Abstract. The temperature proxies $U_{37}^{K'}$, LDI, TEX_{86}^H and RI-OH are derived from lipid biomarkers, namely long-chain alkenones from coccolithophorids, archaeal glycerol dialkyl glycerol tetraethers (GDGTs), long-chain diols ascribed tentatively to eustigmatophytes, and archaeal OH-GDGTs, respectively. The applicability of these proxies has been examined in the South China Sea (SCS), but most of these studies were focused on a single proxy and hence did not allow
15 for a direct comparison between them. In this study, we investigated the above 4 proxies in the same set of surface sediment samples in the northern SCS shelf and related them to local sea surface temperature (SST), which allowed us to assess whether they represent certain seasons or are impaired by terrestrial influences, as well as to infer the preferred habitats of their source organisms. Terrestrial organic inputs appeared to have an impact on LDI, TEX_{86}^H and RI-OH proxies near the coast and lead to colder LDI and TEX_{86}^H derived temperatures, but a warmer RI-OH estimate in this region. After excluding
20 samples influenced by terrestrial organic input, we found that LDI-derived temperature agreed well with annual SSTs, while $U_{37}^{K'}$ reflected mainly spring SST and both TEX_{86}^H and RI-OH indices were correlated with winter SST. The differential seasonal biases of these biomarker-derived temperatures observed here suggest that each biomarker's source organism responds differently to regional marine environmental changes in an annual cycle. Specifically, marine eustigmatophytes are likely insensitive to nutrient variations and hence show the lowest seasonal variations, while coccolithophorids could have
25 bloomed in late spring, when nutrient inputs by freshwater are usually highest. GDGT- and OH-GDGT-producing planktonic archaea likely thrive in winter, when conditions, such as relatively high nutrients levels, low light, and high concentrations of SPM in the upper water due to the enhancement of vertical mixing driven by a combination of surface cooling and strong winter monsoon winds, are favorable, although not clearly known.

1 Introduction

- 30 Over the past three decades, organic proxies have been successfully applied to reconstruct the Quaternary or even Cenozoic temperature history of the Earth's surface ocean. The two most widely used proxies are the $U_{37}^{K'}$ from alkenones (Brassell et al., 1986) and the TEX_{86} based on archaeal isoprenoid tetraethers (Schouten et al., 2002). More recently, two additional organic thermometers, the LDI (long chain diol index) and RI-OH (ring index of hydroxylated isoprenoid glycerol dialkyl glycerol tetraethers (OH-GDGTs)), have been proposed by Rampen et al. (2007) and Lü et al. (2015).
- 35 The $U_{37}^{K'}$ proxy is based on the unsaturation of C_{37} -alkenones that were synthesized by a very restricted group of haptophyte algae, most notably the coccolithophores *Emiliania huxleyi* and *Gephyrocapsa oceanica* in typical marine environments (Farrimond et al., 1986; Volkman and L, 1995). Haptophyte algae are light-dependent and live near the sea surface with a competitive advantage in phosphorous-limited environments (Müller et al., 1998; Paasche, 2002). The TEX_{86} , as well as its modified versions TEX_{86}^H and TEX_{86}^L , is based on the relative abundance of isoprenoid glycerol dialkyl glycerol tetraethers
- 40 (iGDGTs) containing 0–3 cyclopentane moieties (GDGT-0, 1, 2, 3, respectively) or an additional cyclohexane moiety (crenarchaeol and its regio isomer), produced by marine planktonic Thaumarchaeota (Schouten et al., 2013). Thaumarchaeota play an important role in pelagic ammonia oxidation in marine environments, and tend to maximize in abundance at subsurface depths <200 m (Schouten et al., 2013). The LDI index is derived from the long-chain diols (LCDs), the producers of which, albeit not unambiguously identified yet, likely are eustigmatophyte algae in marine environments
- 45 (Rampen et al., 2007, 2014a). Similarly, little is known about the biological sources of OH-GDGTs and their influence on the RI-OH proxy. Culture studies suggest that Thaumarchaeota Group 1.1a (e.g., *Nitrosopumilus maritimus*) and a strain of thermophilic euryarchaeota *Methanothermococcus thermolithotrophicus* could synthesize OH-GDGTs (Liu et al., 2012b; Sinninghe Damsté et al., 2012).
- Due to the distinctive ecology of their source organisms, these temperature proxies differ in reflecting water temperatures in
- 50 terms of, e.g., water depth and seasonality. For instance, in the South China Sea (SCS), the $U_{37}^{K'}$ and TEX_{86}^H indices likely reflect temperatures of the mixed layer (>30 m) and the subsurface (30–125 m), respectively (Jia et al., 2012). However, in the shallow coastal area of the SCS, the $U_{37}^{K'}$ -derived SST estimates are biased toward the spring and summer temperatures, but those based on TEX_{86}^H toward the winter temperature, likely due to different blooming times (Zhang et al., 2013). By contrast, in the East China Sea (ECS), both TEX_{86}^H and RI-OH signals are summer biased (Lü et al., 2014, 2019; Zhang et al.,
- 55 2017). Lopes et al. (2013) compared the $U_{37}^{K'}$, TEX_{86}^H and LDI indices in sediments from offshore southeastern Australia, and found that LDI-derived temperature compares well with the temperatures of the warmest month, TEX_{86}^H with the temperatures of the coolest month and $U_{37}^{K'}$ with mean annual temperature. While in the southeast Australian ocean, $U_{37}^{K'}$ and LDI provide better estimates of winter temperature at the surface, and TEX_{86}^H matches well with annual temperature within 75–100 m (Smith et al., 2013).
- 60 The accuracy of organic thermometers is also prone to be impaired by a low specificity of related biomarkers. For example, the noncalcifying haptophyte genera *Isochrysis galbana* and *Chrysotila lamellose*, are predominantly restricted to non-

marine and marginal settings and expected to produce distinctly different alkenone records, which are likely to “contaminate” the U_{37}^K signal in marginal seas (Bijma et al., 2001). GDGTs synthesized by soil archaea and marine Euryarchaeota are likely different in composition from those produced by marine Thaumarchaeota, which could introduce biases to TEX_{86} values in conditions with inputs of archaeal lipids from multiple sources (Schouten et al., 2013; Turich et al., 2007; Weijers et al., 2006). Recently, the LDI proxy was found to be limited by the input of 1,13 and 1,15-diols from fresh-water eustigmatophyte algae, especially in the coastal seas (Balzano et al., 2018; de Bar et al., 2016). Similarly, OH-GDGTs may occur also in terrestrial environments including rivers (Chen et al., 2016; Kang et al., 2017), lakes (Liu et al., 2012a) and soils (Kang et al., 2017), which could also bias the RI-OH index in marginal seas.

Coastal seas are an ideal place for evaluation of the influences on the organic temperature proxies of various confounding factors, due to its environmental and ecological seasonality and transition from the land to the deep-sea. In this study, we analysed alkenones, LCDs and GDGTs in surface sediments from the northern SCS shelf. U_{37}^K , TEX_{86}^H , LDI and RI-OH indices have been studied in this area (Chen et al., 2018; Ge et al., 2013; Jia et al., 2017, 2012b; Wei et al., 2011; Zhang et al., 2013; Zhu et al., 2018), however most of these studies were focused on a single proxy and hence lacked a direct comparison between them. Here, we investigated all of the above 4 temperature proxies in the same surface sediment samples and evaluated their applicability as water temperature indicators. This effort would benefit regional multi-proxy sea temperature reconstructions, which could be more comprehensive and objective than those based on any single ones (Eglinton and Eglinton, 2008). In addition, such kind of investigation can shed light on the ecology of the related biomarker producers in this region, which is not entirely understood at present.

2 Material and methods

2.1 Study area and sample collection

The Pearl River estuary (PRE) and the northern shelf of SCS lie in a (sub)tropical monsoon climate region, with strong northeast winds in winter and weaker southwest winds in summer (Liu and Xie, 1999). As a result, coastal currents flow southwestward in winter (Fig. 1b), causing a strong vertical mixing and an inshore-offshore temperature gradient, while in summer, coastal currents reverse direction, except for one, which was near the western coast of the Pearl River (PR) and flow southwestward due to the large outflow of the PR (Fig. 1c, Liu and Xie, 1999; Su, 2004).

