9

10 The Bay of Bengal (BoB) has long stood as a biogeochemical enigma with subsurface waters containing  
11 extremely low, but persistent, concentrations of oxygen in the nanomolar range which -for some, yet  
12 unconstrained reason- are prevented from becoming anoxic. One reason for this may be the low productivity  
13 of the BoB waters due to nutrient limitation, and the resulting lack of respiration of organic material at  
14 intermediate waters. Thus, the parameters determining primary production are key to understanding what  
15 prevents the BoB from developing anoxia. Primary productivity in the sunlit surface layers of tropical oceans  
16 is mostly limited by the supply of reactive nitrogen through upwelling, riverine flux, atmospheric deposition,  
17 and biological dinitrogen (N<sub>2</sub>) fixation. In the BoB, a stable stratification limits nutrient supply via upwelling  
18 in the open waters, and riverine or atmospheric fluxes have been shown to support only less than one quarter  
19 of the nitrogen for primary production. This leaves a large uncertainty for most of the BoB's nitrogen input,  
20 suggesting a potential role of N<sub>2</sub> fixation in those waters.

21 Here, we present a survey of N<sub>2</sub> fixation and carbon fixation in the BoB during the winter monsoon season.  
22 We detected a community of N<sub>2</sub> fixers comparable to other oxygen minimum zone (OMZ) regions, with only  
23 a few cyanobacterial clades and a broad diversity of non-phototrophic N<sub>2</sub> fixers present throughout the water  
24 column (samples collected between 10 m and 560 m water depth). While similar communities of N<sub>2</sub> fixers  
25 were shown to actively fix N<sub>2</sub> in other OMZs, N<sub>2</sub> fixation rates were below the detection limit in our samples  
26 covering the water column between the deep chlorophyll maximum and the OMZ. Consistent with this, no  
27 N<sub>2</sub> fixation signal was visible in  $\delta^{15}\text{N}$  signatures. We suggest that the absence of N<sub>2</sub> fixation may be a  
28 consequence of a micronutrient limitation or of an O<sub>2</sub> sensitivity of the OMZ diazotrophs in the BoB. To  
29 explore how the onset of N<sub>2</sub> fixation by cyanobacteria compared to non-phototrophic N<sub>2</sub> fixers would impact  
30 on OMZ O<sub>2</sub> concentrations, a simple model exercise was carried out. We observed that both, photic zone-  
31 based and OMZ-based N<sub>2</sub> fixation are very sensitive to even minimal changes in water column stratification,

32 with stronger mixing increasing organic matter production and export, which would exhaust remaining O<sub>2</sub>  
33 traces in the BoB.

#### 34 **Introduction**

35 Primary production in large areas of the surface ocean is limited by the availability of fixed nitrogen (Moore  
36 et al., 2013). This deficiency in nitrogen creates a niche for dinitrogen (N<sub>2</sub>) fixation, an energy-costly process  
37 carried out only by certain prokaryotes, also referred to as diazotrophs, which are phylogenetically highly  
38 diverse. N<sub>2</sub> fixation in the ocean has been described quantitatively as most important in the oligotrophic  
39 surface waters of the subtropical gyres (Sohm et al., 2011;Luo et al., 2012;Wang et al., 2019) where  
40 cyanobacterial N<sub>2</sub> fixers dominate. Over the last decade, the development of novel molecular tools revealed  
41 that non-cyanobacterial N<sub>2</sub> fixers are widely distributed throughout ocean waters (Farnelid et al.,  
42 2011;Farnelid et al., 2013;Fernandez et al., 2011;Luo et al., 2012;Riemann et al., 2010;Zehr et al., 1998) and  
43 sediments (Fulweiler et al., 2007;Andersson et al., 2014;Bertics et al., 2013;Gier et al., 2017;Gier et al., 2016).  
44 Their quantitative importance for global N<sub>2</sub> fixation, however, is not yet clear. In OMZs of the eastern tropical  
45 North and South Pacific Ocean, hypoxic basins in the Californian Bay and the Arabian Sea, those N<sub>2</sub> fixers  
46 form a unique community consisting of different clades of proteobacteria, clostridia, spirochaetes, chlorobia,  
47 and methanogenic archaea (Christiansen and Loescher, 2019;Dekaezemacker et al., 2013;Fernandez et al.,  
48 2011;Gaby et al., 2018;Gier et al., 2017;Goebel et al., 2010;Halm et al., 2012;Hamersley et al.,  
49 2011;Jayakumar et al., 2012;Jayakumar et al., 2017;Löscher et al., 2014). In contrast, cyanobacterial N<sub>2</sub> fixers  
50 and diatom-diazotroph-associations (DDAs), which are commonly considered the most important N<sub>2</sub> fixers in  
51 the surface ocean, were either absent or were detected only in low abundances in OMZs (Turk-Kubo et al.,  
52 2014;White et al., 2013;Jayakumar et al., 2012). Both, the presence of diazotrophs clustering with  
53 proteobacteria, clostridia, spirochaetes, chlorobia, and methanogenic archaea, and the underrepresentation  
54 of cyanobacterial and DDA N<sub>2</sub> fixers could thus be considered characteristic for OMZ environments.

55 Nutrient stoichiometry and model predictions (Deutsch et al., 2007) suggest that oxygen-deficient waters are  
56 a potentially important niche for N<sub>2</sub> fixation. Based on this suggestion, several studies have focused on N<sub>2</sub>  
57 fixation in the large and persistent OMZ of the eastern tropical South Pacific. In this region N<sub>2</sub> fixation rates  
58 vary, however, with maximum rates of 840  $\mu\text{mol N m}^{-2}\text{d}^{-1}$  detected in nitrogenous sulfidic waters off the  
59 coast of Peru (Löscher et al., 2014), and 117  $\mu\text{mol N m}^{-2}\text{d}^{-1}$  in the oxygen-depleted zone (Bonnet et al., 2013).  
60 Low N<sub>2</sub> fixation rates close to the detection limit were reported from the same area (Chang et al., 2019),  
61 another set of N<sub>2</sub> fixation rates estimated from sediment trap analyses were in the range of 0-23  $\mu\text{mol N}$   
62  $\text{m}^{-2}\text{d}^{-1}$  (Knapp et al., 2016). Taken together, these rates suggest either a strong temporal variation or spatial  
63 patchiness. A similar variation in N<sub>2</sub> fixation rates was described for the eastern tropical North Pacific ranging

64 from close to the detection limit in the OMZ (Jayakumar et al., 2017) up to 795  $\mu\text{mol N m}^{-2}\text{d}^{-1}$  in episodic  
65 diazotroph blooms (White et al., 2013). This apparent temporal or spatial variation in  $\text{N}_2$  fixation rates may  
66 originate from unresolved environmental controls on  $\text{N}_2$  fixation and makes it difficult to quantify  $\text{N}_2$  fixation  
67 in OMZ waters.

