21 **Abstract**

22 Southern Ocean waters are projected to undergo profound changes in their
23 physical and chemical properties in the coming decades. Coccolithophore blooms in the
24 Southern Ocean are thought to account for a major fraction of the global marine calcium
25 carbonate (CaCO₃) production and export to the deep sea. Therefore, changes in the
26 composition and abundance of Southern Ocean coccolithophore populations are likely to
27 alter the marine carbon cycle, with feedbacks to the rate of global climate change.
28 However, the contribution of coccolithophores to CaCO₃ export in the Southern Ocean is
29 uncertain, particularly in the circumpolar Subantarctic Zone that represents about half of
30 the areal extent of the Southern Ocean and where coccolithophores are most abundant.
31 Here, we present measurements of annual CaCO₃ flux and quantitatively partition them
32 amongst coccolithophore species and heterotrophic calcifiers at two sites representative

33 of a large portion of the Subantarctic Zone. We find that coccolithophores account for a
34 major fraction of the annual CaCO_3 export with highest contributions in waters with low
35 algal biomass accumulations. Notably, our analysis reveals that although *Emiliana*
36 *huxleyi* is an important vector for CaCO_3 export to the deep sea, less abundant but larger
37 species account for most of the annual coccolithophore CaCO_3 flux. This observation
38 contrasts with the generally accepted notion that high PIC accumulations during the
39 austral summer in the subantarctic Southern Ocean are mainly caused by *E. huxleyi*
40 blooms. It appears likely that the climate-induced migration of oceanic fronts will initially
41 result in the poleward expansion of large coccolithophore species increasing CaCO_3
42 production. However, subantarctic coccolithophore populations will eventually diminish
43 as acidification overwhelms those changes. Overall, our analysis emphasizes the need for
44 species-centred studies to improve our ability to project future changes in phytoplankton
45 communities and their influence on marine biogeochemical cycles.

46

47 **1. Introduction**

48 The emissions of carbon dioxide (CO_2) into the atmosphere by anthropogenic
49 industrial activities over the past 200 years are inducing a wide range of alterations in the
50 marine environment (Pachauri et al., 2014). These include ocean warming, shallowing
51 of mixed layer depths, changes in nutrient supply to the photic zone, and decreasing
52 carbonate-ion concentrations and pH of the surface ocean, a process known as ocean
53 acidification (Rost and Riebesell, 2004; Stocker et al., 2014). Substantial evidence from
54 CO_2 manipulation experiments indicates that many species of corals, pteropods,
55 planktonic foraminifera and coccolithophores will reduce their calcification rates under
56 future ocean acidification scenarios (Bijma et al., 2002; Langdon and Atkinson, 2005
57 among others; Orr et al., 2005; Bach et al., 2015; Meyer and Riebesell, 2015). Owing to
58 their moderate alkalinity and cold temperatures, Southern Ocean waters are projected to
59 become undersaturated with respect to aragonite no later than 2040 and to calcite by the
60 end of the century (Cao and Caldeira, 2008; McNeil and Matear, 2008; Shadwick et al.,
61 2013). This decline in the saturation state of carbonate, together with other changes in
62 carbonate chemistry speciation, will enhance dissolution of both aragonite and calcite
63 shells and will make the biological precipitation of carbonate difficult in some marine
64 calcifying organisms (Fabry et al., 2008; Gattuso and Hansson, 2011). Since such
65 thresholds will be reached sooner in polar regions, Southern Ocean ecosystems have been

66 proposed as bellwethers for prospective impacts of ocean acidification on marine
67 organisms at mid and low latitudes (Fabry et al., 2009).

68 Cocolithophores are a major component of phytoplankton communities in the
69 Southern Ocean, particularly in its northern-most province, the Subantarctic Zone, where
70 they often exhibit maximum abundances and diversity (e.g. Gravalosa et al., 2008;
71 Saavedra-Pellitero et al., 2014; Malinverno et al., 2015; Charalampopoulou et al., 2016).
72 Cocolithophores play an important and complex role in the Southern Ocean carbon cycle
73 (Salter et al., 2014). On the one hand, the production of calcite platelets (termed
74 coccoliths) decreases the alkalinity of surface waters thereby reducing the atmospheric
75 uptake of CO₂ from the atmosphere into the surface ocean. On the other hand, the
76 production of organic matter through photosynthesis, and its subsequent transport to
77 depth in settling particles, enhances carbon sequestration via the biological carbon pump
78 (Volk and Hoffert, 1985). Additionally, due to their high density and slow dissolution,
79 coccoliths act as an effective ballast for organic matter, increasing organic carbon
80 sequestration depths (Buitenhuis et al., 2001; Boyd and Trull, 2007; Ziveri et al., 2007).
81 Therefore, changes in the abundance, composition and distribution of coccolithophores
82 could have an extensive impact on ocean nutrient stoichiometry, carbon sequestration,
83 and nutrition for higher trophic levels in the Southern Ocean (Deppeler and Davidson,
84 2017).

85 The remoteness and vastness of the Southern Ocean, together with the inherent
86 temporal and spatial variability of pelagic ecosystems, hampers accurate characterization
87 and quantification of Southern Ocean phytoplankton communities. Advances in satellite
88 technology and modelling algorithms have allowed a circumpolar and year-round
89 coverage of the seasonal evolution of major phytoplankton functional groups within the
90 Southern Ocean (e.g. Alvain et al., 2013; Hopkins et al., 2015; Rousseaux and Gregg,
91 2015). In particular, ocean-colour satellite reflectance observations have been used to
92 quantitatively estimate coccolithophore Particulate Inorganic Carbon (PIC)
93 concentrations throughout the Southern Ocean (Gordon et al., 2001; Balch et al., 2005b).
94 These satellite estimates suggest apparent high PIC values during summer near the major
95 Southern Ocean fronts attributed to coccolithophores (Balch et al., 2011; Balch et al.,
96 2016). This band of elevated reflectance and PIC that encircles the entire Southern Ocean
97 was termed the “Great Calcite Belt” by these authors. However, comparison of satellite
98 remote-sensing data with ship-based observations (Holligan et al., 2010; Trull et al.,

99 2018) indicate that satellite ocean-colour-based PIC estimates could be unreliable,
100 particularly in Antarctic waters where they erroneously suggests high PIC abundances.
101 Shipboard observations, on the other hand, provide a detailed picture of phytoplankton
102 community composition and structure, but are dispersed, both temporally and
103 geographically, and provide rather heterogenous data in terms of taxonomic groups
104 investigated, and the sampling scales and methodologies used (e.g. Kopczynska et al.,
105 2001; de Salas et al., 2011; Poulton et al., 2013; Patil et al., 2017, among others). *In situ*
106 year-round monitoring of key strategic regions is critically needed to establish baselines
107 of phytoplankton community composition and abundance and to validate and improve
108 ocean biogeochemical models (Rintoul et al., 2012). This information is also essential if
109 we are to detect possible climate-driven changes in the structure of phytoplankton
110 communities that could influence the efficiency of the biological carbon pump, with
111 consequent feedbacks to the rate of deep-water carbon sequestration and global climate
112 change (Le Quéré et al., 2007; Deppeler and Davidson, 2017).

113 Here, we document coccolithophore and carbonate particle fluxes collected over
114 a year by four sediment trap records deployed at two strategic locations of the Australia
115 and New Zealand sectors of the Southern Ocean considered representative of a large
116 portion of the SAZ (See section 2.2 for further details). Our measurements provide
117 coccolith mass estimates of the main coccolithophore species and quantitatively partition
118 annual carbonate fluxes amongst coccolithophore species and heterotrophic calcifiers.
119 We find that coccolithophores are a major vector for CaCO₃ export out of the mixed layer
120 and that the largest contribution to CaCO₃ export is not from the most abundant species
121 *Emiliania huxleyi* but rather from larger coccolithophores species with substantially
122 different physiological traits (e.g. *Calcidiscus leptoporus*). Our results emphasize the
123 urgent need for diagnostic fitness response experiments on other coccolithophore species
124 aside from *E. huxleyi* (e.g. Feng et al., 2017) in order to be able to be able to predict the
125 impacts of anthropogenically induced changes in Southern Ocean ecosystems and
126 biological carbon uptake mechanisms.