In the study area, a total of 23 core-top sediments (0–1 or 0–2 cm depths) were collected from the PRE and the coastal northern SCS, from water depths ranging from 6.5 to 1307 m (Suppl. Table 1). The samples were collected using a gravity box corer or grab sampler and then frozen at $-20\text{ }^{\circ}\text{C}$ in the laboratory before treatment.

90 2.2 Lipid extraction and separation

After being freeze-dried and homogenized, about 5 g of sediments were ultrasonically extracted three times with DCM: MeOH (9:1, v/v) for 15 min. Before extraction, known amounts of 2-nonadecanone, androstanol and C₄₆ GDGT were added as internal standards. Supernatants of each extraction were obtained by centrifugation. The total lipid extracts were combined and concentrated with rotary evaporation to ~1 mL, and saponified for 2 h at 80 °C with 1 mL of KOH (0.1 M) in MeOH: H₂O (9:1, v/v). The neutral fractions were extracted with *n*-hexane, and were further separated into alkane, alkenone and alcohol sub-fractions (containing diols and GDGTs) by column chromatography on silica gel using *n*-hexane, DCM: *n*-hexane (2:1, v/v) and DCM: MeOH (1:1, v/v), respectively.

2.3 Alkenone analysis and U₃₇^{K'} index

Alkenones were analysed using a 7890A gas chromatograph (GC, Agilent Technologies) equipped with a cold on-column injection system, a DB-5MS fused silica capillary column (60 m, ID 250 µm, 0.25 µm film coupled to a 5 m, ID 530 µm deactivated fused silica precolumn) and a flame ionization detector (FID). Helium was used as carrier gas (constant flow, 1.5 mL/min) and the GC oven was heated using the following temperature program: 60 °C for 1 min, 20 °C/min to 150 °C, 6 °C/min to 320 °C and a final hold time of 35 min. Di-unsaturated (C_{37:2}) and tri-unsaturated (C_{37:3}) alkenones were identified by comparison of the retention times with a reference sample composed of known compounds. Peak areas were determined by integrating the respective peaks, and concentrations were calculated using the response factor of the internal standard 2-nonadecanone.

The U₃₇^{K'} index was calculated using Eq. (1) after Prahl and Wakeham (1987).

$$U_{37}^{K'} = \frac{C_{37:2}}{C_{37:2} + C_{37:3}} \quad (1)$$

SST was estimated using Eq. (2) from Conte et al., (2006):

$$110 \quad SST (^{\circ}C) = \frac{U_{37}^{K'} - 0.0709}{0.0322} \quad (2)$$

2.4 Long chain diol analysis

One half of each alcohol fraction was silylated with N, O-bis(trimethylsilyl)-trifluoroacetamide (BSTFA)/1% trimethylchlorosilane (TMCS) and acetonitrile (30 µL each) and heated at 60 °C for 1 h. Diols were analysed by gas chromatography-mass spectrometry (GC/MS) on an Agilent 6850 GC coupled to an Agilent 5975C MSD operating in electron impact (EI) mode with an ionization energy of 70 eV. The GC was equipped with a fused silica capillary column (Restek Rxi-1ms, length 30 m; 250 µm ID, film thickness 0.25 µm). Helium was used as carrier gas at a constant flow rate of 1.2 mL/min. Samples (1 µL) were injected in splitless mode in a split/splitless injector (S/SL) held at 280 °C. The GC temperature program was as follows: 60 °C start temperature, held for 3 min, increased to 150 °C at a rate of 20 °C/min,

120 increased further to 320 °C at a rate of 4 °C/min and finally held at 320 °C for 15 min. The source temperature of the MS was set to 230 °C and the quadrupole to 150 °C.

For identification of the diols, the MS was operated in single-ion monitoring (SIM) mode with the following m/z : 313.3 (C_{28} 1,13-diol, C_{30} 1,15-diol), and 341.3 (C_{30} 1,13-diol, C_{32} 1,15-diol) (Versteegh et al., 1997; Rampen et al., 2012). Fractional abundances of the long chain diols were calculated from integrated relevant peak areas in respective mass chromatograms.

The LDI was calculated and converted to SST using Eq. (3) and Eq. (4) from Rampen et al. (2012):

$$125 \quad \text{LDI} = \frac{[C_{30} \text{ 1,15}]}{[C_{28} \text{ 1,13}] + [C_{30} \text{ 1,13}] + [C_{30} \text{ 1,15}]} \quad (3)$$

$$\text{SST } (^\circ\text{C}) = \frac{\text{LDI} - 0.095}{0.033} \quad (4)$$

The % C_{32} 1,15 index reflecting riverine input was calculated using Eq. (5) given by Lattaud et al. (2017) as follows:

$$\%C_{32} \text{ 1,15} = \frac{[C_{32} \text{ 1,15}]}{[C_{32} \text{ 1,15}] + [C_{30} \text{ 1,15}] + [C_{28} \text{ 1,13}] + [C_{30} \text{ 1,13}]} \times 100 \quad (5)$$

2.5 GDGT analysis and indices (TEX₈₆^H, BIT, MI, and RI-OH)

130 GDGTs were analysed by high performance liquid chromatography (HPLC) coupled via an atmospheric pressure chemical ionization (APCI) interface to a single quadrupole mass spectrometer (MS), with a method slightly modified from Hopmans et al. (2016). Analyses were performed on an Agilent 1200 series HPLC system and an Agilent 6120 MSD. Separation of the individual GDGTs including the 5-/6-methyl isomers of branched-GDGTs was achieved on two UPLC silica columns in series (Waters Acquity BEH HILIC, 2.1×150 mm, 1.7 μm), with a 2.1×5 mm pre-column of the same material maintained at
135 30 °C. Mobile phase A and B consisted of *n*-hexane: chloroform (99:1, v/v) and *n*-hexane: 2-propanol: chloroform (89:10:1, v/v/v), respectively. After sample injection (20 μL) and 25 min isocratic elution with 18 % mobile phase B, the proportion of B was linearly increased to 50 % within 25 min, and thereafter to 100 % for the next 30 min. After another 5 min and prior to the analysis of the next sample, the column was re-equilibrated with 18 % B for 15 min. The flow rate was 0.22 mL/min and a maximum back pressure of 220 bar was obtained. The total run time was 100 min.

140 GDGTs were detected using positive ion APCI-MS and selective ion monitoring (SIM) of their (M+H)⁺ ions (Schouten et al., 2007) or abundant ion-source fragmentation products of OH-GDGTs (Liu et al., 2012). APCI spray-chamber conditions were as follows: nebulizer pressure 50 psi, vaporizer temperature 350 °C, N₂ drying gas flow 5 L/min and 350 °C, capillary voltage (ion transfer tube) -4 kV and corona current +5 μA. The MS-detector was set for SIM of the following (M+H)⁺ ions:
145 m/z 1302.3 (GDGT-0), 1300.3 (GDGT-1+OH-GDGT 0), 1298.3 (GDGT-2+OH-GDGT-1), 1296.3 (GDGT-3+OH-GDGT-2), 1292.3 (GDGT-4+4'-Crenarch-aeol+regio-isomer), 1050 (GDGT-IIIa/IIIa'), 1048 (GDGT-IIIb/IIIb'), 1046 (GDGT-IIIc/IIIc'), 1036 (GDGT-IIa/IIa'), 1034 (GDGT-IIb/IIb'), 1032 (GDGT-IIc/IIc'), 1022 (GDGT-Ia), 1020 (GDGT-Ib), 1018 (GDGT-Ic) and 744 (C_{46} standard), with a dwell time of 57 ms per ion.