68 The Bay of Bengal (BoB) is a region with a strong seasonality driven by the Asian monsoon system. Massive  
69 rainfall and river discharge with maximum freshwater inputs in September (e.g. Mahadevan (2016)) cause a  
70 considerable lowering of surface water salinity during and after the monsoons throughout the whole basin  
71 (Subramanian, 1993). This, together with increased surface water temperatures, leads to intensive and  
72 persistent stratification of the water column (Kumar et al., 2004), restricting nutrient fluxes to the surface  
73 from below and promoting a strong OMZ (McCreary et al., 2013; Paulmier and Ruiz-Pinto, 2009; Sarma, 2002)  
74 with minimum oxygen ( $\text{O}_2$ ) concentrations in the lower nanomolar range (Bristow et al., 2017).

75 The potential importance of  $\text{N}_2$  fixation in the BoB can be derived from a simple N budget estimate with an  
76 overall N loss of  $7.9 \pm 0.6 \text{ Tg N yr}^{-1}$  and N sources other than  $\text{N}_2$  fixation of  $3.15 \pm 2.25 \text{ Tg N yr}^{-1}$  (Tab. 1, data  
77 from (Naqvi, 2008; Naqvi et al., 2010; Bristow et al., 2017; Singh et al., 2012; Krishna et al., 2016; Srinivas and  
78 Sarin, 2013; Suntharalingam et al., 2019)). This implies a deficit of  $4.7 \pm 2.4 \text{ Tg N yr}^{-1}$  within the given range of  
79 uncertainty indicating the potential importance of  $\text{N}_2$  fixation assuming a coupling of nitrogen loss and  $\text{N}_2$   
80 fixation as proposed by (Deutsch et al., 2007). Naqvi et al. (2010) proposed  $\text{N}_2$  fixation to contribute  $1 \text{ Tg N}$   
81  $\text{yr}^{-1}$  in the BoB, while Srinivas and Sarin (2013) interpolated a contribution of 0.6-  $4 \text{ Tg N yr}^{-1}$  from phosphate  
82 availability. Measurements of  $\text{N}_2$  fixation rates from the BoB are not available, isotope analysis of sediment  
83 trap samples indeed suggests that the BoB is a site of active  $\text{N}_2$  fixation. Indeed, the composition of the  
84 organic material produced in BoB surface waters is characterized by a high portion of biogenic opal (20%)  
85 and a low  $\delta^{15}\text{N}$  nitrate signal (3.2 - 5‰, Gaye-Haake et al. (2005)). This points towards a production of a  
86 considerable part of organic matter produced by diatoms in symbiotic association with or in close proximity  
87 to diazotrophs (Subramaniam et al., 2008). Only few studies report the presence of diazotrophs including  
88 *Trichodesmium* in the BoB (Wu et al., 2019; Shetye et al., 2013; Sahu et al., 2017; Jyothibabu et al.,  
89 2006; Mulholland and Capone, 2009), with only one of them using a functional gene approach.

90 To investigate the diazotrophic community and to quantify  $\text{N}_2$  and carbon fixation in the BoB OMZ, we used  
91 a combination of gene sequencing and quantification, rate measurements, isotope tracing and box modeling.

92

## 93 **Methods**

94 Geochemical sampling

95 Samples were collected from the top 500 m of the water column during the SK-308 cruise with the ORV *Sagar*  
96 *Kanya* to the BoB during the winter monsoon between 24 January and 3 February 2014. Seawater samples  
97 were collected using 5 L and 30 L-Niskin bottles on a CTD- rosette equipped with a Seabird SBE 43 oxygen  
98 sensor and a WET Labs ECO-AFL/FL chlorophyll sensor as previously described in Bristow et al. (2017). To  
99 resolve oxygen dynamics below the Seabird sensor's detection limit a STOX (Switchable Trace amount  
100 OXYgen) amperometric oxygen sensor was used (Revsbech et al., 2009), which had a detection limit of 7 –  
101 12 nmol L<sup>-1</sup> during this sampling campaign (Bristow et al., 2017). Nutrients, including nitrate, nitrite and  
102 phosphate were determined according to Grasshoff (1999).

103

104 N<sub>2</sub>/C-fixation rate measurements

105 Seawater was collected from depth between 60 and 280 m water depth. Water was taken from Niskin bottles  
106 and filled into 2.4-L glass bottles or 2.8-L polycarbonate bottles for (near-) anoxic and all other (oxic) waters,  
107 respectively. Bottles were capped with black rubber stoppers (anoxic waters) or Teflon-coated butyl rubber  
108 septa (oxic waters). Incubations were performed with the method developed by Mohr et al. (2010) as  
109 described in (Grosskopf et al., 2012). Batches of <sup>15</sup>N<sub>2</sub> gas (Cambridge Isotopes, USA) –enriched water was  
110 prepared with degassed water from two – three of the six sampling depths. Each incubation bottle was  
111 supplemented with 50 mL of the <sup>15</sup>N<sub>2</sub>-enriched seawater. Discrete samples for the measurement of the <sup>15</sup>N<sub>2</sub>  
112 concentration were taken from each incubation bottle and were measured by membrane-inlet mass  
113 spectrometry (MIMS). Final <sup>15</sup>N<sub>2</sub> enrichments were on average 1.65 atom % <sup>15</sup>N. For carbon fixation  
114 measurements, NaH<sup>13</sup>CO<sub>3</sub> was dissolved in sterile MilliQ water (1g/117mL), and 5 mL were added to each  
115 incubation (~8 atom% final, based on total DIC of 2.2 mM). Bottles with water from the upper two depths  
116 were kept in surface seawater-cooled on-deck incubators. Bottles from the lower depths were incubated at  
117 13-15°C in the dark. Incubations were stopped after approximately 24 h (samples with less than 20h  
118 incubation time were excluded from our analysis). Volumes between 2.1 and 2.7 L of seawater were filtered  
119 onto pre-combusted (450°C, 4-6 hours) 25 mm diameter GF/F filters (Whatman, GE Healthcare, Chalfont St  
120 Gile, UK) under gentle vacuum (200 mbar). Filters were either frozen at -20°C and oven-dried prior to  
121 processing or oven-dried (50°C) directly for 24 h and stored dry until analysis. Untreated seawater was  
122 filtered and prepared as described above to obtain background natural abundance values. For elemental and  
123 isotopic analysis, GF/F filters were acidified over fuming HCl overnight in a desiccator to remove inorganic C.  
124 Filters were then oven-dried for 2 hours at 50°C and pelletized in tin cups. Samples for particulate organic  
125 carbon and nitrogen (POC and PON) and C and N isotopic composition were analyzed on an Elemental

126 Analyzer Flash EA 1112 series (Thermo Fisher) coupled to a continuous-flow isotope ratio mass spectrometer  
127 (Finnigan Delta Plus XP, Thermo Fisher). Table 2 summarizes N<sub>2</sub> and C fixation rate measurements is given in  
128 the supplementary material. Data sets were deposited on PANGAEA.

129

#### 130 Molecular methods

131 Nucleic acid samples were collected at stations 1, 4 and 5 (Fig. 1) from water depths between 10 and 560 m.  
132 Between 5 and 27 L of seawater were filtered in two size fractions (3 µm and 0.22 µm pore size, Supor PES  
133 membrane disc filters; Pall, Portsmouth, UK), exact filtration volumes were recorded. Filters were stored in  
134 2.7 mL sucrose lysis buffer at -20 °C.

