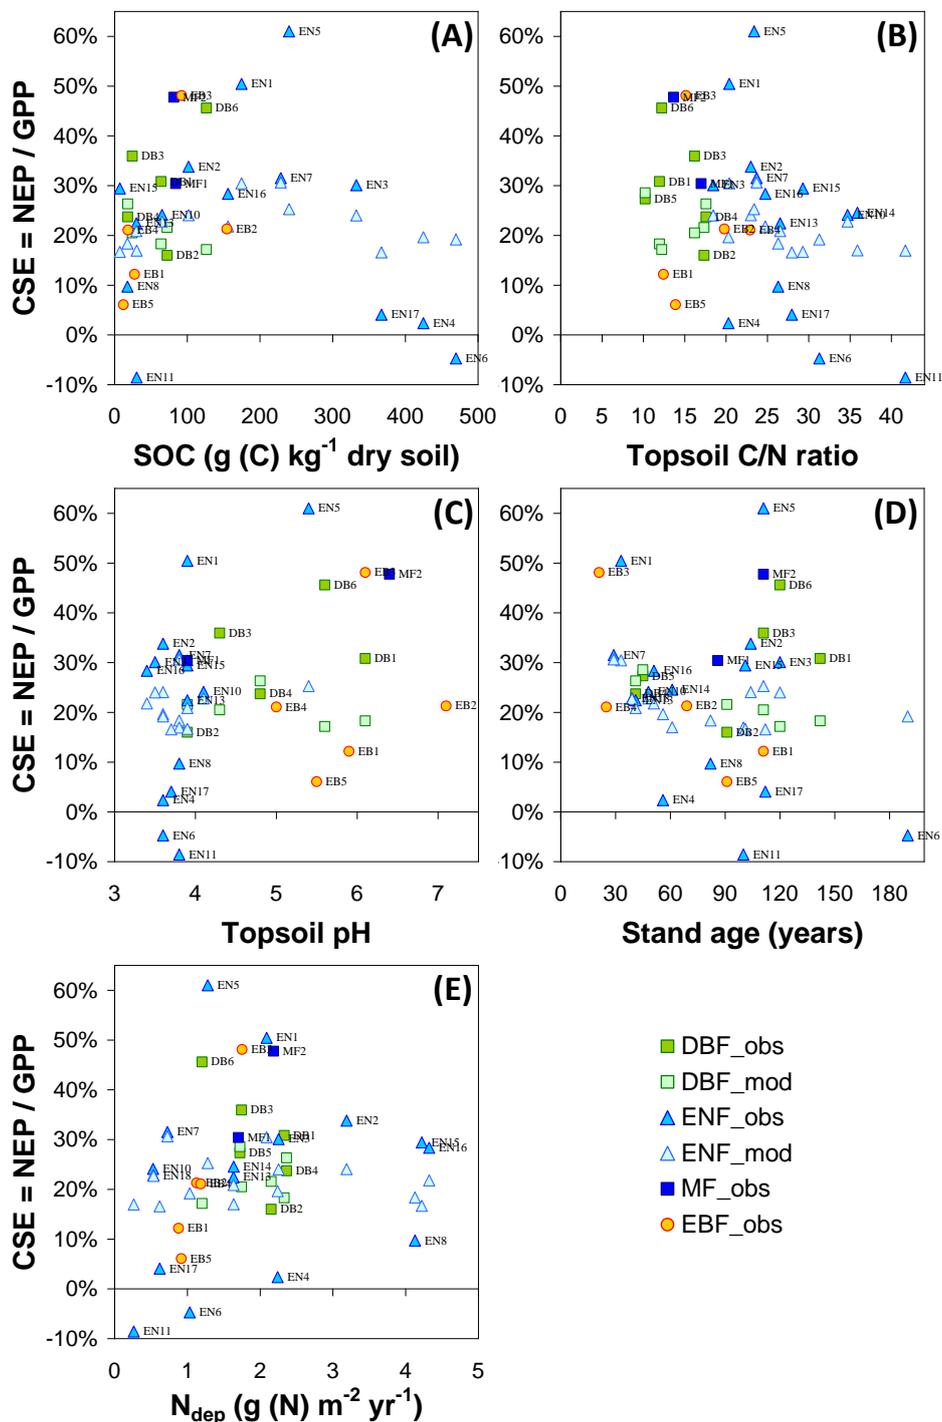

Figure 9. Variability of observation-based (obs) and modelled 5-yr (mod) carbon sequestration efficiency defined as the NEP/GPP ratio calculated over the ~5-yr measurement period, plotted as a function of (A) topsoil organic carbon content, (B) topsoil C/N ratio, (C) topsoil pH, (D) forest stand age, and (E) nitrogen deposition. DBF: deciduous broadleaf forests; ENF: coniferous evergreen needleleaf forests; MF: mixed needleleaf/broadleaf forests; EBF: Mediterranean evergreen broadleaf forests.