Quantification of the individual GDGTs was achieved by integrating the respective peak areas. Compound contents were calculated using the response factor obtained from the C₄₆ standard and by normalizing to the amount of extracted sediment. Due to the lack of appropriate standards, individual relative response factors between the C₄₆ standard and the different GDGTs could not be considered, the obtained concentrations should therefore be regarded as being only semi-quantitative. The TEX₈₆ and TEX₈₆^H were calculated following Eq. (6) and Eq. (7) and converted to SST according to Eq. (8) given by Kim et al. (2010), which is suitable to reconstruct SST between 15 and 30 °C.

$$\text{TEX}_{86} = \frac{\text{GDGT-2} + \text{GDGT-3} + \text{Cren}'}{\text{GDGT-1} + \text{GDGT-2} + \text{GDGT-3} + \text{Cren}'} \quad (6)$$

$$\text{TEX}_{86}^{\text{H}} = \log(\text{TEX}_{86}) \quad (7)$$

$$\text{SST} (\text{°C}) = 68.4 \times \text{TEX}_{86}^{\text{H}} + 38.6 \quad (8)$$

The BIT index was calculated according to Hopmans et al. (2004) including 6-methyl brGDGTs (DeJonge et al., 2013):

$$\text{BIT} = \frac{\text{Ia} + \text{IIa} + \text{IIIa} + \text{IIa}' + \text{IIIa}'}{\text{Ia} + \text{IIa} + \text{IIIa} + \text{IIa}' + \text{IIIa}' + \text{Cren}} \quad (9)$$

where Ia is the basic tetramethyl brGDGT; IIa and IIIa are 5-methyl brGDGTs; IIa' and IIIa' are 6-methyl brGDGTs (DeJonge et al., 2013).

The methane index (MI) was calculated using the Eq. (10) given by Zhang et al. (2011):

$$\text{MI} = \frac{\text{GDGT-1} + \text{GDGT-2} + \text{GDGT-3}}{\text{GDGT-1} + \text{GDGT-2} + \text{GDGT-3} + \text{Cren} + \text{Cren}'} \quad (10)$$

The RI-OH index was calculated using Eq. (11), and converted to annual mean SST according to Eq. (12) (Lü et al., 2015):

$$\text{RI-OH} = \frac{[\text{OH-GDGT-1}] + 2 \times [\text{OH-GDGT-2}]}{[\text{OH-GDGT-1}] + [\text{OH-GDGT-2}]} \quad (11)$$

$$\text{SST} (\text{°C}) = \frac{\text{RI-OH} - 0.92}{0.028} \quad (12)$$

2.6 Climatological mean temperature data

Annual and seasonal SST data for each sampling site were 8–years average values (2005–2012) taken from the NOAA World Ocean Atlas 2013 (WOA13 V2) on a 0.25° grid resolution (<https://www.nodc.noaa.gov/cgi-bin/OC5/woa13/woa13.pl>), which is the latest version and close to the estimated deposition time ([sampling time, 2012–2017]) – [depth, 0–2 cm]/[deposition rate, 2–6 mm yr⁻¹] = [deposition time, 2002–2014]) (Ge et al., 2014; Liu et al., 2014). According to the description of WOA13, seasons were defined as follows: Winter: January–March; Spring: April–June; Summer: July–August; Autumn: September–December. In addition, the residual of a proxy-derived SST relative to the WOA13 SST was calculated as follows:

$$\text{Residual} (\text{°C}) = [\text{proxy-derived temperature}] - [\text{WOA13-derived temperature}] \quad (13)$$

175 3 Results

3.1 Hydrological parameters

Except one sample taken from deeper waters (LD-21, WD = 1307 m), the sites of surface sediment samples in this study were mainly located on the shelf area (WD <200 m) (Fig. 1a). The measured annual mean SSTs (0 m depth, from the WOA13 dataset) in the study area ranged between 24.2 °C and 26.8 °C (25.5 °C average), and showed clear seasonal variations exhibiting low values in winter (21.2 °C average), highest in summer (29.0 °C average), and intermediate in spring (26.3 °C average) and autumn (25.6 °C average) (Fig. 2). The temperatures of the mixed layer (0–30 m) were slightly (<0.8 °C) lower than SST and also varied seasonally in a similar pattern (Suppl. Table 1). The annual mean and seasonal SSTs displayed an increasing trend offshore with the largest difference of ca. 6 °C in winter between inshore and offshore.

3.2 U_{37}^K and alkenone-derived temperatures

185 The U_{37}^K index ranged between 0.81 and 0.94 (0.91 average) (Suppl. Table 2), corresponding to 23.0–27.0 °C (26.0 °C average, Fig. 2) based on the calibration proposed by Conte et al. (2006). Compared with the measured SSTs, the U_{37}^K -SSTs were closest to the spring SST at most sites, except two inshore samples (WD <50 m), which had slightly lower U_{37}^K -SSTs (Fig. 2). We also compared results from different calibrations for 0 m or 0–30 m SSTs (Suppl. Fig. 1), and found that all derived U_{37}^K -SSTs exhibited similar values that differed from the calibration of Conte et al. (2006) by <0.7 °C (0.1 °C average; Suppl. Table 2). For this study, we considered only the temperatures calculated by Conte et al. (2006).

3.3 LCD distribution and LDI-derived temperatures

In the total 1,13- and 1,15-diols, the C_{30} 1,15-diol was the most abundant (>80 %) at most sites outside the PRE, followed by C_{32} 1,15-diols (<15 %) and C_{28} and C_{30} 1,13-diols (<4 %) (Fig. 3). However, the C_{32} 1,15-diols were more abundant (>41 %) than the C_{30} 1,15-diols (>19 %) in the PRE sediments. The C_{28} and C_{30} 1,13-diols exhibited a similar spatial distribution pattern as the C_{32} 1,15-diol, showing higher relative abundances in the PRE and coastal area (Fig. 3).

195 The LDI values of surface sediments varied from 0.56 to 0.98, but were ≥ 0.90 at most sites, corresponding to LDI-derived temperatures (LDI-SST) varying from 14.0 to 26.9 °C (Fig. 2). The river input index (% C_{32} 1,15) values ranged from 1.9 % to 66.3 %, showing an overall decreasing trend offshore (Suppl. Table 3-1). A comparison of our LDI values and the global data from Rampen et al. (2012) indicated that our data agreed well with the global data, except for three samples with low LDI values and hence resulting in substantial annual SST residuals (<-7 °C) (Suppl. Fig. 2). Two of the three samples were located in the PRE and the other one in the inshore area (Site MMDB, WD = 26 m). In addition, we also found that the third PRE sample at PRE-Y11 as well as samples GLB and SXCB near the coast (WD = 15 m and 14 m, respectively) exhibited significant annual SST residuals (<-2.1 °C). When excluding data from these six samples, our LDI-SSTs were close to 200 annual SSTs, with residuals ranging between -0.3 °C and 1.2 °C (Suppl. Table 3-1 and 3-2).

205 3.4 Distribution of GDGTs, $\text{TEX}_{86}^{\text{H}}$ and RI-OH-derived temperatures

The iGDGTs were dominated by crenarchaeol ([Cren], 43.2–65.9 %) and GDGT-0 ([0], 18.1–37.0 %) (Fig. 4a), and the ratios of both compounds, i.e. [0]/[Cren], ranged between 0.28 and 0.75 (Fig. 4c). Two samples with relatively high values of [0]/[Cren] were from the PRE (0.75, PRE-A8) and the deep sea (0.69, LD-21) (Fig. 4c). The least abundant iGDGTs is the crenarchaeol regio isomer ([Cren'], 0.8–5.4 %), showing an overall increasing trend offshore (Fig. 4a). The ratio of GDGT-0 and crenarchaeol regio isomer, i.e. [0]/[Cren'], maximized in the river mouth (47.3, PRE-A8) and exhibited a declining trend offshore (Fig. 4d). The ratio of GDGT-2 versus GDGT-3, i.e. [2]/[3], ranged from 2.6 to 7.2, and was low at shelf and coastal sites (WD <200 m, 2.6–3.6), but high at the deep-sea site (7.2, LD-21) (Fig. 4d). Similar spatial distribution patterns appeared also for the [2]/[Cren] ratio and the MI value, exhibiting low values of 0.07–0.15 for [2]/[Cren] and 0.16–0.26 for MI at shelf and coastal sites, and slightly higher values of 0.25 for [2]/[Cren] and 0.31 for MI at the deep-sea site (LD-21) (Fig. 4c). In addition, higher BIT values (0.49) were found in the PRE, relative to the inshore area (0.1–0.3, WD <50 m) and the offshore area (<0.1) (Fig. 4c).