135 DNA was extracted using an established protocol based on a phenol/chloroform extraction (Giovannoni et  
136 al., 1996). The quality and concentration of the purified DNA was checked spectrophotometrically and using  
137 the Quant-iT PicoGreen dsDNA kit (Invitrogen, Carlsbad, USA).

138 A metagenome from the deep chlorophyll maximum (DCM, 84m water depth) at station 4 was Illumina HiSeq-  
139 sequenced using a 2x125bp read length on a NexteraXT library at the Institute for Clinical Microbiology  
140 (IKMB) at Kiel University, Germany. Sequencing resulted in 321Mbp. Sequences were analyzed using the  
141 MetPathways pipeline (Konwar et al., 2013), a modular annotation and analysis pipeline for predicting  
142 diversity and metabolic interaction from environmental sequences consisting of a quality control, an open  
143 reading frame prediction and annotation, diversity analysis, and environmental pathway reconstruction.  
144 Phylogenetic identification of OTUs was derived via a comparison with the RefSeq and Greengenes databases  
145 (DeSantis et al., 2006). After quality check, 6,454 sequences of ribosomal RNA were identified, 622,286  
146 sequences (27.56%) of proteins with known functions, and 1,628,841 sequences (72.15%) were predicted  
147 proteins with unknown function.

148 *nifH* gene amplification was performed using a nested PCR protocol (Zehr et al., 1998). PCRs were performed  
149 using the GoTaq kit (Promega, Fitchburg, USA) adding one additional µL BSA (20 mg mL<sup>-1</sup> (Fermentas,  
150 Waltham, USA). The TopoTA Cloning® Kit (Invitrogen, Carlsbad, USA) was used for cloning of PCR amplicons,  
151 according to the manufacturer's protocol. Sanger sequencing (340 *nifH* sequences) was performed by the  
152 Institute of Clinical Molecular Biology, Kiel, Germany. Negative controls were performed using the PCR  
153 mixture as described without template DNA; no amplification was detected. Samples from the particulate  
154 fraction >3 µm were consistently negative for *nifH* gene copies and were thus not further investigated.  
155 Sequences were ClustalW aligned in MEGA 7 (Kumar et al., 2016) and a maximum likelihood tree was  
156 constructed on a 321 base pair fragment. Reference sequences were obtained using BlastX on the NCBI

157 database. Sequences were submitted to Genbank, submission ID 2245434. The metagenome has been  
158 submitted to the NCBI's sequence read archive, accession number SRR9696254.

159 Quantitative real time PCRs for *nifH* were performed using cluster specific TaqMan-probe qPCRS as described  
160 in Löscher et al (2014), with primers, probes, environmental standards and PCR conditions as presented in  
161 there. Samples were run in duplicates on a Biorad qPCR machine (Biorad, Hercules, USA).

162

163 Box model exercise

164 We used a simplistic five-box representation of an upwelling system with a deep and intermediate water iron  
165 source, with primary and export production as well as respiration derived from the original models (Canfield,  
166 2006;Boyle et al., 2013). The model was used to distinguish a N<sub>2</sub> fixation state of the BoB and a non-N<sub>2</sub> fixation  
167 state with primary production driven by recycled dissolved nitrogen compounds. In contrast to the previous  
168 model versions, we applied a non- Redfield-based N<sub>2</sub> fixation scenario. Ammonia concentrations were set to  
169 zero in all boxes, in accordance with our direct measurements. Fe concentrations were set to 0.1 μmol L<sup>-1</sup> in  
170 the deep and intermediate water boxes and 0.00044 μmol L<sup>-1</sup> in the productive zone (Grand et al.,  
171 2015a;Grand et al., 2015b). Oxygen concentrations were adjusted to our measurements with 220, 0.02 and  
172 50 μmol L<sup>-1</sup> in the surface (corresponding to the upper 60 m of the water column), OMZ and deep water,  
173 respectively (Bristow et al., 2017). Phosphate and nitrate concentrations were taken from our measurements  
174 with phosphate concentrations of 0, 2.7 and 2.5 μmol L<sup>-1</sup> in the surface, OMZ and deep boxes, respectively;  
175 and oxidized nitrogen compounds (nitrate+ nitrite) at a concentration of 0, 38 and 35 μmol L<sup>-1</sup> in the surface,  
176 intermediate and deep boxes, respectively. Further information on the model stoichiometry is given in the  
177 supplementary material.

178

## 179 **Results and discussion**

180 We explored the diversity, distribution and activity of N<sub>2</sub> fixing microbes and carbon fixers in the OMZ of the  
181 northern BoB during the Northeast monsoon in January 2014. During the time of the cruise, low sea surface  
182 temperatures (SST; surface waters refer to water depths shallower than the mixed layer depth of 60 m) and  
183 low surface water salinity reaching from the coasts of India, Bangladesh and Myanmar southwards to  
184 approximately 16°N were present (Figure 1A, B). At the coast, this low salinity/low SST plume co-occurred  
185 with increased chlorophyll concentrations (Fig 1C), thus suggesting a stimulation of primary production by  
186 waters possibly of riverine origin (Fig 1C). This is in line with earlier suggestions of riverine nutrient runoff  
187 promoting primary production close to the shelf, where nutrients are consumed rapidly thus preventing their  
188 offshore transport (Kumar et al., 2004;Singh et al., 2012;Singh and Ramesh, 2011;Krishna et al., 2016).

189 Chlorophyll concentrations in the BoB during the time of the cruise detected via satellite monitoring ranged  
190 between 0.08 mg m<sup>-3</sup> in open waters and 15 mg m<sup>-3</sup> at the northern coast and were consistent with previous  
191 in-situ measurements during low productivity periods in the BoB (Kumar et al., 2010).

192 The sampling stations were located offshore in the central BoB (Fig. 1), where waters were strongly stratified  
193 with low sea surface salinity, but warmer SST compared to the coast, and a steep oxycline reaching O<sub>2</sub>  
194 concentrations close to anoxia at around 100 m water depth. No in-situ chlorophyll measurements are  
195 available from the cruise, but a fluorescence sensor attached to the CTD showed a maximum of up to 0.8 mg  
196 m<sup>-3</sup> between 32-90 m water depth (Fig. 2). Satellite derived chlorophyll concentrations in the coastal BoB  
197 were in the range from 0.08 to 0.35 mg m<sup>-3</sup>, slightly higher than in a previous study of this region (0.06 mg m<sup>-3</sup>  
198 <sup>3</sup>, Kumar et al. (2002)). Carbon fixation rates ranged between 286-1855 nmol C L<sup>-1</sup> d<sup>-1</sup> at the depth of the DCM  
199 (Fig. 2, 84 m), however, our rate measurements did not cover the water column above 60 m water depth  
200 where rates may have been higher. Consistent with previous descriptions of primary producers at our study  
201 site (Loisel et al., 2013) and with satellite imaging (Fig. S1), we identified cyanobacteria related to  
202 *Synechococcus* and *Prochlorococcus* as the most abundant primary producers in the in our metagenome from  
203 the BoB DCM, accounting for 3.3% of OTUs while eukaryotic phytoplankton accounted for only 0.3% of OTUs  
204 (Table S1).