127

128 **2. Material and methods**

129

130 **2.1 Oceanographic setting**

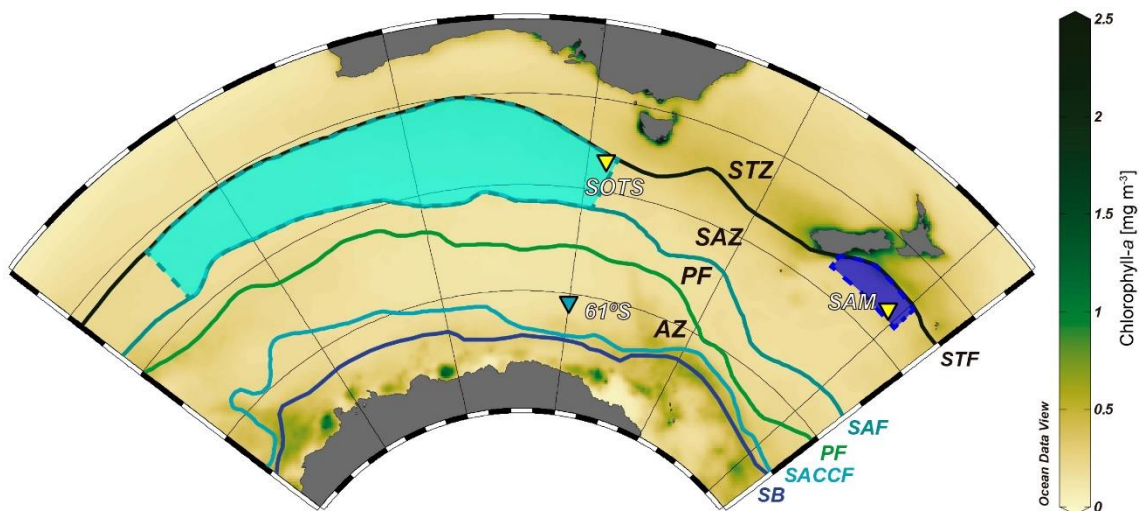

131 The SAZ alone accounts for more than half of the Southern Ocean area (Orsi et
132 al., 1995) and represents a transitional boundary between the warm, oligotrophic waters
133 of the subtropical gyres to the north and the cold, silicate-rich waters south of the Polar
134 Front (PF). The SAZ is arguably the largest high nutrient, low chlorophyll (HNLC)
135 province in the world's ocean and is central to the linkages between the ocean–
136 atmosphere CO₂ exchange and climate. The deep winter convection in the SAZ, which
137 exceeds 400 m, results in the formation of a high-oxygen water masses known as
138 Subantarctic Mode and Antarctic Intermediate Waters that connect the upper and lower
139 limbs of the global overturning circulation (Sloyan and Rintoul, 2001a, b). The formation
140 of these water masses are responsible for the sequestration of a large fraction of
141 anthropogenic CO₂ (Sabine et al., 2004), with an estimated 1 Gt C yr⁻¹ transported to
142 intermediate depths annually (Metzl et al., 1999). Macronutrient concentrations display
143 pronounced seasonal changes in the SAZ with fully replete levels during winter to
144 substantial depletion during summer, particularly for silicate (Dugdale et al., 1995;
145 Rintoul and Trull, 2001; Bowie et al., 2011). Phytoplankton community in the
146 subantarctic zone is dominated by pico- and nanoplankton including cyanobacteria,
147 coccolithophores and autotrophic flagellates with lower abundances of diatoms than polar
148 waters south the Polar Front (Chang and Gall, 1998; Kopczynska et al., 2001; de Salas et
149 al., 2011; Rigual-Hernández et al., 2015b; Eriksen et al., 2018).

150

151 **2.2 Field experiments**

152 Here we report on the coccolithophore and biogeochemical fluxes collected over
153 a year at the Australian Southern Ocean Time Series (SOTS) observatory (Trull et al.,
154 2010) and the New Zealand Subantarctic Mooring (SAM) site (Nodder et al., 2016) (Fig.
155 1). The SOTS observatory is located in the abyssal plane of the central SAZ
156 approximately 530 km southwest of Tasmania (46° 56' S, 142° 15' E) within an anti-
157 cyclonic gyre in a region characterized by weak circulation (Trull et al., 2001; Herraiz-
158 Borreguero and Rintoul, 2011). SOTS was equipped with three vertically moored, conical
159 time-series sediment traps (McLane Parflux Mk 7G-21) placed at ~1000, 2000 and 3800
160 m depth between August 2011 until July 2012. The physical, chemical and biological
161 parameters of SOTS site are regarded as representative for large portion of the Indian and
162 Australian sectors of the SAZ (~90°E and 140°E; Trull et al., 2001). The SAM site is
163 located in the Bounty Trough in in the subantarctic waters south east of New Zealand

164 (46°40'S, 178° 30'E) and was equipped with conical, time-incremental sediment trap
 165 (McLane PARFLUX Mk7G-21) placed at 1500 m depth, with samples used in the present
 166 study collected between November 2009 until November 2010. The SAM site is
 167 considered to be representative of a wide area of the northern sector of the SAZ off eastern
 168 New Zealand, approximately 171°E to 179°W and 45 to 47°S (Law et al., 2014; Fig. 1).
 169 Full details of the field experiments from these two localities in the Australian and New
 170 Zealand sectors of the SAZ can be found in Trull et al. (2001) and Nodder et al. (2016),
 171 respectively.

172

173 **Figure 1:** Chlorophyll-*a* composite map of the Australian-New Zealand sector of the
 174 Southern Ocean (July 2002 to July 2012) from the MODIS Aqua Sensor showing the
 175 location of the sediment trap moorings sites: SOTS, 61°S and SAM. The regions for
 176 which the SOTS and SAM sites are representative are marked with light and dark blue
 177 areas, respectively. Abbreviations: Subtropical Zone – STZ, Subtropical front - STF,
 178 Subantarctic Zone – SAZ, Subantarctic Front - SAF, Polar Frontal Zone - PFZ, Polar
 179 Front - PF, Antarctic Zone – AZ, Southern Antarctic Circumpolar Current Front –
 180 SACCF, southern boundary of the ACC – SB. Oceanic fronts after Orsi et al. (1995).