The OH-GDGTs contributed 1.5–4.1% to the total GDGT pool (Suppl. Table 5), consistent with the lower relative OH-GDGTs abundance found in (sub)tropical regions (Huguet et al., 2013). The most abundant OH-GDGT is OH-GDGT-2 ([OH-2], 39.2–67.0 %), with high values at shelf and coastal sites (WD \leq 186 m) (Fig. 4b), but low contribution at the deep-sea site (LD-21). In contrast, the relative abundance of OH-GDGT-0 ([OH-0]) remained low at shelf and coastal sites, but was elevated at the deep-sea site (Fig. 4b). In addition to the twenty sediment samples used in this study, there have been 47 other reported data of OH-GDGTs in the surface sediments in the SCS from water depths ranging between 3 m and 4405 m (Lü et al., 2015; Yang et al., 2018). By combining these data, we observed a positive logarithmic correlation between [OH-0] and water depth ($R^2 = 0.58$), but a negative logarithmic correlation between [OH-2] and water depth ($R^2 = 0.66$) (Fig. 4b).

$\text{TEX}_{86}^{\text{H}}$ values varied in the range between -0.33 and -0.18 (Suppl. Table 4), corresponding to SST values of 16.2 to 26.0 °C based on the calibration by Kim et al. (2010). The annual residuals ranged from -8.8 to -0.8 °C. Seasonally, the mean absolute values of residuals were 2.0 °C, 6.0 °C, 8.7 °C and 5.3 °C, respectively, from winter to autumn (Suppl. Table 4), indicating $\text{TEX}_{86}^{\text{H}}$ -SSTs were closer to winter temperature. Spatially, consistently low temperature estimates were found in the coastal area and PRE with water depth <50 m, some of them even colder than winter SST (Fig. 2). However, the offshore samples had relatively high $\text{TEX}_{86}^{\text{H}}$ -SSTs, which were ca. 2 °C higher than winter SST and close to autumn and annual SSTs (Fig. 2).

The RI-OH values varied from 1.57 to 1.79 (Suppl. Table 5), which agree with recently reported data for the same region (1.50–1.75) (Lü et al., 2015; Yang et al., 2018). SST estimates based on the calibration suggested by Lü et al. (2015) for the Chinese marginal sea (CMS), were within a range of 23.3–31.2 °C (Fig. 2). In comparison with the measured annual SST, three higher RI-OH-SSTs occurred in the PRE, with annual residuals of 2.6–6.2 °C, and other samples exhibited slightly higher or lower RI-OH-SSTs, with annual residuals of -2.5 – 3.1 °C (Fig. 2 and Suppl. Table 5).

4 Discussion

4.1 Seasonality of the $U_{37}^{K'}$ proxy

Although the relationship between $U_{37}^{K'}$ and SST is robust and well supported by culture studies, the seasonality of production of C_{37} alkenones and the response of $U_{37}^{K'}$ to temperature at very warm and cold environments remain unresolved (Tierney and Tingley, 2018). Sediment trap studies demonstrated that alkenone production varies markedly across the oceans, with factors such as temperature, nutrients, light availability, and competition regulating the timing of haptophyte blooms (Rosell-Melé and Prah, 2013). The seasonality of alkenone production may be transferred to sediments, but this signal could also be altered by the complex sedimentation processes (Rosell-Melé and Prah, 2013). Our results indicated that $U_{37}^{K'}$ -SST estimates were spring biased in this region (Fig. 2). A similar finding has been reported by Zhang et al. (2013), who proposed $U_{37}^{K'}$ -SST to be summer-biased. We note that summer in that work included June, July and August, differing from the definition used here, where the month of June is part of spring. These suggest that the alkenone production is biased to late spring, when alkenone-source organisms are mostly bloomed. However, it has been reported that water-column coccolithophore abundance is highest both in winter and spring in the northern SCS (Chen et al., 2007), when higher nitrate concentrations occur in the surface water and favour growth of coccolithophores, e.g., *E. huxleyi*. The difference between this study and others could relate to the influence of the Pearl River, and our study area was significantly impacted by the river runoff as well as the supply of terrestrial nutrients, which was highest in late spring (May to June) in an annual cycle (Dai et al., 2008; Lu and Gan, 2015; Zhang et al., 2013). The high river input with N:P ratios as high as ~100:1 could stimulate growth of alkenone-producing haptophytes, e.g., *E. huxleyi*, during this period (Xu et al., 2008), since *E. huxleyi* was reported to be nitrate limited and have a competitive advantage over other phytoplankton when inorganic phosphate is limiting but nitrate is still abundant (Bijma et al., 2001).

Although a slightly lower $U_{37}^{K'}$ -SST was observed in the river mouth, most of our samples exhibited a spring-biased $U_{37}^{K'}$ -SST, possibly indicating that there was a low contribution of freshwater alkenones or they had less influence on $U_{37}^{K'}$ -SST.

4.2 LCDs and LDI-derived temperatures

4.2.1 Source of LCDs in the surface sediments

The unusually low LDI-derived SST estimates relative to the measured SSTs observed near the coast and close to the river mouth (Fig. 2) suggest that LDI may be influenced by terrestrial/freshwater sources other than marine producers. Similar findings were reported from the Iberian margin (de Bar et al., 2016), in the Gulf of Lion, the Berau Delta and the Kara Sea (Lattaud et al., 2017), suggestive of terrestrial influence on LCD compositions. Culture studies show that marine eustigmatophyte algae mainly produce 1,13 and 1,15-diols (Rampen et al., 2007, 2014a; Volkman et al., 1999). In freshwater environments, eustigmatophyte algae primarily produce C_{32} 1,15-diol, especially in stagnant waters during dry seasons, when rivers have low-stands (Häggi et al., 2019; Lattaud et al., 2017; Rampen et al., 2014b). However, C_{30} 1,15-diols are

generally found to be dominant both in the marine water column and sediments and are likely produced by marine eustigmatophyte algae (Balzano et al., 2018).

270 To confirm the potential sources of different diols in our study area, we performed a Pearson Correlation Analysis (Table 1). We found that C_{28} and C_{30} 1,13-diols and C_{32} 1,15-diols were significantly correlated between each other (correlation coefficient: 0.56–0.83, P-value <0.005, Table 1), suggesting a similar source origin in this region. The co-occurrence of high abundance of above three diols in the PRE and along the coast rather than in the offshore area (Fig. 3) is consistent with the correlation analysis, and further suggests a terrestrial/freshwater source of them. In contrast, these three diols were
275 negatively correlated with C_{30} 1,15-diol (correlation coefficient from –0.68 to –0.90, P-value <0.005, Table 1), with the latter exhibiting an opposite pattern and showing an overall increasing trend towards the offshore. Such a spatial distribution pattern becomes more apparent when diol compositions in SPM and sediments are illustrated from the PRE to the offshore (Fig. 5). The negative correlation of C_{30} 1,15-diol with three other diols could be attributed to their different sources, i.e. marine vs. terrestrial, or an opposite response to ambient temperature of C_{30} 1,15-diol to C_{28} and C_{30} 1,13-diols.

280 4.2.2 Influence of riverine LCDs

Recently, Lattaud et al. (2017) presented evidence that LCDs delivered by rivers can substantially affect LDI-derived SSTs estimates in coastal regions close to river mouths. In our samples, the LDI-SST underestimated annual SST in the PRE and the near-coastal area with water depth <25 m (Fig. 2, up to –11.0 °C), but was similar to the measured annual SST at some inshore sites with water depth <25 m and all offshore sites (Fig. 2). The river input index (% C_{32} 1,15) was strongly
285 negatively correlated with annual residuals ($R^2 = 0.95$, Fig. 6), and samples, with % C_{32} 1,15 <20 %, have smaller annual residuals ranging between –0.3 °C and 1.2 °C (Fig. 6). After removal of data points ($n = 6$) with % C_{32} 1,15 >20%, indicating significant influence of riverine LCDs, the LDI-SST of the reduced data set had mean absolute values of annual SST residuals of 0.5 °C, nearly half of those of the full data set. This is similar to previous studies that % C_{32} 1,15 in the typical marine sediments generally did not exceed a value of 20 % (Lattaud et al., 2017), which could be proposed as a cut-off for
290 the reliable reconstruction of LDI-SST, and % C_{32} 1,15 above 20 % implies an increased contribution of riverine LCDs.