205 Similar to chlorophyll, particulate organic carbon (POC, Tab. S2; see also Fig. S2 for a distribution of POC in  
206 the BoB) concentrations were low, ranging between 4.96 and 7.84 μmol C L<sup>-1</sup> in surface waters, and resulting  
207 in an average POC:chlorophyll ratio of 68:1 to 115:1 at the depth of the DCM (Fig. 1). This ratio, is comparable  
208 to POC:chlorophyll ratios reported from cyanobacteria-dominated communities (74:1–126:1; e.g., (Lorenzoni  
209 et al., 2015; Sathyendranath et al., 2009)), but it is higher compared to other OMZ regions (e.g. 50:1 in the  
210 eastern tropical South Pacific (Chavez and Messié, 2009; Chavez et al., 1996)). Similarly, carbon fixation rates  
211 were 1-2 orders of magnitude lower compared to the Arabian Sea, the tropical South Pacific and tropical  
212 Atlantic (e.g. Longhurst et al. (1995)). While our POC concentrations from DCM are one order of magnitude  
213 higher than the satellite-derived POC estimates (Fig. S2) from surface waters indicating that POC and primary  
214 production in surface waters was not higher than in the DCM, it must be noted that our measurements did  
215 not cover the entire mixed layer and are thus likely a rather conservative minimum estimate.

216 N<sub>2</sub> fixation in the upper water column and the oxycline

217 Based on the dissolved inorganic nitrogen (NO<sub>3</sub><sup>-</sup> + NO<sub>2</sub><sup>-</sup>) to phosphate (PO<sub>4</sub><sup>3-</sup>) ratio which has a negative  
218 intercept with the y-axis (Fig. 3; Benitez-Nelson (2000)), primary production in BoB waters appeared nitrogen

219 limited during the cruise assuming Redfield stoichiometry. This nitrogen limitation would be expected to  
220 create a niche for N<sub>2</sub> fixation, but except for two samples for which in both cases only one out of three  
221 technical replicates showed an isotope enrichment, N<sub>2</sub> fixation rates were below the detection limit (Tab. 2).  
222 In this context, it is important to note that our rate measurements only cover water depths between 60 and  
223 280 m, thus excluding the upper part of the euphotic zone. However, the absence of N<sub>2</sub> fixation even in  
224 waters shallower than 60 m is consistent with the observed  $\delta^{15}\text{N}$  signatures (data available from 3 to 2300 m  
225 water depth, Bristow et al. (2017)) of both the nitrate and the particulate organic nitrogen (PON) pool.  $\delta^{15}\text{N}$   
226 signatures were only slightly decreased in the top 100 m of the water column to 5-8‰ (Fig. S3), thus not  
227 speaking for the presence of active N<sub>2</sub> fixation which would be expected to create substantially lighter  $\delta^{15}\text{N}$   
228 signatures of -2- 2‰ (e.g. Dähnke and Thamdrup (2013)). Several clusters of N<sub>2</sub> fixing microbes were,  
229 however, identified by screening for the key functional marker gene *nifH* (Fig. 4). Only a few *nifH* sequences  
230 were associated with cyanobacteria commonly abundant in ocean surface waters, even in the euphotic zone  
231 at 10 m water depth. This pattern seems to be typical for OMZ areas (Fernandez et al., 2011; Jayakumar et  
232 al., 2012; Löscher et al., 2014) and for the eastern Indian Ocean (Wu et al., 2019), where cyanobacterial *nifH*  
233 sequences are also rare. Similar to earlier studies, which identified *Trichodesmium* in BoB surface waters  
234 (Bhaskar et al., 2007; Hegde, 2010; Wu et al., 2019), we detected *nifH* copies related to *Trichodesmium* in our  
235 samples, both by sequencing and by qPCR (Fig. 4, Tab. S3). These sequences clustered closely to  
236 *Trichodesmium-nifH* previously recovered from the Arabian Sea (Jayakumar et al., 2012; Mazard et al., 2004),  
237 where those N<sub>2</sub> fixers were found in low abundances, but possibly actively fixing N<sub>2</sub> as indicated by *nifH*  
238 presence in a cDNA library. No sequences related to the different groups of unicellular cyanobacterial  
239 diazotrophs (UCYN-A, -B, or -C; Zehr et al. (2001)) were present in our *nifH* dataset. UCYN-A and UCYN-B  
240 have previously been found in the Arabian Sea, but only at oligotrophic stations with warm water  
241 temperatures >30°C (Mazard et al., 2004). While UCYN-A may occur at temperatures below 25°C,  
242 *Trichodesmium* and UCYN-B may be limited by the water temperatures at our sampling stations, which were  
243 possibly too low with around 25°C. *Trichodesmium* is usually abundant in high-iron input regions such as the  
244 tropical Atlantic Ocean (Martínez-Pérez et al., 2016). The absence of *Trichodesmium* and other cyanobacterial  
245 N<sub>2</sub> fixers may thus also result from an insufficient iron source (Moore et al., 2013). Additionally, light  
246 limitation due to severe atmospheric pollution (known as the 'South Asian Brown Cloud') which lasts over  
247 the BoB from November to May (e.g. Ramanathan et al. (2007)) may influence the distribution of  
248 cyanobacteria in the BoB (Kumar et al., 2010). While earlier studies also detected *Chaetoceros* (Bhaskar et  
249 al., 2007; Hegde, 2010; Wu et al., 2019), a diatom known to live in association with diazotrophs, no diatom-  
250 associated N<sub>2</sub> fixers could be identified from our sequences. Thus our data does not directly support previous

251 suggestions of those specific diazotrophs producing low  $\delta^{15}\text{N}$  nitrate signatures along with high opal  
252 concentrations previously detected in sediment trap samples (Gaye-Haake et al., 2005).

253

254  $\text{N}_2$  fixation in the OMZ

255 In the cruise area, we detected again the genetic potential for  $\text{N}_2$  fixation, but  $\text{N}_2$  fixation rates were below  
256 the detection limit and  $\delta^{15}\text{N}$  signatures of nitrate and PON indicated nitrogen loss instead of  $\text{N}_2$  fixation (Fig.  
257 S3). The community of  $\text{N}_2$  fixers in the BoB consisted mostly of the non-phototrophic, proteobacterial  
258 representatives of *nifH*- clusters I and III (Fig. 4), most of them related to previously identified OMZ  
259 diazotrophs (Fernandez et al., 2011; Jayakumar et al., 2012; Löscher et al., 2014).