181 2.3 Sample processing

182 In short, the recovered trap bottles were refrigerated upon recovery and then
 183 allowed to settle. The sample slurry was then wet-sieved through a 1 mm screen in the
 184 case of SOTS (no attempt to extract zooplankton "swimmers" was made for the <1 mm
 185 fraction analysed here) and through a 200 µm sieve to remove "swimmers" for the SAM
 186 site. The remaining fraction was then split using a McLane wet sample divider; the SOTS

187 samples were subdivided into one tenth aliquots while one fifth splits were made for the
188 SAM samples. For the SOTS samples, a total of 55 samples were processed for calcareous
189 nanoplankton analysis. The one-tenth splits dedicated to phytoplankton analysis were
190 further subdivided into four aliquots with the McLane splitter. One aliquot was used for
191 calcareous nanoplankton analysis and the remaining three were kept refrigerated for
192 biomarker and non-calcareous microplankton analyses. In the case of the SAM samples,
193 the one-fifth aliquots were further subdivided into five subsplits, and one of those was
194 used for calcareous nanoplankton analysis. Two different types of glass slides per
195 sample were prepared. The first preparation was used for the estimation of coccosphere
196 and calcareous dinocyst (calcispheres of thoracosphaerids) fluxes and for coccolith
197 imaging. A volume ranging between 1000 and 5000 μl of the raw sample was mounted
198 on a glass slide using Canada balsam following Flores and Sierro (1997). This technique
199 produces random settling of the coccoliths for microscopic identification and
200 enumeration. The second type of glass slide was prepared following a modified protocol
201 for non-destructive disintegration of aggregates modified from Bairbakhish et al. (1999).
202 The objective of this chemical treatment is to reduce biases in the coccolith flux
203 estimations associated with the presence of different types of aggregates and
204 coccospheres (Bairbakhish et al., 1999). In brief, 2000 μl were extracted from the aliquot
205 for calcareous nanoplankton analysis and then treated with a solution comprising 900 μl
206 sodium carbonate and sodium hydrogen carbonate, 100 μl ammonia (25%) and 2000 μl
207 hydrogen peroxide (25%). The sample was agitated for 10 seconds every 10 minutes and
208 this process was repeated over an hour. Then, the reaction was stopped with catalase
209 enzyme and samples were allowed to settle for at least 48 hours before preparation on
210 microscope slides. pH controls indicate that the solution kept pH levels near 9, therefore
211 precluding coccolith dissolution. Finally, trap samples were mounted on microscope
212 slides following the same decantation method as used for the first type of glass slides (i.e.
213 Flores and Sierro, 1997).

214 **2.4 Determination of CaCO_3 fluxes**

215 A detailed description of the geochemical analytical procedures for the SOTS
216 samples is provided in Trull et al. (2001) and Rigual-Hernández et al. (2015a) while more
217 detailed procedures of the SAM trap can be found in Nodder et al. (2016). In short, for
218 the SOTS site three of the one tenth splits were filtered onto 0.45 pore size filters. Then
219 the material was removed from the filter as a wet cake of material, dried at 60°C, and

220 ground in an agate mortar. This material was used to determine the total mass and
221 composition of the major components of the flux. Particulate inorganic Carbon (PIC)
222 content was measured by closed system acidification with phosphoric acid and
223 coulometry. For the SAM site, one-fifth split was analysed for elemental calcium (Ca)
224 concentration using ICP-MS techniques. The samples were oven-dried, digested in
225 nitric/hydrochloric acid and then analysed according to the methods under US EPA 200.2.
226 Ca was used to estimate CaCO₃ content in the samples assuming a 1:1 molar ratio in
227 CaCO₃.

228

229 **2.5 Quantification and characterization of coccolithophore sinking assemblages**

230 Qualitative and quantitative analyses of coccospheres and coccoliths were
231 performed using a Nikon Eclipse 80i polarised light microscope at 1000 x magnification.
232 The taxonomic concepts of Young et al. (2003) and the Nannotax website (Young et al.,
233 2019) were used. A target of 100 coccospheres and 300 coccoliths was established;
234 however, owing to the pronounced seasonality in coccolithophore export, there were
235 some periods with very low abundance of coccospheres in the samples and therefore the
236 target of 100 coccospheres was not always met. Coccosphere and coccolith species counts
237 were then transformed into relative abundances and daily fluxes using the following
238 formula:

239

$$240 \quad F = \frac{N \times \frac{A}{n \times a} \times V \times S}{d \times T}$$

241

242 where F = coccolith flux, N = number of coccoliths, A = area of the Petri dish, n
243 = number of fields of view, a = area of a field of view, V = dilution volume, S = sample
244 split, d = number of days of collection and T = sediment trap aperture area.

245

246 **2.6 Determination of coccolith mass and size**

247 Birefringence and morphometric methods are the two most commonly used
248 approaches for estimating the calcite content of isolated coccoliths. The circularly-
249 polarized light-microscopy-based technique (Fuertes et al., 2014) is based on the
250 systematic relationship between the thickness of a given calcite particle (in the thickness
251 range of 0 - 1.55 mm) and the first-order polarization colours that it displays under

252 polarized light (Beaufort, 2005; Beaufort et al., 2014; Bolton et al., 2016). The advantages
253 of this approach are that: (i) it directly measures complete coccoliths with no assumptions
254 regarding their shape or thickness and (ii) it allows for quantification of calcite losses
255 associated with missing parts or etching of the coccoliths. Disadvantages of this technique
256 are the errors associated with the coccolith-calcite calibration and their consequent effect
257 on the coccolith mass estimates (Fuertes et al., 2014; González Lemos et al., 2018). The
258 morphometric approach, on the other hand, allows better taxonomic identification of the
259 coccoliths and has smaller errors in the length measurements (~0.1 to 0.2 μm ; Poulton et
260 al. 2011). However, this method does not allow direct measurement of coccolith thickness
261 and assumes identical shape and width proportions for all specimens of the same species,
262 among other uncertainties (see Young and Ziveri, 2000 for a review). Since the two
263 methods have different associated errors (Poulton et al., 2011), we applied both
264 approaches to our coccolith flux data in order to obtain two independent estimates of the
265 fractional contribution of coccolithophores species to total carbonate export in the SAZ.

266 For the birefringence-based approach, a minimum of 50 coccoliths of each of the
267 main coccolithophore species were imaged using a Nikon Eclipse LV100 POL light
268 microscope equipped with circular polarisation and a digital camera (Nikon DS-Fi1 8-bit
269 colour). The only exception was *E. huxleyi* for which coccolith mass values had already
270 been estimated in all the same samples at high resolution by Rigual-Hernández et al.
271 (under review). For the minor components of the flux assemblage, a lower number of
272 coccoliths were measured (Table 1). A photograph of the same apical rhabdolith of the
273 genus *Acanthoica* was taken and used for calibration at the beginning of each imaging
274 session during which microscopy light and camera settings were kept constant. A
275 different number of fields of view of multiple samples representative of different seasons
276 were photographed until the target number of coccoliths for each species was reached.
277 Photographs were then analysed by the image processing software C-Calcita. The output
278 files for single coccoliths were visually selected and classified into the lowest possible
279 taxonomic level. Length and weight measurements were automatically determined by C-
280 Calcita software. Morphometric measurements of all the species are summarized in Table
281 1. For further methodological details see Fuertes et al. (2014) and Bolton et al. (2016).

282 The second approach consisted of performing morphometric measurements on the
283 coccoliths followed by the estimation of their coccolith mass assuming a systematic
284 relation between length and thickness (Young and Ziveri, 2000). Young and Ziveri (2000)

285 proposed that the calcite content of a given coccolith could be estimated using the
286 following formula:

287
$$\text{Coccolith calcite (pg)} = 2.7 \times k_s \times l^3$$

288 where 2.7 is the density of calcite (CaCO_3 ; $\text{pg } \mu\text{m}^3$), “ k_s ” is a shape constant that varies
289 between species and morphotypes and whose value is based on the reconstruction of
290 coccolith cross profiles and “ l ” is the distal shield length (DSL). In order to undertake
291 coccolith measurements on the same coccoliths used for the birefringence-based
292 approach, we employed the distal shield length values measured by C-Calcita using
293 circularly polarized light instead of morphometric measurements on Scanning Electron
294 Micrographs (SEM) as made in Young and Ziveri (2000).