4.2.3 Seasonality of LDI index

Our results indicated that LDI-SSTs with minimal river influences may reflect annual SSTs (Fig. 2 and Suppl. Table 3-2), suggesting unbiased seasonal production of the source organisms of LDI in this study area. Similar results have been reported by Zhu et al. (2014), who found that LDI-SSTs in downcore sediments matched well with local annual SSTs in the
295 northern SCS. Rampen et al. (2007) found comparable annual flux of 1,15-diols at different stations in the Arabian Sea, and suggested that the biological producers of 1,15-diols do not require a high level of nutrients as needed by, e.g., *Proboscia* diatoms. Thus, LDI may reflect annual SST due to a lack of sensitivity of marine eustigmatophytes to nutrient variations in an annual cycle.

4.3 $\text{TEX}_{86}^{\text{H}}$ and isoprenoid GDGT-derived temperature estimates

300 4.3.1 Sources of iGDGTs in the surface sediments

In marine sediments, the iGDGTs composition may sometimes be impacted with or even controlled by non-thermal factors, e.g., sources of iGDGTs other than Thaumarchaeota (Zhang et al., 2016), and several indices (e.g., the MI and ratios of [2]/[Cren] and [0]/[Cren]) have been developed to assess the impact of these other sources on the iGDGTs distribution.

305 Relatively low MI values (≤ 0.25) were observed at most sites here accompanied by low [2]/[Cren] ratios (0.07–0.15) and [0]/[Cren] ratios (0.42–0.57) (Fig. 4c). These values may suggest little input of methane-related archaeal lipids, which are typically characterized by a high MI value (> 0.3) or substantially elevated [2]/[Cren] and [0]/[Cren] ratios (Weijers et al., 2011; Zhang et al., 2016). The exception was the deep-sea sample (LD-21), which had a slightly higher MI value (0.31), higher [2]/[Cren] ratio of 0.25 and higher [0]/[Cren] ratio of 0.69, which could be associated with archaea involved in methane-cycling. The highest BIT value (0.49) and [0]/[Cren] ratio (0.75) were observed in the PRE (sample PRE-A8) (Fig. 310 4c), similar to the finding of Zhang et al. (2012) and indicating a significant input of soil-derived GDGTs, because BIT index in soils generally tends to be > 0.9 (Hopmans et al., 2004) and [0]/[Cren] ratios in sediments in the lower reaches of the Pearl River and soils in its catchments are also high (2.6) (Wang et al., 2015).

Moreover, slightly different from other iGDGTs, [Cren'] increased clearly with increasing water depth, with the lowest value of 0.8 % found in the PRE (PRE-A8) and ~ 1.0 % close to the PRE (Fig. 4a). This pattern was unlikely caused by soil 315 iGDGTs input, as [Cren'] in the soils in the catchments of the Pearl River is ~ 3 % (Wang et al., 2015). Recently, [Cren'] as low as 0.2–0.7 %, with a mean of 0.4 %, was observed in the SPM of the lower Pearl River, which was attributed to the predominance of Euryarchaeota (Wang et al., 2015; Xie et al., 2014). In contrast, [Cren'] in deep-sea sediments in the SCS is also characterized by higher values > 4 % (Jia et al., 2017).

320 Recently, several studies suggested that tetraether lipids of Thaumarchaeota dwelling in shallow waters are characterized by [2]/[3] ratios < 4 and [Cren'] < 4 %, whereas for “deep-water” Thaumarchaeota lipids are characterized by higher values (Jia et al., 2017; Kim et al., 2015, 2016). It should be noted that it remains unclear what causes the different iGDGTs distribution between those two eco-types, and the depth boundary to separate the two, likely 200–300 m, is not exactly determined (Jia et al., 2017; Kim et al., 2015, 2016). Based on these criteria, only one sample, i.e. the deep-sea sample LD-21 with a [2]/[3] ratio of 7.2 and [Cren'] of 5.4 % (Fig. 4a, 4c), likely received significant contributions from deep Thaumarchaeota. The 325 sample at the second deepest site, i.e. E503 at 186 m, showed a [2]/[3] ratio of 3.6 and [Cren'] of 4.3 % (Fig. 4a, 4c), which suggests only a small contribution from deep Thaumarchaeota.

4.3.2 Seasonality of $\text{TEX}_{86}^{\text{H}}$ index

Based on the above discussion on iGDGTs indices, only two samples, one in the PRE (PRE-A8) and the other in the deep sea (LD-21), were markedly different from the remaining samples that appeared minimally influenced by soil/freshwater-

330 derived archaea and deep-dwelling Thaumarchaeota or methane-cycling archaea. After excluding data from these two samples, we examined the temperature signal of the $\text{TEX}_{86}^{\text{H}}$ index as below.

In the coastal area of northern SCS, $\text{TEX}_{86}^{\text{H}}$ -derived SST in surface sediments and surface water SPM has been found lower than annual SST and hence attributed to winter-biased archaeal production and associated iGDGTs burial (Ge et al., 2013; Wei et al., 2011; Zhang et al., 2012; Zhou et al., 2014). Our $\text{TEX}_{86}^{\text{H}}$ -SST estimates were 0.9–8.8 °C lower than annual SST, 335 similar to previous studies. However, when compared with winter SST, the residuals varied between –4.2 and 2.3 °C, still showing some large negative residuals (Fig. 2).

We note that different from the global dataset utilized to establish the $\text{TEX}_{86}^{\text{H}}$ -SST (i.e. Eq. (8)), which includes a large number of deep-sea sediment samples, our data here were exclusively from shallow sediments receiving iGDGTs predominantly from shallow dwelling Thaumarchaeota. Therefore, we surmise that the global $\text{TEX}_{86}^{\text{H}}$ -SST calibration might 340 not be suitable for our study area, due to that the shallow and deep Thaumarchaeota exhibit slightly different tetraether compositions. Alternatively, a local “shallow water” calibration could be more appropriate for temperature reconstruction in this study. So a recent seasonal calibration based on winter surface water SPM in the SCS (Jia et al., 2017) was applied to our data as a comparison. By applying the equation established from winter SPM ($\text{SST}_{\text{winter}} = 47.18 \times \text{TEX}_{86}^{\text{H}} + 34.44$, $n = 45$, $R^2 = 0.6$) by these authors, we found that winter residuals were greatly reduced, ranging between –1.8 to 2.8 °C (Fig. 7a), 345 with only three samples having residuals ≥ 2.5 °C. Nevertheless, the correlation between $\text{TEX}_{86}^{\text{H}}$ and SST, although better than annual and other seasonal SSTs, was not strong ($R^2 = 0.41$, Fig. 7b). This could be due to other factors such as production in other seasons, or seasonal and spatial community variations in surface water Euryarchaeota, which have been proposed as a significant source of iGDGTs in oceanic settings (Jia et al., 2017; Lincoln et al., 2014; Turich et al., 2007; Wang et al., 2015).

350 4.4 RI-OH and RI-OH-derived temperatures

4.4.1 Source of OH-GDGTs and their influences on RI-OH-SST estimates

A few studies have detected OH-GDGTs in marine, river, lacustrine and soil environments, indicating ubiquitous and multiple sources of OH-GDGTs (Chen et al., 2016; Huguet et al., 2013; Kang et al., 2017; Liu et al., 2012; Park et al., 2019; Wang et al., 2012). Kang et al. (2017) noted that OH-0 dominated in marine and estuarine environments ($56 \pm 10\%$), but OH- 355 2 was abundant in lake, river and soil environments, which may lead to overestimated RI-OH-SSTs in case of substantial terrestrial input. Our results showed that RI-OH-SSTs were warm-biased in the PRE (Fig. 2), where terrestrial input is significant.