260 A statistical comparison of BoB *nifH* sequences with OMZ diazotroph communities from the Arabian Sea, the  
261 ETSP, ETNP and hypoxic basins in California Bay revealed a strong similarity suggesting that certain  
262 diazotrophs are characteristic for OMZs (Fig. 5). Those typical OMZ-clusters include uncultured  $\gamma$ -,  $\delta$ - and  $\epsilon$ -  
263 proteobacteria and clostridia. Only one cluster was uniquely represented in the BoB and absent from the  
264 other OMZ datasets, with only three individual sequences related to *Azotobacter chroococum*. Another  
265 difference between the BoB and in the other OMZ diazotroph communities was the composition of Cluster  
266 IV *nifH* sequences, which are present but cluster in different groups as compared to for instance the Arabian  
267 Sea Cluster IV community. It is, however, unlikely that Cluster IV diazotrophs are important for  $\text{N}_2$  fixation in  
268 the BoB or other OMZs because they were never shown to be transcribed (Fernandez et al., 2011; Jayakumar  
269 et al., 2012; Löscher et al., 2014) and Cluster IV-*nif* is generally considered to encode non-functional *nif* or  
270 paralogous sequences (Gaby and Buckley, 2014; Angel et al., 2018). In addition, the presence of Cluster IV  
271 *nifH* sequences has previously been ascribed to PCR-contamination (Zehr et al., 2003). Thus, the importance  
272 of this cluster for  $\text{N}_2$  fixation in OMZs is generally debatable and the different composition of the Cluster IV  
273 diazotroph community does likely not explain the absence of  $\text{N}_2$  fixation in the BoB.

274 While diazotroph communities highly similar to the identified BoB diazotrophs promote active  $\text{N}_2$  fixation in  
275 other OMZ waters, we have no consistent indication for  $\text{N}_2$  fixation in the BoB (Table 2). One explanation for  
276 the absence of  $\text{N}_2$  fixation could be the sensitivity of the BoB OMZ diazotrophs to  $\text{O}_2$  as opposed to the relative  
277  $\text{O}_2$  tolerance of cyanobacterial  $\text{N}_2$  fixers. We identified BoB diazotrophs closely related to cultivated  $\text{N}_2$  fixers,  
278 including *Vibrio diazotrophicus* and *Desulfonema limnicola*, which fix  $\text{N}_2$  only under strictly anaerobic  
279 conditions (Urdaci et al., 1988; Bertics et al., 2013; Gier et al., 2016). Further, communities of diazotrophs from  
280 other OMZs highly similar to the BoB diazotroph community were described to transcribe their *nifH* gene and

281 to actively fix N<sub>2</sub> only under strictly anoxic or anoxic-sulfidic conditions (Löscher et al., 2016; Löscher et al.,  
282 2014; Jayakumar et al., 2012; Jayakumar et al., 2017), and are unable to fix N<sub>2</sub> in the presence of even minimal  
283 concentrations of O<sub>2</sub> (reviewed in Bombar et al. (2016)). N<sub>2</sub> fixation in our samples (Tab. 2) may therefore be  
284 directly inhibited by the detected traces of O<sub>2</sub>. Thus, our data suggest that even only nanomolar O<sub>2</sub>  
285 concentrations such as present in the BoB may prevent non-phototrophic N<sub>2</sub> fixers from actively fixing N<sub>2</sub>,  
286 which could ultimately limit the supply of new nitrogen to the BoB.

#### 287 Role of Fe and mesoscale activities (eddies)

288 The high iron (Fe) requirement of N<sub>2</sub> fixing microbes (60 times higher compared to other marine organisms,  
289 Gruber and Galloway (2008)) limits N<sub>2</sub> fixation in large parts of the ocean (Moore et al., 2013). However,  
290 aeolian Fe fluxes to surface waters of the southern BoB were estimated to be comparable to those detected  
291 underneath Saharan dust plumes in the Atlantic ( $290 \pm 70 \mu\text{mol m}^{-2} \text{yr}^{-1}$ ; Grand et al. (2015a)). Indeed,  
292 dissolved Fe (dFe) accumulates in the BoB OMZ reaching comparably high concentrations of up to 1.5 nM  
293 (Grand et al., 2015b; Chinni et al., 2019). In surface waters, dFe concentrations were described to range from  
294 0.4 nM in the area of the cruise to up to 0.5 nM towards the north of the BoB, with increasing concentrations  
295 coinciding with decreasing salinity north of 15°N (Grand et al., 2015a; Grand et al., 2015b; Chinni et al., 2019).  
296 While the reported Fe concentrations do not indicate Fe limitation of N<sub>2</sub> fixation in the OMZ, surface primary  
297 production and N<sub>2</sub> fixation may be limited by any other micro-nutrient. Indication for such a limitation can  
298 be derived from eddy-induced Ekman pumping, mesoscale dynamics and the summer monsoon current have  
299 been shown to trigger plankton blooms with high productivity (Jyothibabu et al., 2015; Vinayachandran and  
300 Mathew, 2003; Chen et al., 2013; Fernandes et al., 2009) possibly induced by upwelling of certain nutrients to  
301 surface waters. Besides locally increasing surface water chlorophyll concentrations, erosion of the strong  
302 stratification and subsequent nutrient input to surface waters result in a change of phytoplankton size class  
303 (Prasanna Kumar et al., 2004). While usually smaller phytoplankton dominate the primary producer pool (60  
304 – 95 % of the total chlorophyll), the contribution of larger phytoplankton has been observed to double in the  
305 regions influenced by the summer monsoon current and in mesoscale eddies, which impacts the vertical  
306 organic carbon flux in the BoB temporally and locally (Jyothibabu et al., 2015; Prasanna Kumar et al.,  
307 2004; Huete-Ortega et al., 2010; Gomes et al., 2016). The resulting increase of organic matter production, the  
308 modified composition of organic matter (i.e. production fresh and labile POM), a faster export and  
309 subsequent respiration could promote anoxic OMZ conditions in the BoB. This may subsequently allow for  
310 O<sub>2</sub>-sensitive processes to take place, which may include N<sub>2</sub> fixation and nitrogen loss processes (Johnson et  
311 al., 2019), locally or regionally. Rapid changes in dissolved O<sub>2</sub> induced by increased surface productivity and  
312 organic matter export were reported in the context of mesoscale water mass dynamics in the BoB (Johnson

313 et al., 2019), and also in other eddy systems in the Atlantic, which showed rapid O<sub>2</sub> exhaustion in otherwise  
314 oxic waters (Fiedler et al., 2016; Löscher et al., 2015). Episodes of increased biological productivity have also  
315 been reported from the BoB during both the pre-southwest monsoon and northeast monsoon (Kumar et al.,  
316 2004). Under those scenarios, large parts of the BoB's surface waters exhibited a strong pCO<sub>2</sub> undersaturation  
317 compared to the atmosphere (~350 µatm), resulting in an air-sea pCO<sub>2</sub> gradient sometimes exceeding 100  
318 µatm. This gradient is explainable only by an increase in biological primary production fueled by temporal  
319 external nutrient input (Kumar et al., 2004). As Singh et al. (2012) pointed out, these high productivity  
320 episodes cannot be explained by riverine or atmospheric deposition of nutrients alone, but that upwelling or  
321 N<sub>2</sub> fixation would be required to sustain the nitrogen demand.