295 Since coccolith distal shield length (DSL) has been reported to be systematically
296 underestimated using cross-polarized light microscopy (e.g. D’Amario et al., 2018), we
297 evaluated the possible errors in the DSL measurements made by C-Calcita. For this
298 assessment, we measured 40 detached coccoliths of *C. leptoporus* under the SEM from
299 samples of the SOTS sediment traps using the image processing software Image-J.
300 Average DSL measurements under the SEM were then compared with those made by C-
301 Calcita on 40 randomly selected *C. leptoporus* coccoliths. The average coccolith length
302 obtained with the SEM analysis (6.37 ± 1.02 , $n = 40$) was ~ 4% shorter than that estimated
303 with C-Calcita (6.62 ± 1.47 , $n = 40$). Therefore, we assumed the error for the DSL
304 measurements with circularly polarized light is < 5%. Given the low numbers of the rest
305 of species in the samples we considered that this error is applicable for the rest of the taxa
306 measured in the current study. The subtle differences in coccolith distal length
307 measurements between techniques are most likely due to the fact that the peripheral limit
308 of the coccolith shield under the circularly-polarized light microscope (LM) is not as sharp
309 as is the case for SEM images. It follows that differences in DSL measurements between
310 SEM and LM techniques will be likely similar or smaller in the case of larger species.
311 Since the majority of coccolith species identified in the current study display a similar
312 (e.g. *Gephyrocapsa oceanica*, *Syracosphaera pulchra*, *Umbellosphaera tenuis* and
313 *Umbilicosphaera sibogae*) or larger size (e.g. *Coccolithus pelagicus* and *Helicosphaera*
314 *carteri*) than *C. leptoporus*, it could be assumed that the <5% error on DSL estimates for
315 *C. leptoporus* is applicable for the rest of the species found in the current study. For the
316 k_s value of each taxa, data from the literature was employed (Table 1). *E. huxleyi*
317 assemblages in the SAZ are composed of a mixture of five different morphotypes: A, A

318 overcalcified, B, B/C and C, each of which is characterized by different shape factors (k_s).
319 Since k_s is not available for all the morphotypes found in the SAZ and it is not possible
320 to differentiate between morphotypes in our light microscopy images, we used the mean
321 shape factor constant for *E. huxleyi* (i.e. $k_s = 0.0275$) to provide a range of coccolith mass
322 estimates for this species (Table 1 and Fig. 4).

323 **2.7 Calculation of annual estimates**

324 Since the trap collection periods encompassed a period shorter than a calendar
325 year, annual estimates of coccolith and CaCO_3 fluxes and species relative abundances had
326 to be estimated. For the SOTS site, a total of 336 days were sampled for the 1000 and
327 2000 m traps and 338 days for the 3800 m. Since the unobserved interval occurred in
328 winter, the missing sampling period was filled using an average flux value of the winter
329 cups (first and last trap bottles). In the case of the SAM trap, the number of samples
330 available for CaCO_3 and calcareous nannoplankton analyses was different, covering a
331 period of 313 and 191 days respectively. Since gaps were quasi-equally distributed along
332 the time series, annual fluxes were estimated by filling the gaps in the record with average
333 fluxes calculated from the available data. The estimated range of the annual contribution
334 of coccolithophores to total CaCO_3 export at the SOTS and SAM traps was calculated by
335 multiplying the coccolith flux of each species in each sampling interval by its average
336 coccolith weight values obtained with the birefringence and morphometric techniques.

337 **2.8 Remotely sensed chlorophyll-*a* and PIC concentrations**

338 Weekly Chlorophyll-*a* and PIC concentrations for the sampling intervals at the
339 SOTS and SAM sites were derived from Giovanni online data system, developed and
340 maintained by the NASA Goddard Earth Sciences Data Active Archive Center (Acker
341 and Leptoukh, 2007). Each value is a weekly value is produced by computing spatial
342 averages within the area 48.5-45.5°S and 130-150°E for the SOTS site and 47-45° S and
343 171°E-179°W for the SAM site (Fig. 5).

344

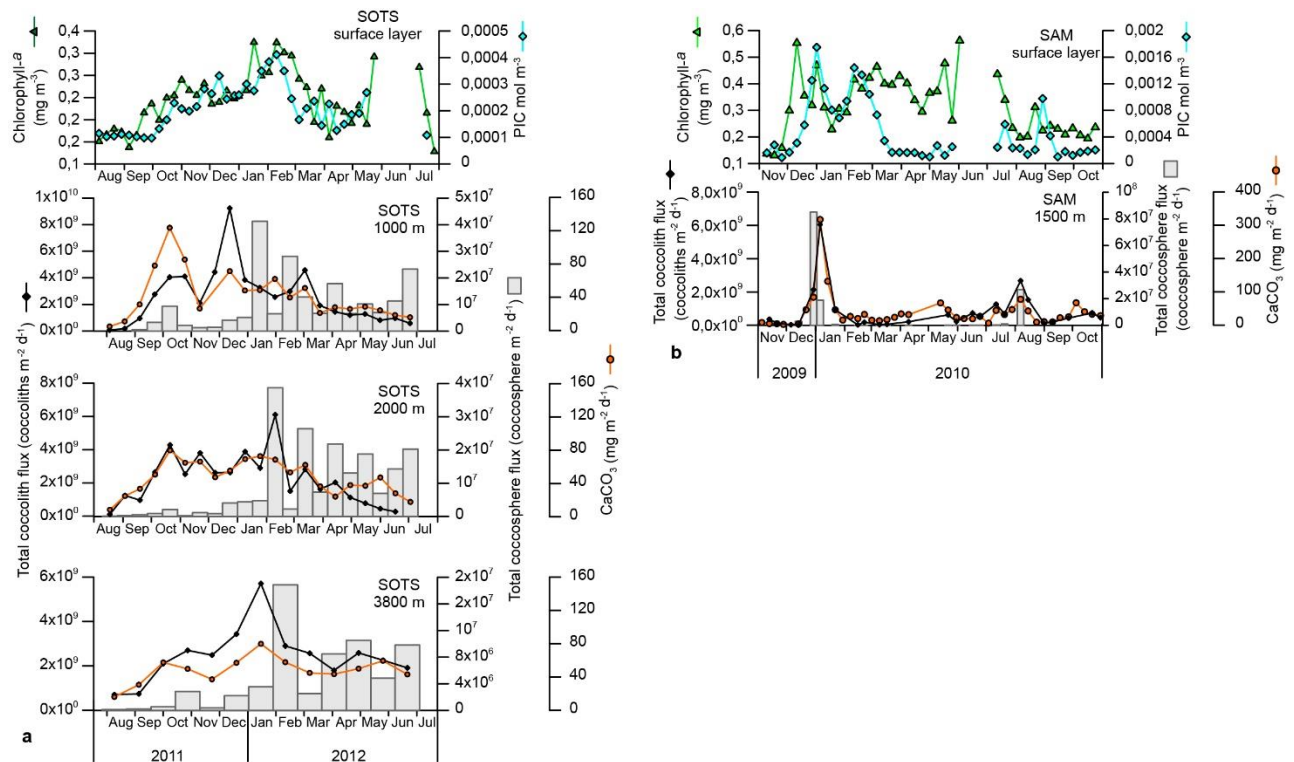

345 **3. RESULTS**

346 **3.1 Magnitude and seasonality of coccolithophore and CaCO_3 fluxes**

347 Annualized coccolith fluxes were similar at the SOTS three trap depths, with 8.6,
348 7.3 and 8.6 x 10¹¹ liths m⁻² yr⁻¹ at 1000, 2000 and 3800 m respectively, and about three

349 times larger than those of the SAM site (3.0×10^{11} liths $\text{m}^{-2} \text{yr}^{-1}$). The contribution of
350 intact coccospheres to the total coccolith export was low at both sites, with annual
351 coccosphere fluxes two orders of magnitude lower than coccolith fluxes at SOTS (3.5,
352 3.3 and 1.8×10^9 coccospheres $\text{m}^{-2} \text{yr}^{-1}$ at 1000, 2000 and 3800 m, respectively) and SAM
353 (2.2×10^9 coccospheres $\text{m}^{-2} \text{yr}^{-1}$). Annualized CaCO_3 export was similar at both sites with
354 14.6, 16.2 and 17.1 $\text{g m}^{-2} \text{yr}^{-1}$ at 1000, 2000 and 3800 m at the SOTS site and 13.9 g m^{-2}
355 yr^{-1} at the SAM sediment trap (1500 m).