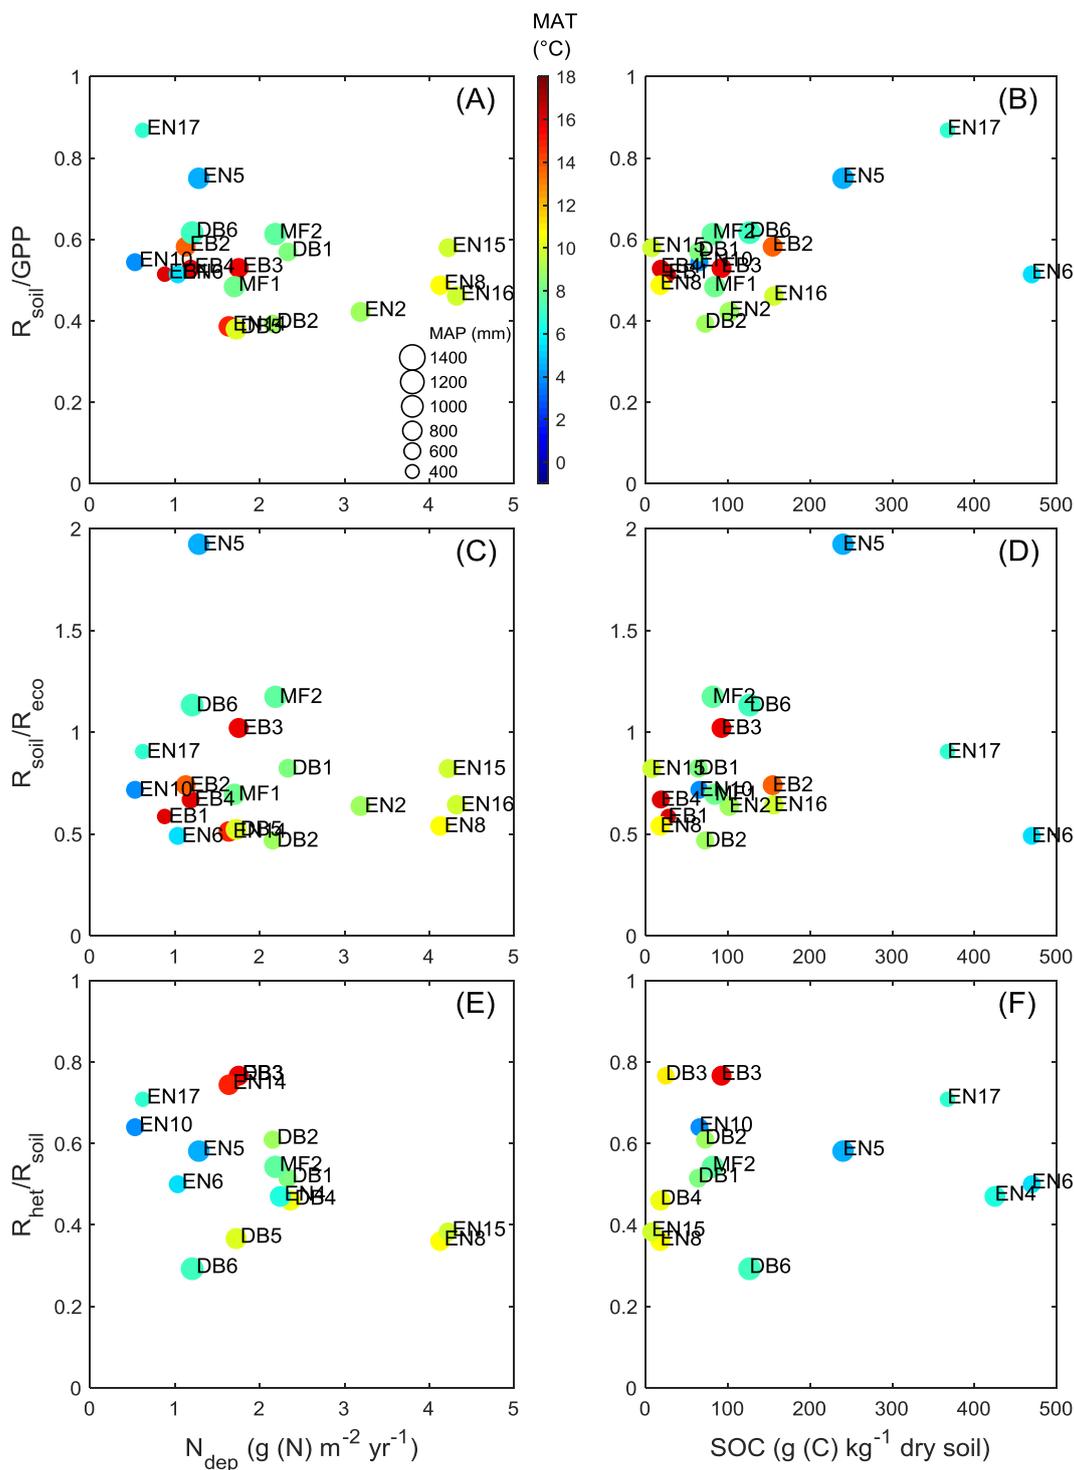

Figure 10. Variability of normalized soil respiration metrics as a function of nitrogen deposition (A, C, E) and soil organic carbon (B, D, F). In all plots, the color scale indicates mean annual temperature (MAT), and the symbol size is proportional to mean annual precipitation (MAP).

Table 1. BASFOR model state variables, inputs and outputs, and other acronyms used in the study.

BASFOR variables	Description
Tree state variables	
CL	Carbon pool in Leaves
CB	Carbon pool in Branches
CS	Carbon pool in Stems
CLBS	Carbon pool in Leaves, Branches and Stems
CR	Carbon pool in Roots
CRES	Carbon pool in Reserves
NL	Nitrogen pool in Leaves
SD	Forest stand density
Soil state variables	
CLITT	Carbon pool in Litter layers
CSOMF	Carbon pool in Soil Organic Matter (Fast turnover)
CSOMS	Carbon pool in Soil Organic Matter (Slow turnover)
NLITT	Nitrogen pool in Litter layers
NSOMF	Nitrogen pool in Soil Organic Matter (Fast turnover)
NSOMS	Nitrogen pool in Soil Organic Matter (Slow turnover)
NMIN	Soil Mineral (inorganic) Nitrogen pool
WA	Water pool in the root zone
Soil parameters	
Φ_{SAT}	Saturation soil water content
Φ_{FC}	Field capacity
Φ_{WP}	Wilting point
ROOTD	Root depth
Model inputs (daily time step)	
R_g	Daily global radiation
T_a	Daily average air temperature
P	Daily accumulated rain
WS	Daily average wind velocity
RH	Water vapour pressure
CO ₂	Annual mean CO ₂ mixing ratio
N _{dep}	Annual atmospheric nitrogen deposition
thinFR	Fraction of trees removed by thinning
Model outputs	
H	Tree height
DBH	Diameter at breast height
LAI	Leaf area index
LeafN	Leaf N content
GPP	Gross primary productivity