In addition to terrestrial influence, RI-OH could respond to SST differently between shallow and deep environments. We combined our data with the published values from surface sediments of the SCS, and found that, with the exception of one 360 sample ($\text{WD} = 41$ m), two clusters of samples can be separated based on $[\text{OH-0}]/[\text{OH-2}]$ ratio, with shallow-water samples ($\text{WD} \leq 186$ m) < 0.55 and deep-water samples ($\text{WD} \geq 330$ m) > 0.55 (Fig. 8a). The shallow-water samples had annual RI-OH-

SST residuals of -2.5 °C to 3.4 °C, but the deep-water samples had a larger range between -8.1 °C and 2.3 °C, implying a different thermal response or winter bias of deep-water RI-OH. Higher correlation ($R^2 = 0.65$) between annual residuals and annual SST were observed for deep-water samples (ca. 26 – 29 °C annual range) compared to those for shallow-water samples (ca. 24 – 27.5 °C annual range, $R^2 = 0.05$) (Fig. 8b), indeed suggesting different thermal responses of distinct archaeal communities. This is supported by an observation of a “concave” relationship between the relative abundance of OH-2 and SST in SCS, which was explained as being due to the different responses of archaeal lipids to ambient temperature depending on whether SST is below or above 25 °C (Yang et al., 2018).

4.4.2 Seasonality of RI-OH-temperature relation in surface sediments

By excluding three samples from the PRE and one sample in the deep sea, we thought OH-GDGTs in the remaining samples could reflect SST in the shallow shelf waters (see section 4.3.1). We found that RI-OH index of the reduced data-set showed a relatively stronger correlation with the annual and winter SSTs ($R^2 = 0.39, 0.44$, respectively, Fig. 9) and poor correlations with other seasonal SST, indicating that RI-OH may reflect winter SST in the coastal SCS. This observation is similar to that for iGDGTs as discussed above (section 4.3.2), suggesting comparable ecology of the source organisms of OH-GDGTs and iGDGTs if they are not even derived from identical organisms. This is likely attributed to favorable conditions for planktonic archaea in winter, although not clearly known, such as relatively high nutrient levels, low light, and high concentrations of SPM in the upper water due to the enhancement of vertical mixing driven by a combination of surface cooling and strong winter monsoon winds (Wong et al., 2015).

However, sedimentary RI-OH has been observed to be more significantly correlated with summer and autumn SSTs than with SSTs from other seasons in the China coastal seas (CCSs), including the northern SCS studied here (Lü et al., 2015). We noted that the SCS is located at the warmest region of CCSs with the smallest seasonal and spatial SST amplitudes, as compared with the higher-latitude seas, e.g., the ECS. The response of RI-OH to SST in such an environment could be different from that for wider SST ranges in larger scale investigations. In other words, local investigations and calibrations are generally preferable for a specific study. Nevertheless, we admit that more studies on OH-GDGTs in various regions are needed for a better assessment of the proxy.

5 Conclusions

Temperature estimates from $U_{37}^{K'}$, LDI, TEX_{86}^H and RI-OH proxies in surface sediments from the northern South China Sea shelf, including the Pearl River Estuary and the coastal area, were compared with annual and seasonal satellite-derived SST (WOA13). $U_{37}^{K'}$ -SST was found to be spring-biased, likely due to the blooming of alkenone source-organisms in late spring, when river runoff, as well as the abundant terrestrial nutrients, are highest. The results also showed that terrestrial inputs have an appreciable impact on LDI, TEX_{86}^H and RI-OH proxies and lead to cold-biased (LDI and TEX_{86}^H) or warm-biased (RI-OH) temperature relative to SSTs. After excluding from the data set the samples subject to terrestrial input, these indices

exhibited different seasonal variabilities, which reflect distinctive ecologies of their source organisms as results of seasonal changes in environmental conditions. LDI-SST matched well with annual SSTs, possibly related with the insensitivity of marine eustigmatophytes to nutrient variations in an annual cycle. For the $\text{TEX}_{86}^{\text{H}}$ proxy, a local “shallow water” calibration based on winter surface water SPM in the SCS appeared more appropriate for temperature reconstruction in this study and greatly reduced winter residuals. Similar to the $\text{TEX}_{86}^{\text{H}}$, RI-OH seems to reflect winter SST, and hence indicates comparable ecology of the source organisms of OH-GDGTs and iGDGTs if they are not identical. The winter biased $\text{TEX}_{86}^{\text{H}}$ and RI-OH proxies can likely be attributed to favorable conditions for planktonic archaea in winter, impacted by the enhancement of local vertical seawater mixing.

Table 1: Pearson correlation analysis of different diols in surface sediments in this study.

Pearson correlation coefficient	C ₂₈ 1,13-diol	C ₃₀ 1,13-diol	C ₃₀ 1,15-diol	C ₃₂ 1,15-diol
C ₂₈ 1,13-diol	1			
C ₃₀ 1,13-diol	0.83**	1		
C ₃₀ 1,15-diol	−0.68**	−0.90**	1	
C ₃₂ 1,15-diol	0.56**	0.78**	−0.90**	1

605 ** P-value < 0.005

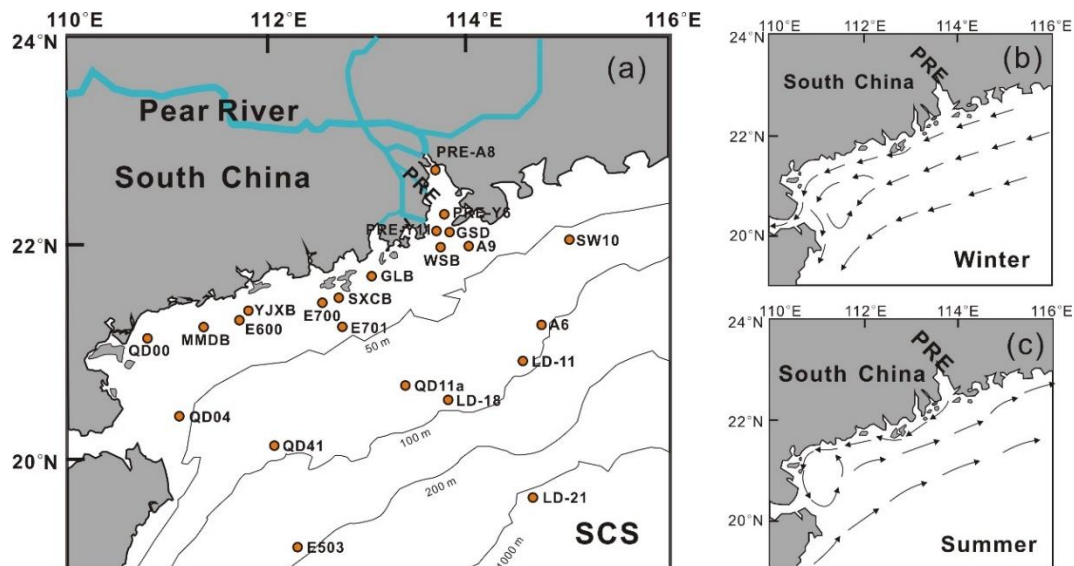

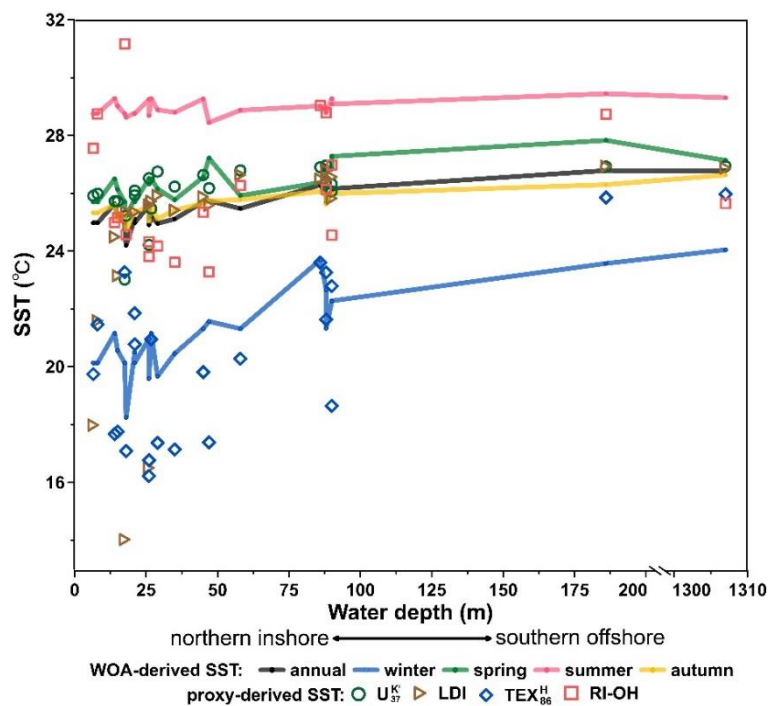

Figure 1: (a) Sampling sites and patterns of the surface coastal currents in (b) winter and (c) summer, respectively (modified from Liu et al. (2014)).