356 Both coccolith and coccosphere fluxes displayed a marked seasonality that
357 followed the general trend of algal biomass accumulation in the surface waters at the
358 SOTS and SAM sites (Fig. 2). Coccolith fluxes at 1000 m started to increase in early
359 October and remained above the threshold of 1×10^9 coccoliths $\text{m}^2 \text{d}^{-1}$ until mid-April
360 (Fig. 2). Three maxima were recorded during the period of high coccolith export:
361 October-early November 2011 (4×10^9 coccoliths $\text{m}^2 \text{d}^{-1}$), late December 2011 (9×10^9
362 coccoliths $\text{m}^2 \text{d}^{-1}$) and March 2012 (4×10^9 coccoliths $\text{m}^2 \text{d}^{-1}$). Coccolith fluxes of the
363 main coccolithophore species generally followed the similar seasonal pattern to that of
364 the total coccolith flux (Supplementary figure 1) and are not discussed further.
365 Coccolithophore fluxes registered by the 2000 and 3800 m sediment traps followed a
366 generally similar seasonal pattern to those of the shallower trap at the SOTS site (Fig. 2).
367 At SAM, coccolith fluxes exhibited a strong seasonality with peak fluxes in early January
368 2010 (up to 6×10^9 coccoliths $\text{m}^2 \text{d}^{-1}$) and a secondary peak in August 2010 (3×10^9
369 coccoliths $\text{m}^2 \text{d}^{-1}$). Coccosphere fluxes at both sites displayed maximum fluxes during the
370 austral summer and minima during winter; however maximum coccosphere export peaks
371 did not always match those of coccolith export (Fig. 2). The seasonality of total CaCO_3
372 followed a similar pattern to coccolith fluxes with peak values in the spring-summer and
373 minima during winter at both study sites.

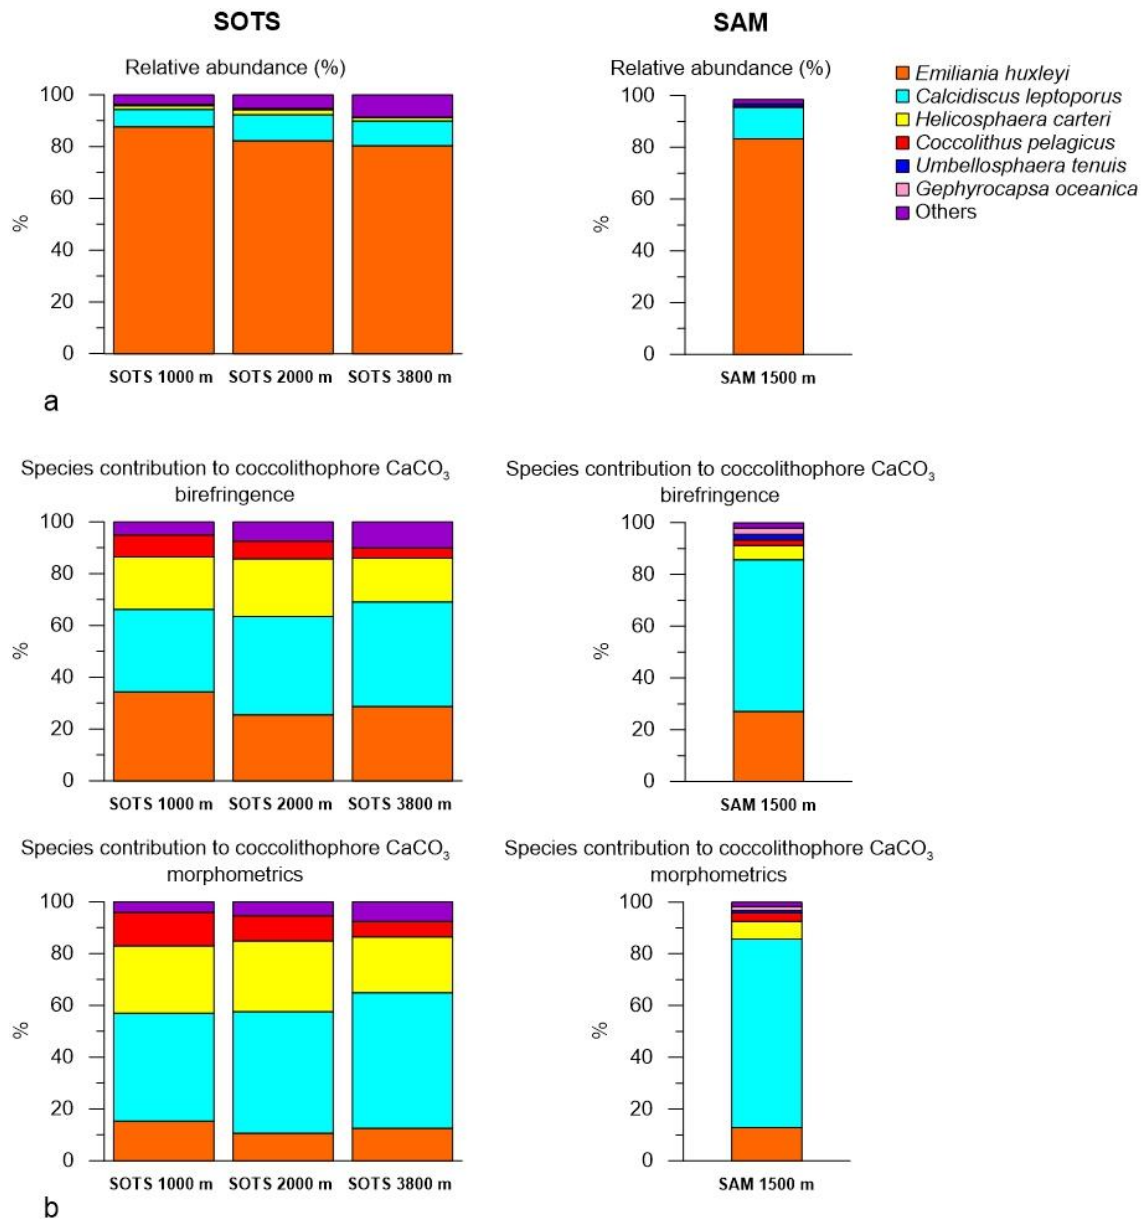

374

375 **Figure 2: Ocean-colour** satellite-derived chlorophyll-*a* and Particulate Inorganic Carbon
 376 (PIC) concentration in the surface layer and total CaCO₃, coccolith and coccosphere
 377 fluxes registered by the sediment traps at the SOTS (a) and SAM (b) sites.

378 **3.2. Coccolithophore assemblage composition**

379 Coccolith sinking assemblages were overwhelmingly dominated by *Emiliana*
 380 *huxleyi* for all sediment trap records analysed (Fig. 3a). At the SOTS site, the annualized
 381 flux-weighted relative contribution of *E. huxleyi* decreased slightly with depth,
 382 comprising 88% of the total coccolithophore assemblage at 1000 m, 82% at 2000 m and
 383 80% at 3800 m. Secondary components of the coccolith sinking assemblage were
 384 *Calcidiscus leptoporus (sensu lato)* (6.8, 10.1 and 9.6% at 1000, 2000 and 3900 m,
 385 respectively), *Helicosphaera carteri* (1.4, 2 and 1.3%) and small *Gephyrocapsa* spp. (<
 386 3 μm) (1.4, 1.5 and 4.7%). Background concentrations (≤ 1%) of *Calciosolenia* spp.,
 387 *Coccolithus pelagicus*, *Gephyrocapsa muelleriae*, *Gephyrocapsa oceanica*,
 388 *Gephyrocapsa* spp. (> 3 μm), *Syracosphaera pulchra*, *Syracosphaera* spp.,
 389 *Umbellosphaera tenuis (sensu lato)*, and *Umbilicosphaera sibogae* were also registered.
 390 At the SAM site, *E. huxleyi* accounted for 83% of the annualized coccolith flux, with
 391 subordinate contributions of *C. leptoporus* (12.2%) and *Gephyrocapsa* spp. (< 3 μm)
 392 (1.5%). Background concentrations (< 1%) of *Calciosolenia* spp., *Coccolithus pelagicus*,

393 *G. oceanica*, *Gephyrocapsa muellerae*, *Gephyrocapsa* spp. (> 3 μm), *H. carteri*,
 394 *Syracosphaera pulchra*, *Syracosphaera* spp., *U. sibogae* and *U. tenuis* were observed.