R _{eco}	Ecosystem respiration
R _{net}	Soil heterotrophic respiration
NPP	Net primary productivity
NEE	Net ecosystem exchange
ET	Evapotranspiration
N _{miner}	Nitrogen supply from SOM mineralization
N _{upt}	Root N uptake by trees
N _{leach}	Inorganic N leaching
NO	Nitric oxide
N ₂ O	Nitrous oxide
N _{emission}	Gaseous soil NO + N ₂ O emissions
Other variables	
GPP _{obs} , NEP _{obs}	Observation-based (eddy covariance) GPP or NEP
GPP _{base}	Baseline model run for GPP
GPP*, NEP*	Model-standardized observation-based GPP or NEP
f _{CLIM} , f _{SOIL} , f _{AGE}	Model-derived standardization factors to account for climate, soil, age
NECB	Modelled net ecosystem carbon balance, calculated as d(CLBS+CR+CSOM+CLITT)/dt
R _{aut}	Autotrophic respiration
R _{soil}	Soil (heterotrophic and rhizospheric) respiration
SCE	Soil CO ₂ efflux measured by chamber methods
CSE _{obs}	Observation-based carbon sequestration efficiency (NEP _{obs} /GPP _{obs})
CSE _{5-yr, lifetime}	Modelled carbon sequestration efficiency; = NEP/GPP (5-yr), or NECB/GPP (lifetime)
NUE	Modelled nitrogen use efficiency, calculated as N _{upt} / N _{supply}
N _{supply}	Total mineral N supply, calculated as (modelled) N _{miner} + (observation-based) N _{dep}
N _{loss}	Modelled percentage ecosystem N losses, calculated as (N _{leach} + N _{emission}) / N _{supply}
dC/dN, dGPP/dN _{dep} , dNEP/dN _{dep}	Response (slope) of ecosystem C productivity versus atmospheric N _i deposition
SWHC	Soil water holding capacity, = (Φ_{FC} - Φ_{WP}) x ROOTD
MAT, MAP	Mean annual temperature or precipitation
CEXP	Carbon exported by thinning or harvest in forests