322

### 323 Feedbacks between N<sub>2</sub> fixation and OMZ intensity

324 We used a simple model to test the conditions allowing for N<sub>2</sub> fixation in the surface waters and in the OMZ  
325 of the BoB, and the interplay of N<sub>2</sub> fixation with primary production in response to changes in stratification  
326 (i.e. upwelling). We further explored in how far N<sub>2</sub> fixation controls O<sub>2</sub> concentrations in the BoB OMZ. We  
327 simulated a nitrate-driven primary production, and a N<sub>2</sub> fixation-dependent primary production, which is  
328 representative of N<sub>2</sub> fixation in the photic zone and governed by excess phosphorus and Fe availability as  
329 previously used in Canfield (2006) and Boyle et al. (2013). In addition, we simulated primary production that  
330 is dependent on OMZ-associated N<sub>2</sub> fixation, which in contrast to the classical N<sub>2</sub> fixation scenario is  
331 independent of a Redfield-based nitrogen deficit with N<sub>2</sub> fixation being active as long as phosphorus and Fe  
332 are available in concentration > 0 (Bombar et al., 2016; Löscher et al., 2014). One weakness of this model  
333 simulation is that it only includes Fe as potentially limiting nutrient for N<sub>2</sub> fixation, which is according to the  
334 available datasets (Grand et al., 2015b; Chinni et al., 2019) not necessarily correct but may be valid as an  
335 indicator for any other unrecognized micro-nutrient limitation. Consistent with the previous deep-time  
336 models of Canfield (2006) and Boyle et al. (2013), our model exercise revealed that additional nitrogen supply  
337 by N<sub>2</sub> fixation or other external nitrogen sources would generally exhaust the remaining traces of O<sub>2</sub> with  
338 increasing upwelling (Fig. 6). According to our model, this would lead to denitrification, which is in line with  
339 O<sub>2</sub>-manipulated experiments as presented in Bristow et al. (2017) and consistent with the available isotope  
340 records from the OMZ (Fig. S3). A weaker stratification (in the model depicted as increased upwelling fluxes)  
341 would have the strongest effect on oxygen exhaustion and the onset of denitrification if primary production  
342 is dependent on N<sub>2</sub> fixation in the photic zone, followed by OMZ-located N<sub>2</sub> fixation, and last by nitrogen  
343 recycling. Given that OMZ regions are sites of massive nitrogen loss characterized by a nitrogen deficit in the

344 water column (Deutsch et al., 2007), the similar diazotroph community in the OMZ paired with an absence  
345 of N<sub>2</sub> fixation in the euphotic zone suggest that OMZ-associated N<sub>2</sub> fixation is the most likely scenario. Thus,  
346 nitrogen limited primary production in the BoB and in OMZs in general would be susceptible to changes in  
347 stratification, with increased upwelling of nutrient-rich waters causing O<sub>2</sub> exhaustion. Considering the  
348 potential O<sub>2</sub> sensitivity of OMZ diazotrophs based on the comparison with other OMZs, the interplay between  
349 O<sub>2</sub> concentrations, stratification and N<sub>2</sub> fixation may act as a stabilizing feedback on the BoB OMZ, preventing  
350 full O<sub>2</sub> depletion.

351 One factor possibly disturbing a possible stabilizing feedback is the external anthropogenic supply of nitrogen  
352 to the northern Indian Ocean. This additional nitrogen source is projected to increase over the next decades  
353 (Duce et al., 2008) potentially accelerating primary production in the future ocean including the BoB. An  
354 atmospheric input in the range of 1.1 (model-based) to 1.6 Tg N yr<sup>-1</sup> (observation based) has been reported,  
355 which will likely increase in the future (Suntharalingam et al., 2019). This additional nitrogen fertilization  
356 would cause the same effect as N<sub>2</sub> fixation in our model, thus exhausting the present traces of O<sub>2</sub> in the OMZ  
357 rapidly. Until an increased supply of atmospheric or riverine nitrogen would become significant, changes in  
358 water column stratification, however, likely impose the strongest control on N<sub>2</sub> fixation and primary  
359 production, and thus on respiration, nitrogen loss processes and ultimately on the O<sub>2</sub> status of the OMZ in  
360 the BoB.

361

## 362 **Conclusion**

363 We detected a diazotrophic community similar to those from other OMZ regions, however, we could not  
364 obtain consistent evidence for active N<sub>2</sub> fixation in the BoB. Coming back to our original question ‘No N<sub>2</sub>  
365 fixation in the BoB?’ our data suggest ‘No.’. In other OMZs, N<sub>2</sub> fixation has been observed to largely vary  
366 temporally and spatially but never reaching rates comparable to oligotrophic open ocean systems such as  
367 the Pacific gyres. Episodes of N<sub>2</sub> fixation, however, could be induced by changes in water mass dynamics,  
368 riverine or atmospheric nutrient input. Resulting increased N<sub>2</sub> fixation and primary production would possibly  
369 lead to O<sub>2</sub> exhaustion in the BoB, which otherwise doesn’t become fully anoxic.

370 Previous observations describing the absence of nitrogen loss processes in the BoB were explained by the  
371 remaining traces of O<sub>2</sub> (Bristow et al., 2017) and possibly by a nitrogen deficiency relative to carbon in the  
372 organic matter pool. While we acknowledge that our dataset represents only a snapshot of the BoB’s  
373 biogeochemical setting, our observations may help to predict the future development of N<sub>2</sub> fixation in the

374 BoB and of the BoB OMZ with regard to increasing atmospheric dust deposition and ocean fertilization (Duce  
375 et al., 2008), altered ocean circulation patterns (Yeh et al., 2009), and deoxygenation of the ocean as a  
376 consequence of global warming (Schmidtko et al., 2017;Stramma et al., 2008).

377

378 **Code/Data availability:** Sequence data is available from Genbank, submission ID 2245434 and from NCBI's  
379 sequence read archive, accession number SRR9696254. The model code and other biogeochemical data are  
380 available from the Pangaea database (<https://doi.pangaea.de/10.1594/PANGAEA.905498>,  
381 <https://doi.pangaea.de/10.1594/PANGAEA.905496>).

382 **Author contribution:** CRL carried analyzed the data together with WM, CRL ran the model simulations and  
383 wrote the manuscript with substantial contributions from all co-authors.

384 **Competing interests:** The authors declare no competing interests.

385

386

### 387 **Acknowledgements**

388 We thank the captain and crew of the ORV *Sagar Kanya* for their support during sampling. We especially  
389 thank the Ministry of Earth Sciences (MoES), India, for funding the research through the SIBER (INDIA) project  
390 GAP2425 and for making ORV *Sagar Kanya* available for this work. We thank J. Dekaezemacker and L.  
391 Piepgras for sampling on board, providing nitrogen and carbon fixation rates and for helpful comments on  
392 the dataset, and R. Boyle for providing the backbone model. We thank L. Bristow for helpful comments on  
393 an earlier version of the manuscript, and we acknowledge E. Laursen for technical assistance, C. Callbeck and  
394 G. Lavik for sampling, A. Treusch and M. Forth for providing access to subsamples for molecular analysis. We  
395 further thank G. Krahnmann for help with the analysis of fluorescence data from the CTD. This study was  
396 supported by the H2020 program of the European Union (NITROX, grant #704272 to CRL) and the Max Planck  
397 Society. Further funding was received from VILLUM FONDEN (Grant No. 16518; DEC) and the German  
398 Research Foundation in the frameworks of the Cluster of Excellence 'The Future Ocean' and the Collaborative  
399 Research Center SFB754.