395 **Figure 3:** a. Annualized integrated relative abundance of the most important
 396 coccolithophore species in the SOTS and SAM sediment trap records. b. Fractional
 397 contribution of coccolithophore species to total coccolithophore CaCO₃ export in the
 398 SOTS and SAM sediment traps.

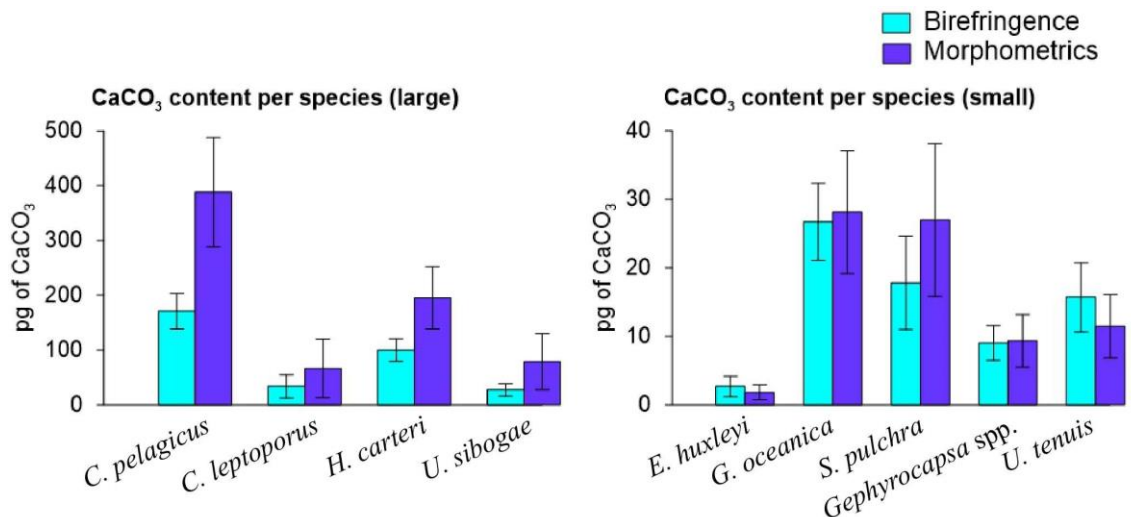

399 3.3 Calcite content per species

400 Coccolith length and mass for all species measured using birefringence and
 401 morphometric techniques are provided in Table 1. Overall, the average coccolith mass
 402 estimates for the coccolithophore species at SOTS and SAM sites using both approaches

403 are within the range of values in the published literature. The Noelaerhabdaceae family
 404 members, *G. oceanica* and *Gephyrocapsa* spp., display almost identical mass values with
 405 both approaches (Fig. 4). In contrast, substantial discrepancies are identifiable for *C.*
 406 *pelagicus*, *C. leptoporus*, *H. carteri* and *U. sibogae*, for which coccolith mass estimates
 407 are about two-fold greater using morphometrics than with the birefringence approach.
 408 The range of annual contributions of coccolithophores to carbonate is illustrated in Figure
 409 5.

 414 (1990), (4) Poulton et al. (2010), (5) Poulton et al. (2011), (6) Holligan et al. (2010) and
 415 (7) Charalampopoulou et al. (2016). * coccolith mass range obtained applying the
 416 minimum and maximum k_s values for *E. huxleyi* found in the literature (i.e. 0.015 and
 417 0.04, respectively).

418

419 **Figure 4:** Average and standard deviation of the coccolith mass estimates of the most
 420 important coccolithophore species captured by the SOTS and SAM sediment traps using
 421 birefringence (C-Calcita) and morphometric approaches. For *E. huxleyi*, the
 422 morphometric-based coccolith mass estimate was calculated by applying a mean shape
 423 factor constant (k_s) value estimated from the range of all the morphotypes found at the
 424 SAZ (i.e. $k_s = 0.0275$, Table 1).

425

426 **Figure 5: Total annual CaCO₃ export (chemically determined) and fractional**
 427 **contribution of coccolithophores to CaCO₃** estimated using birefringence (C-Calcita)
 428 and morphometric approaches for the SOTS and SAM sites.

429 4. Discussion

430 4.1 Coccolithophore phenology in the SAZ: satellite versus sediment trap records

431 Total coccolith flux seasonality at the SOTS site shows good congruence with satellite-
432 derived PIC in the surface layer, with both parameters suggesting enhanced
433 coccolithophore productivity between October and March (austral mid-spring to early
434 autumn; Fig. 2a). Interestingly, substantial coccosphere export ($> 1 \times 10^7$ coccospheres
435 $\text{m}^2 \text{d}^{-1}$) does not occur until January indicating that coccolith and coccosphere export are
436 not tightly coupled in the subantarctic waters south of Australia. Two different processes
437 could be invoked to explain the mismatch between coccolith and coccosphere fluxes at
438 this site. Firstly, *E. huxleyi*, the dominant coccolithophore species in the Southern Ocean,
439 is able to produce coccoliths rapidly (up to three coccoliths per hour; Paasche, 1962;
440 Balch et al., 1996) and shed the excess of coccoliths into the surrounding water under
441 certain environmental conditions (Paasche, 2002). Although the coccolith shedding rate
442 of *E. huxleyi* increases linearly with cellular growth rate (Fritz and Balch, 1996; Fritz,
443 1999), the tiny size and low weight of detached coccoliths allow them to remain in the
444 upper water column long after cell numbers have begun to decline. It follows that high
445 concentrations of detached coccoliths do not necessary imply a proportional abundance
446 of coccospheres in the surface layer (Tyrrell and Merico, 2004; Poulton et al., 2013) or in
447 the traps. Additionally, a substantial fraction of the coccospheres produced in the surface
448 layer may experience substantial mechanical breakage by zooplankton before reaching
449 the trap depths. Indeed, microzooplankton grazing pressure can remove up to 82% of
450 primary production in mid-summer in the subantarctic waters south of Tasmania
451 (Ebersbach et al., 2011) and about 60% of the daily coccolithophore growth in the North
452 Atlantic (Mayers et al., 2019), therefore suggesting a strong top-down control on
453 coccolithophore populations. Additionally, a polyacrylamide gel sediment traps study in
454 the subantarctic waters south of Tasmania by Ebersbach et al. (2011) revealed that most
455 of the particles exported out the mixed layer during the productive period occur in the
456 form of faecal aggregates. Therefore, it is highly likely that: (i) the intensity of
457 coccosphere export registered by the traps is influenced by grazing pressure in the surface
458 layer, and (ii) that the impact of grazing on coccolithophores varies throughout the year
459 (Calbet et al., 2008; Lawrence and Menden-Deuer, 2012; Quéguiner, 2013).

460 In contrast, seasonal variations in satellite-derived PIC concentration and
461 coccolith fluxes at SAM show some discrepancies not observed at SOTS. While
462 maximum PIC concentrations in the surface layer and coccolith and coccosphere fluxes
463 co-occur in December and January (austral early to mid-summer), satellite-derived PIC
464 suggests a secondary maximum in February-early-March not recorded by the trap (Fig.