610 Figure 2: Changes with water depth of WOA-derived and proxy-derived SSTs.

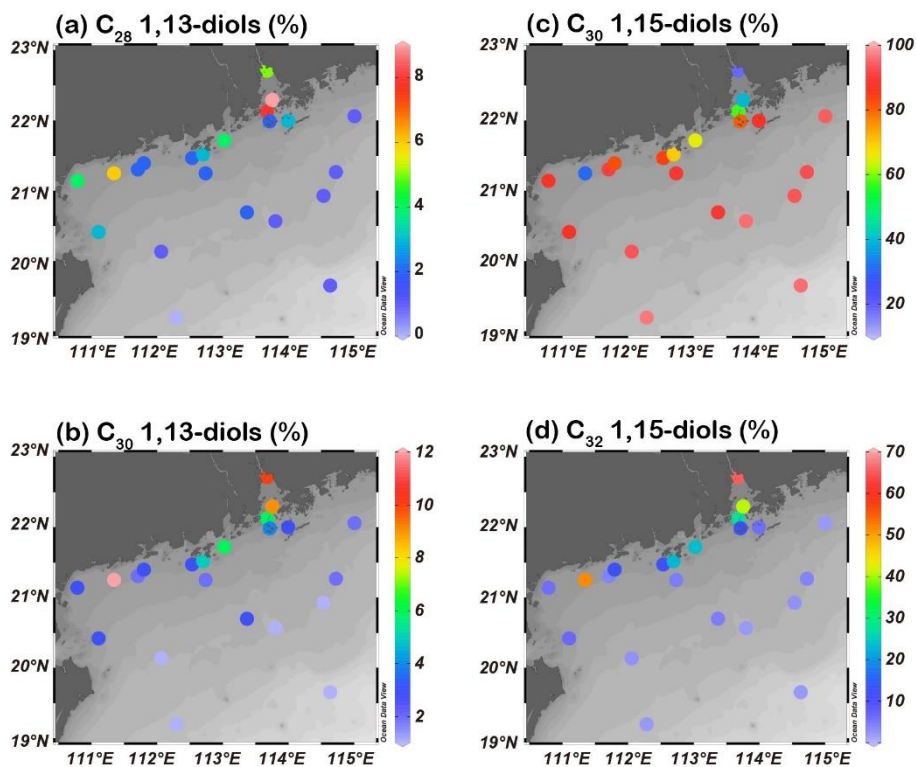

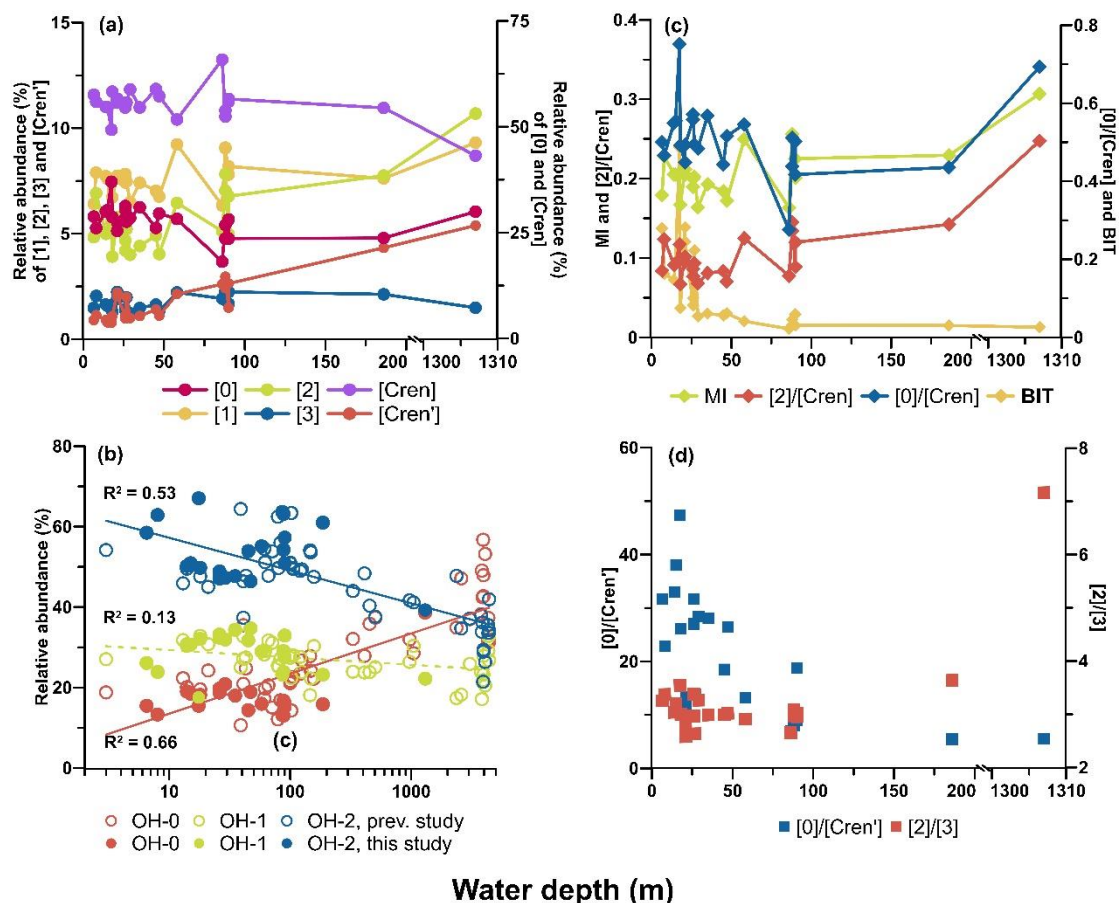

Figure 3: Distribution of relative abundances of: (a) C₂₈ 1,13-diol, (b) C₃₀ 1,13-diol, (c) C₃₀ 1,15-diol, and (d) C₃₂ 1,15-diol.

615 **Figure 4: Depth profiles of (a) the relative abundance of individual iGDGTs, (b) the relative abundance of individual OH-GDGTs (open dots represent data from Lü et al., 2015 and Yang et al., 2018, and solid dots represent data from this study), (c) MI and BIT index values, as well as [0]/[Cren] and [2]/[Cren] ratios, and (d) [0]/[Cren'] and [2]/[3] ratios.**