680 **Tables:**

681 Table 1: Nitrogen fluxes in the BoB ( $\text{Tg N yr}^{-1}$ ); N loss fluxes are given in black, N sources are given in gray;  
 682 DIN = dissolved inorganic nitrogen, PON = particulate organic nitrogen, IO = Indian Ocean.  $\text{N}_2$  loss by  
 683 denitrification was excluded by Bristow et al. (2017). Naqvi et al. (2010) reported possible N loss to the  
 684 atmosphere in the form of  $\text{N}_2\text{O}$ .

	Flux [ $\text{Tg N yr}^{-1}$ ]	reference
Net exchange with the IO	3.3	Naqvi , 2010
Sedimentary denitrification	3 - 4.1	Naqvi , 2008; Naqvi 2010
PON burial	1	Naqvi , 2010
Water column N loss to the atmosphere	0 - 0.07	Naqvi , 2010; Bristow, et al. 2017
Atmospheric deposition	0.5 - 1.6	Naqvi , 2010; Singh et al., 2012; Suntharalingam et al., 2019
Riverine/ land input	0.4 - 4	Naqvi , 2010; Singh et al., 2012; Krishna et al., 2016
$\text{N}_2$ fixation	0.6-11.3	Naqvi , 2010; Srinivas & Sarin, 2013

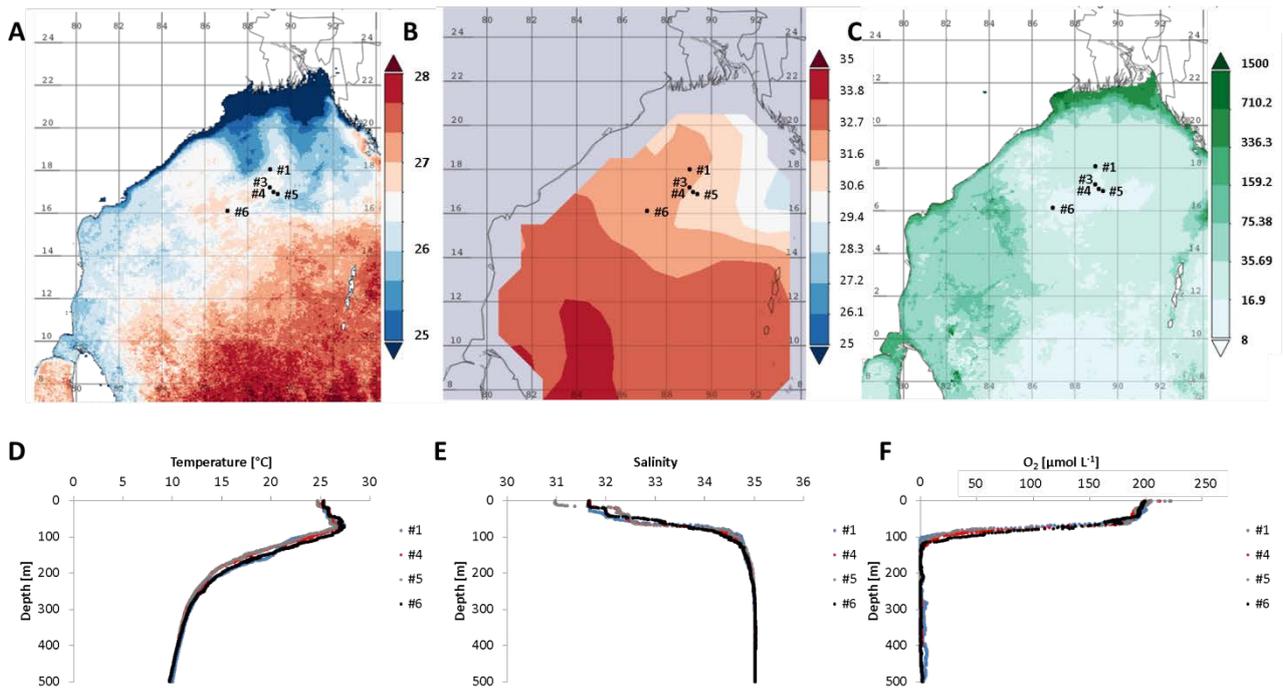

685

686 Table 2:  $\text{CO}_2$  and  $\text{N}_2$  fixation rates based on triplicate measurements at stations 1 ( $17.9970^\circ\text{N}$ ,  $88.9968^\circ\text{E}$ ), 4  
 687 ( $16.9828^\circ\text{N}$ ,  $89.2063^\circ\text{E}$ ) and 5 ( $17.2075^\circ\text{N}$ ,  $89.4282^\circ\text{E}$ ).  $\text{N}_2$  fixation was only measurable in two individual  
 688 samples, but only in one out of three technical replicates.

station #	Incubation depth	$\text{CO}_2$ fixation [ $\text{nmol L}^{-1} \text{d}^{-1}$ ]	SD	$\text{N}_2$ fixation [ $\text{nmol L}^{-1} \text{d}^{-1}$ ]	SD

690 **Figures:**

691

692 Fig. 1: Time-averaged maps from 15. Jan 2014 – 15. Feb 2014 of (A) sea surface temperature (SST in °C (night  
 693 only, 8-daily, 4 km resolution obtained from MODIS-Aqua, <https://giovanni.gsfc.nasa.gov>), (B) sea surface  
 694 salinity, (C) chlorophyll a concentration in  $10^{-2} \text{ mg m}^{-3}$ , note the log scale (8-daily, 4 km resolution obtained  
 695 from MODIS-Aqua, <https://giovanni.gsfc.nasa.gov>). (D) CTD data-based water temperature in °C, (E) salinity  
 696 at the cruise stations. (F)  $\text{O}_2$  (in  $\mu\text{mol L}^{-1}$ ) over the top 500 m of the water column, data from Bristow et al.  
 697 (2017)