465 2b). One possibility is that the satellite secondary maximum is not coccoliths. The higher
466 chlorophyll-a levels at the SAM site (Fig. 2) suggests that other phytoplankton groups,
467 such as diatoms, are more abundant than in the subantarctic waters south of Tasmania.
468 Empty and broken diatom valves have been suggested to display similar spectral
469 characteristics than those of coccolithophore blooms (Broerse et al., 2003; Tyrrell and
470 Merico, 2004; Winter et al., 2014). Therefore, the second peak in satellite-derived PIC
471 could have been caused by a senescent diatom bloom. This hypothesis is likely since
472 diatom blooms in the SAZ are known to develop early in the productive season (Rigual-
473 Hernández et al., 2015b) and rapidly decay following the depletion of silicate and/or iron
474 stocks in the surface layer (Lannuzel et al., 2011). However, no secondary late summer
475 maximum was observed in biogenic silica fluxes in the SAM. Another possible
476 explanation is a contribution to the satellite record from lithogenic material or storm-
477 induced microbubble injection (Zhang et al., 2002). Fully resolving causes of mismatches
478 between *in-situ* and satellite PIC estimates is not achievable for the SAM site (nor more
479 broadly for the Southern Ocean; Trull et al., 2018).

480 A second difference between the SAM and SOTS sites is that maximum annual
481 coccosphere export occurred one week earlier than maximum coccolith fluxes at SAM,
482 (Fig. 2). The different seasonalities between the sites suggest that different export
483 mechanisms may operate. The formation of rapidly sinking algal aggregates by diatoms
484 is known to scavenge particles they have collided with and increase particle sinking
485 (Alldredge and McGillivray, 1991; Passow and De La Rocha, 2006), thus the formation
486 of such rapid-sinking aggregates could potentially facilitate the preservation of
487 coccospheres early in the productive season at the SAM site. However, the lack of
488 accompanying *in situ* information on plankton community structure in the study region
489 precludes the assessment of these hypotheses.

490 Despite the uncertainties involved in our interpretations, the overall picture that
491 emerges from our comparison of satellite and sediment trap flux data is that the duration
492 of the coccolithophore bloom based on ocean-colour-based PIC concentrations most
493 likely provides an over-estimation of the coccolithophore productive season. Our
494 observations motivate caution in describing coccolithophore phenology solely based on
495 satellite-derived PIC concentrations (e.g. Hopkins et al., 2015).

496

497 **4.2 Magnitude and composition of subantarctic coccolithophore assemblages**

498 Annual coccolith export across the major zonal systems of the Australian sector
499 of the Southern Ocean exhibits a clear latitudinal gradient, with maximum fluxes at the
500 SAZ (8.6×10^{11} liths $m^{-2} yr^{-1}$) and eight-fold lower fluxes in the polar waters of the AZ
501 (1.0×10^{11} liths $m^{-2} yr^{-1}$; Rigual Hernández et al., 2018). Coccolithophore species
502 occurrence documented by our subantarctic sediments traps are consistent with previous
503 reports on coccolithophore assemblage compositions in the surface layer (Findlay and
504 Giraudeau, 2000; Saavedra-Pellitero et al., 2014; Malinverno et al., 2015; Chang and
505 Northcote, 2016) and sediments (Findlay and Giraudeau, 2000; Saavedra-Pellitero and
506 Baumann, 2015) and are more diverse than those found in the AZ (Rigual Hernández et
507 al., 2018). The southward decline in coccolithophore abundance and diversity is most
508 likely due to the decrease in sea-surface temperature (SST) and light availability moving
509 poleward (Charalampopoulou et al., 2016; Trull et al., 2018). In particular, the close
510 relationship between temperature and growth rates has been demonstrated in a range of
511 coccolithophore species and strains (Buitenhuis et al., 2008), and seems to be a critical,
512 if not the most important, control on the biogeographical distribution of coccolithophore
513 species in the Southern Ocean (Trull et al., 2018). This pronounced latitudinal change in
514 coccolithophore assemblage composition contrasts with the little longitudinal variability
515 between the subantarctic SOTS and SAM sites (Fig. 3). These observations underscore
516 the role of circumpolar fronts as natural physical barriers for plankton species distribution
517 in the Southern Ocean (Medlin et al., 1994; Boyd, 2002; Cook et al., 2013).

518 Notably, the rare occurrence of the cold-water species *Coccolithus pelagicus* at
519 the SOTS and SAM sites contrasts with the high contribution of *C. pelagicus* to the living
520 coccolithophore communities in the subpolar and polar waters of the North Atlantic and
521 North Pacific oceans, where it is often the second most abundant species after *E. huxleyi*
522 (McIntyre and Bé, 1967; Baumann et al., 2000; Broerse et al., 2000a; Broerse et al.,
523 2000b; Ziveri et al., 2000). This important difference in species composition between
524 Northern and Southern hemisphere subpolar ecosystems could have important
525 implications in the calibration of the satellite PIC signal in the Southern Ocean. Previous
526 research in the Southern Ocean comparing satellite and shipboard observations identified
527 a substantial over-estimation of coccolithophore PIC in the Southern Ocean waters by
528 satellite ocean-colour-based PIC algorithms (Holligan et al., 2010; Trull et al., 2018).
529 Since satellite reflectance observations are mainly calibrated against Northern
530 Hemisphere PIC results (Balch et al., 2011; Balch et al., 2016), the lower the calcite
531 content of dominant *E. huxleyi* morphotypes (B/C) in the Southern Ocean compared to

532 their northern hemispheric counterparts has been suggested as a possible factor causing
533 the over-estimation of PIC concentrations in the Southern Ocean. Following this
534 reasoning, we speculate that differences in other components of the coccolithophore
535 assemblages, and particularly, differences in *C. pelagicus* numbers, could contribute to
536 the over-estimation of PIC concentrations by the satellite PIC algorithm in the Southern
537 Ocean. Indeed, the scaling of reflectance (in satellite images) to PIC (in ocean) is very
538 dependent on coccolith area:mass ratios (Gordon and Du, 2001; Balch et al., 2005a).
539 *Coccolithus pelagicus* has remarkably heavier and thicker coccoliths (100-400 pg per
540 coccolith; Table 1) than *E. huxleyi* (~3 pg per coccolith), i.e. about 100 times heavier.
541 However, the average coccolith area of *C. pelagicus* is only about ten times greater than
542 that of *E. huxleyi*. Thus, this lack of proportional relationship between area and mass
543 between these species should be taken into consideration when calibrating the satellite
544 signals of coccolithophore-related PIC in the Southern Ocean. However, it should be
545 noted that this is only one possible factor contributing to the overestimation of PIC
546 concentrations in Southern Ocean waters. Other factors such as the presence of
547 microbubbles -- that are a source of enhanced reflectance -- must also play an important
548 role (Balch et al., 2011).