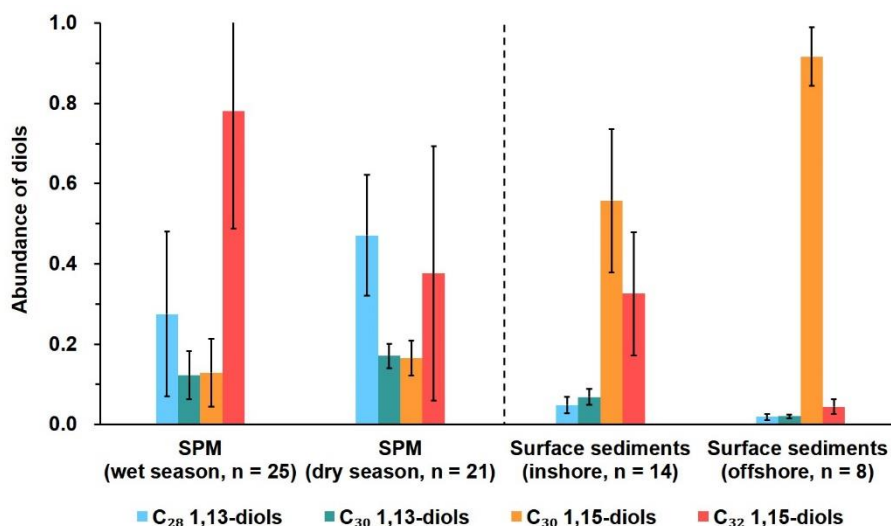

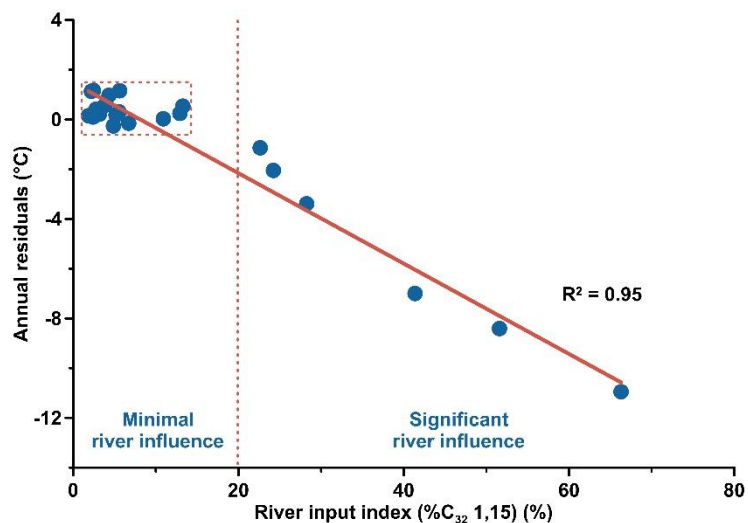

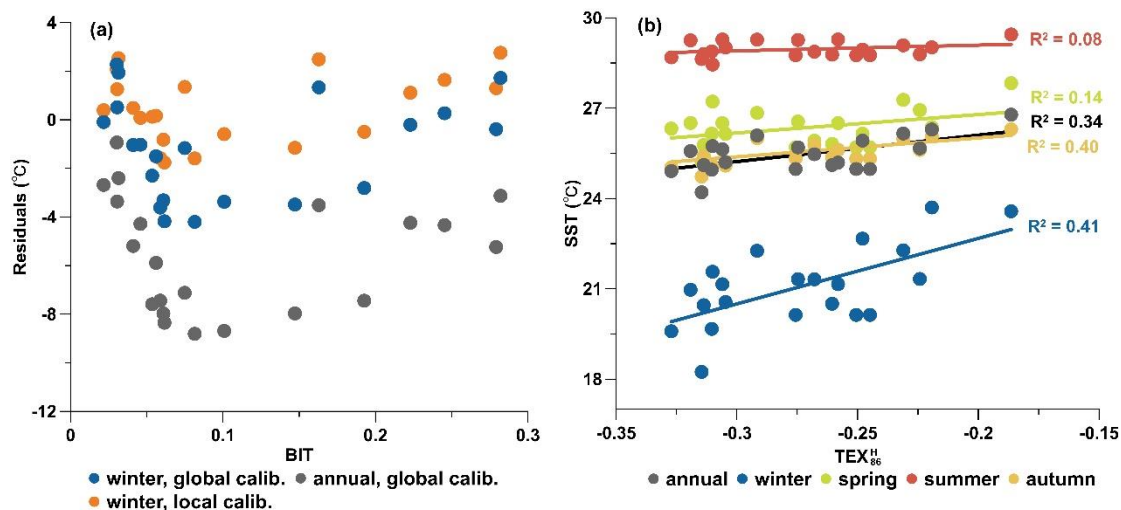

Figure 5: Average diol distributions in SPM in the PRE (data from Zhu et al. (2018)), inshore and offshore surface sediments (data from this study) (Error bars indicate the standard deviations).

620

Figure 6: Annual SST residuals with %C₃₂ 1,15 diol suggestive of river input.

625

Figure 7: (a) Residual changes with BIT values of the annual and winter estimates based on the global calibration (Kim et al., 2010) and winter residuals based on the local calibration from winter SPM (Jia et al., 2017), and (b) relationships of TEX₈₆^H with annual and seasonal SSTs.

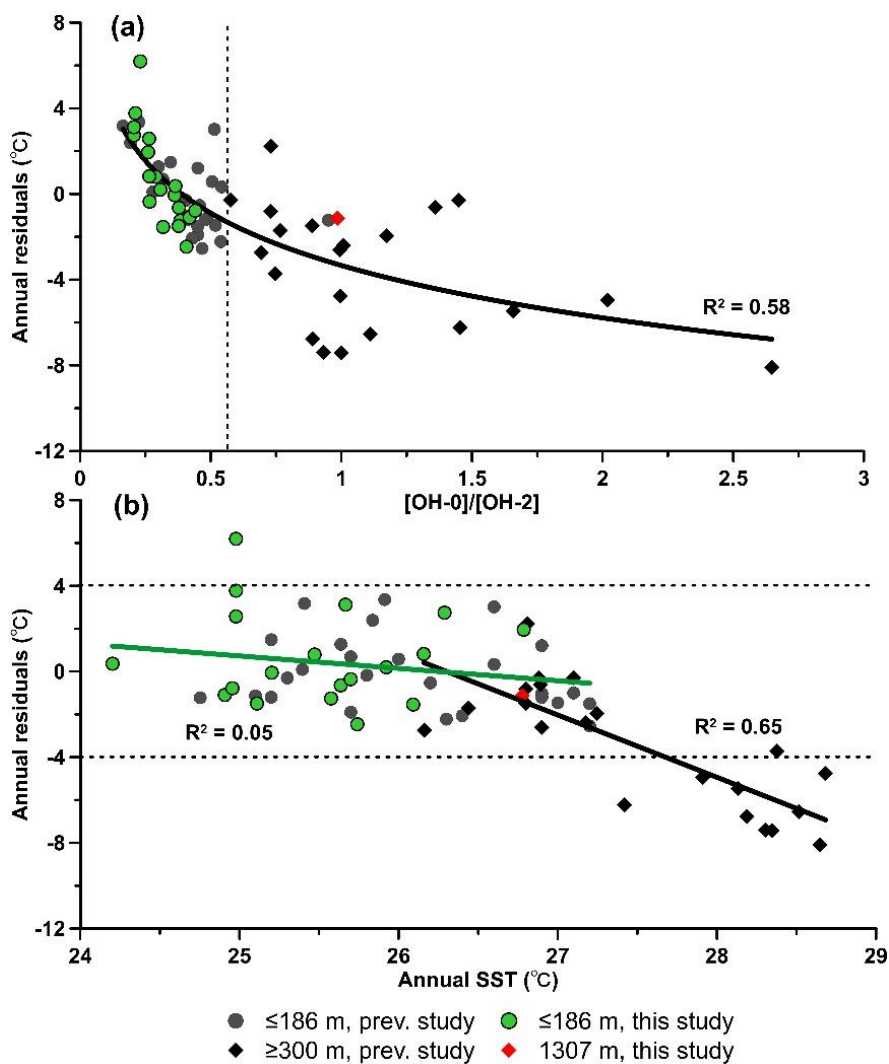

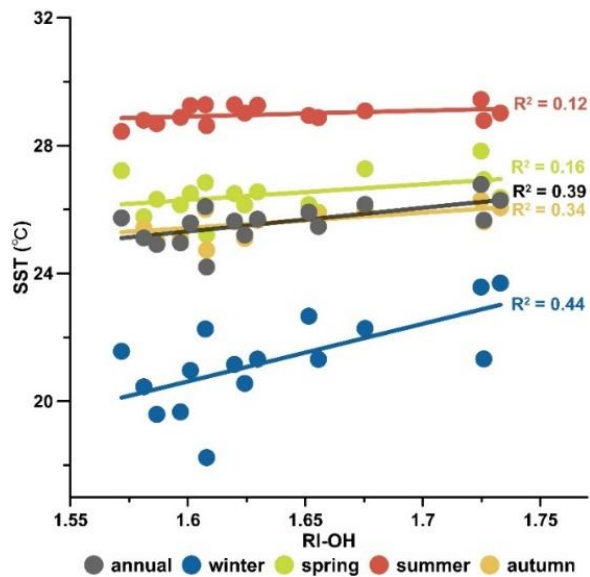

Figure 8: Changes of annual residuals with (a) $[OH-0]/[OH-2]$ ratios (solid line is a fitting line), and (b) annual SST (green and black solid lines are fitting lines for “shallow water” and “deep water” samples, respectively).

630 Figure 9: Correlation plots of RI-OH with annual and seasonal SST (solid lines are linear fitting lines).