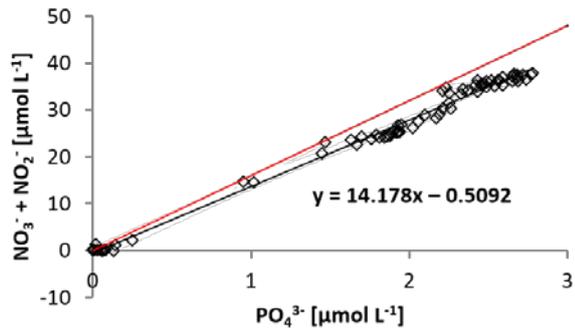

698

699

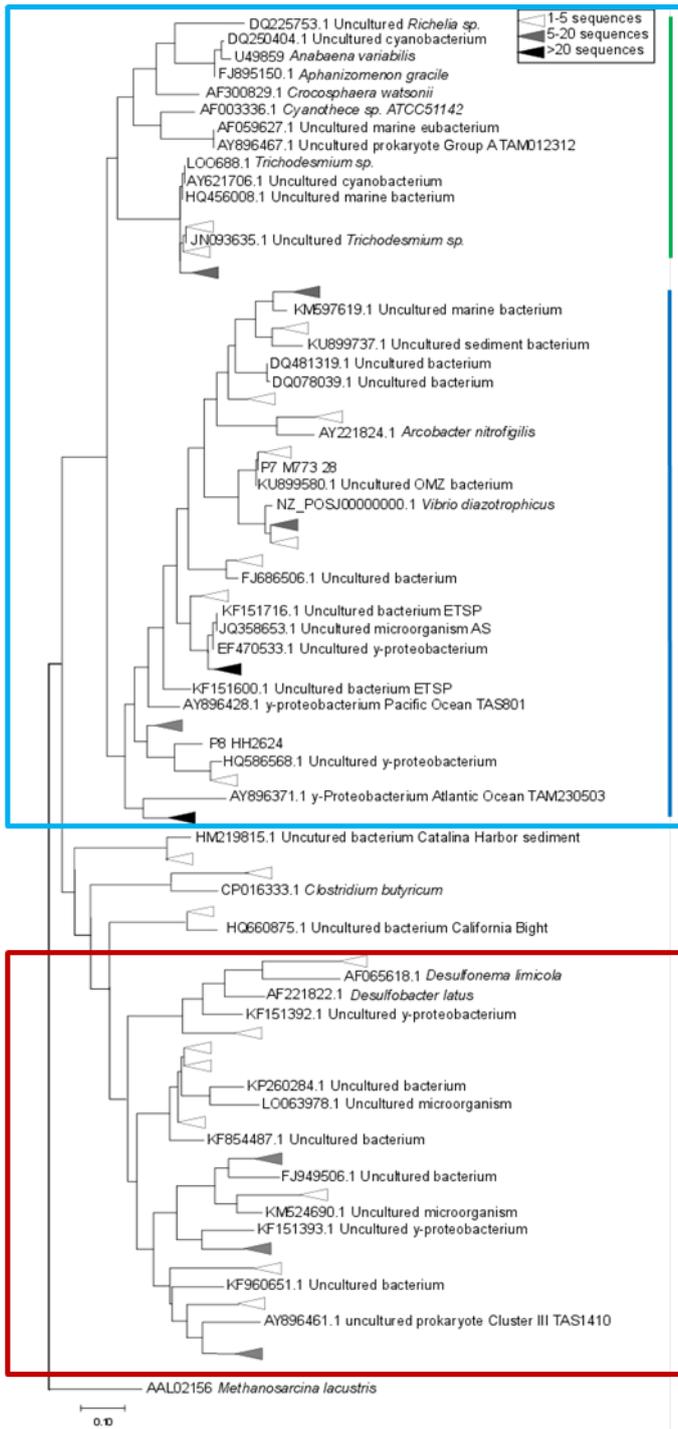

700 Fig. 2: (A) Carbon fixation rates at stations 1, 4 and 5, and (B) sensor-based fluorescence measurements from  
 701 station 1, 4, 5 and 6.

702

703

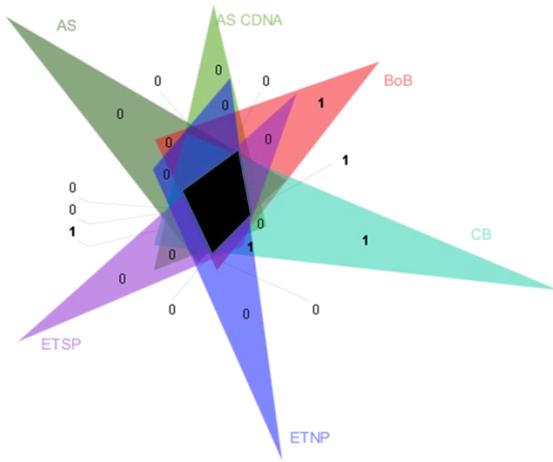

704 Fig. 3: N:P ratio at station 1, 4, 5 and 6, with the Redfield ratio of N:P = 16:1 indicated with a red line, the  
705 negative intercept of the trendline indicates a deficit in dissolved inorganic nitrogen.

706

707 Fig. 4: Maximum likelihood tree of a 321 bp fragment of the *nifH* gene. Clusters identified by Sanger  
 708 sequencing are indicated with triangles with colors denoting the sequence abundances in our dataset. The  
 709 light blue box indicates Cluster I sequences including cyanobacteria (green line) and proteobacteria (blue  
 710 line). Cluster III sequences are indicated with a red box.

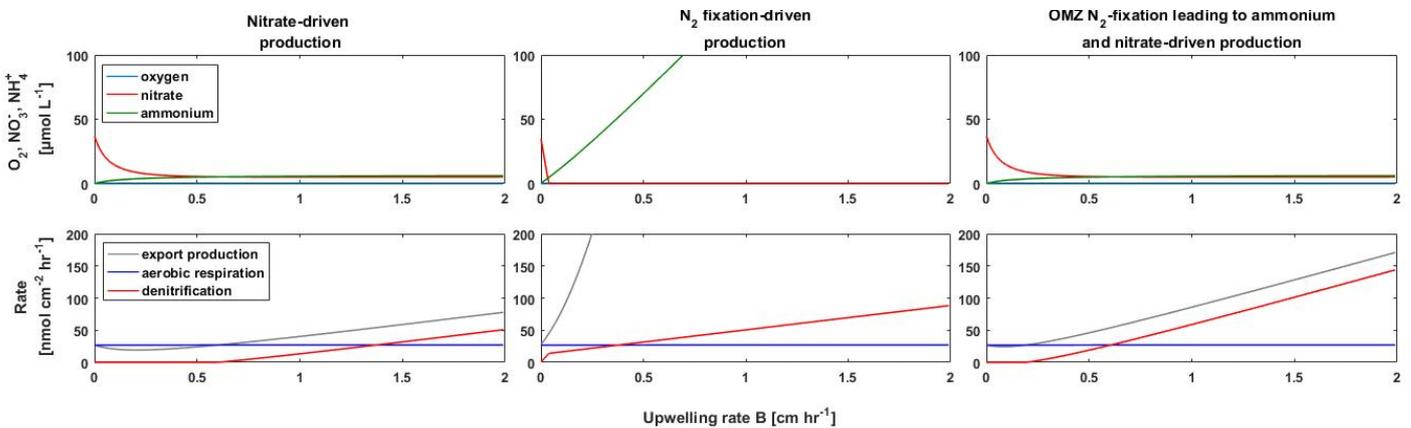

711

712

713 Fig. 5: Venn diagram of *nifH* clusters present in Arabian Sea DNA libraries (AS), and in cDNA libraries (AS  
 714 cDNA), clusters identified in the BoB, in O<sub>2</sub>-depleted basins of the Californian Bay (CB), the eastern tropical  
 715 North Pacific (ETNP) and the eastern tropical South Pacific (ETSP). Clusters as depicted by triangles in Fig. S  
 716 6) were collapsed based on a 98% identity. The black area shows the clusters present in all OMZs. Numbers  
 717 indicate the individual clusters in fields which would otherwise appear unproportionally large.

718

719 Fig. 6: Model of the response of the BoB OMZ to a weaker stratification corresponding to increased upwelling  
 720 in this model, under a non-N<sub>2</sub> fixation scenario with nitrate driven production, a photic zone N<sub>2</sub> fixation-  
 721 dependent primary production, and a scenario of N<sub>2</sub> fixation in the OMZ, which would result in built-up of a  
 722 nitrogen stock and export to the productive surface if stratification becomes weaker.