549

550 **4.3 Coccolith calcite content of subantarctic coccolithophore species**

551 Multiple methodological biases associated with each of the methods used for
552 estimating coccolith calcite content (i.e. birefringence, morphometrics) could be invoked
553 to explain the different estimates observed for some of the species (see Young and Ziveri,
554 2000; Fuertes et al., 2014 and references therein). However, the fact that these
555 discrepancies vary greatly across species suggests that the composition of the crystal-
556 units of the coccoliths could be the most important factor causing these differences. All
557 the heterococcoliths of the species analysed are mainly composed of either V- or R-
558 calcite crystal units or a combination of both (Young et al., 2003; Table 1). R units are
559 characterized by sub-radial c-axes that are reasonably well measured by the birefringence
560 technique, but, the almost vertical optical axes of the V units (Young, 1992; Young et al.,
561 1999) make the same thickness less birefringent (Fuertes et al., 2014). Thus, it is likely
562 that differences in the birefringence properties of the R and V units could be responsible
563 for the different estimates provided by the two approaches. This is supported by our
564 results which show coccolith mass estimates of those species composed of R units, such

565 as *G. oceanica* and *Gephyrocapsa* spp. exhibit almost identical values with both
566 techniques (Table 1). In contrast, those species with coccoliths composed by a
567 combination of R and V units, such as *C. pelagicus*, *C. leptoporus*, *H. carteri* and *U.*
568 *sibogae*, display divergent mass estimates between approaches. The case of *E. huxleyi* is
569 more complex due to the large intraspecific genetic variability that results in substantial
570 differences in the profile and degree of calcification between specimens (Young and
571 Ziveri, 2000). Our birefringence mass estimate for *E. huxleyi* (2.67 ± 1.49 pg) is less than
572 one picogram lower than the mean range value calculated with the morphometric
573 technique (i.e. 1.81 ± 1.10 pg with an average k_s value of all the morphotypes found at
574 the SAZ, i.e. $k_s = 0.0275$), but identical to the maximum (2.64 ± 1.60 pg; using $k_s = 0.04$).
575 These results suggest a reasonably good consistency between techniques for *E. huxleyi*.

576 Taking into consideration all the above, it is likely that the coccolith mass of some
577 species is underestimated by the birefringence technique, and therefore, the fractional
578 contribution of coccolithophores to total PIC using this approach should be taken as a
579 conservative estimate. Since both methods for estimating calcite content have inherent
580 uncertainties, the range of values provided by both techniques is used here as an
581 approximation of the fractional contribution of coccolithophores to total annual CaCO_3
582 export to the deep sea in the Australian and New Zealand sectors of the SAZ.

583 **4.4 Contribution of coccolithophores to carbonate export in the Australian-New** 584 **Zealand sectors of the Southern Ocean**

585 The magnitude of the total PIC export in the subantarctic waters was similar
586 between the SOTS and SAM sites (range $14\text{-}17$ g m^{-2} yr^{-1}), and thus slightly above the
587 global average (11 g m^{-2} yr^{-1} ; Honjo et al., 2008). Our estimates indicate that
588 coccolithophores are major contributors to CaCO_3 export in the Australian and New
589 Zealand waters of the SAZ, accounting for 40-60% and 15-25% of the annual CaCO_3
590 export, respectively (Fig. 5). Heterotrophic calcifiers, mainly planktonic foraminifera
591 (Salter et al., 2014), must therefore account for the remainder of the annual CaCO_3 export
592 at both sites. Previous work on foraminifera fluxes in our study regions allows an
593 approximate estimate of the contribution of foraminifera to total CaCO_3 flux that can be
594 used to assess the validity of our estimates. Combining counts of foraminifera
595 shells (King and Howard, 2003) with estimates of their average shell weights ($20\text{-}40$ μg
596 per shell depending on size; Moy et al., 2009) suggests contributions of 1/3 to 2/3 of
597 planktonic foraminifera to the total CaCO_3 flux in the Australian SAZ (Trull et al., 2018).

598 In the subantarctic waters south of New Zealand, Northcote and Neil (2005) estimated
599 that planktonic foraminifera accounted for about 78-97% of the total CaCO₃. Thus,
600 estimations of the contribution of heterotrophic calcifiers to total carbonate in both study
601 regions are in reasonable agreement with our coccolithophore CaCO₃ estimates at both
602 sites. The lower contribution of coccolithophores to CaCO₃ export at the SAM site in
603 comparison with that of SOTS may be explained by differences in the ecosystem structure
604 between sites. Algal biomass accumulation in the surface waters of the SAM region
605 (average chlorophyll-*a* concentration between 2002 and 2018 is 0.31 mg m⁻³) is
606 substantially higher than that at SOTS (0.23 mg m⁻³). We speculate that the higher
607 abundance of non-calcareous phytoplankton (e.g. diatoms) in the subantarctic waters
608 south of New Zealand could simultaneously reduce coccolithophore biomass through
609 resource competition (Quéré et al., 2005; Sinha et al., 2010) while stimulating
610 foraminifera growth (Schiebel et al., 2017). The combination of both factors could be
611 responsible for the lower coccolithophore productivity at the SAM site despite similar
612 total CaCO₃ export. Assuming that both the SOTS and SAM sites can be considered
613 representative of a broad longitudinal swath of the SAZ south of Australia and New
614 Zealand (ca. 1% of areal extent of the global ocean), the coccolithophore CaCO₃ export
615 in these two regions together account for approximately 0.4 Tmol C_{inorg} yr⁻¹. This value
616 represents approximately 1% of the global annual PIC export to the deep ocean (Honjo et
617 al., 2008) and underscores the notion that the high nutrient low-chlorophyll waters of the
618 circumpolar SAZ should not be taken as indicative of low biological activity or export.

619 Our results indicate that although *E. huxleyi* overwhelmingly dominates the
620 coccolithophore sinking assemblages at both study sites, other species with lower relative
621 contribution but substantially heavier coccoliths are more important contributors to the
622 annual coccolithophore CaCO₃ export budget (Fig. 3). Particularly relevant is the case of
623 *C. leptoporus* that despite its relatively low abundance (~ 10% of the annual assemblage
624 at both sites; Fig. 3), it accounts for between 30-50% and 60-70% of the annual
625 coccolithophore-CaCO₃ export at the SOTS and SAM sites, respectively (Fig. 3).
626 Similarly, other species with heavy coccoliths, such as *H. carteri* and *C. pelagicus*, are
627 important contributors to the annual coccolithophore PIC export to the deep sea (up to
628 ~30% and ~10% of the annual coccolithophore PIC, respectively) despite their low annual
629 relative abundance (<2% at both sites) (Fig. 3). These results serve as an important
630 reminder that it is often not the most abundant species, but rather the largest

631 coccolithophore species that account for the greatest contribution to coccolithophore
632 CaCO₃ production and export (Young and Ziveri, 2000; Baumann et al., 2004; Daniels et
633 al., 2016).

634 The important contribution made by the coccolithophore community in setting the
635 magnitude of carbonate production and export to the deep sea is evidenced when we
636 compare the coccolith and total CaCO₃ fluxes of the SOTS sediment trap with those
637 deployed in the AZ along the 140°E meridian (Fig. 1). Although both total and
638 coccolithophore CaCO₃ export decrease with increasing latitude these changes are largely
639 uneven. While total CaCO₃ decreases two-fold from the SAZ to the AZ, coccolithophore
640 CaCO₃ export decreases 28-fold (Supplement Figure 2). This lack of proportional
641 latitudinal change can be attributed to two main factors. First, subantarctic
642 coccolithophore populations are diverse and relatively rich in species with large and
643 heavy coccoliths such as *C. leptoporus* or *H. carteri* that account for a large fraction of
644 the annual carbonate production and export. South of the PF, assemblages become
645 monospecific, or nearly monospecific, dominated by the small and relatively lightly
646 calcified *E. huxleyi*. Second, latitudinal variations in the abundance of heterotrophic
647 calcifiers (mainly foraminifera but also pteropods) must play a major role in modulating
648 the observed variations in CaCO₃ export. In particular, our data suggests that the
649 fractional contribution of heterotrophic calcifiers to CaCO₃ production increases from
650 ~40-60 % in the Australian SAZ to up to 95% in the AZ (Rigual Hernández et al., 2018).
651 This pattern is consistent with previous shipboard and sediment trap studies that reported
652 higher abundances of planktonic foraminifera at the PFZ and AZ compared to that of the
653 SAZ in the Australian sector (King and Howard, 2003; Trull et al., 2018). Controls on the
654 biogeographic distribution of foraminifera species are complex and beyond the scope of
655 this paper, however, we provide a few observations. Both temperature and diet are critical
656 factors controlling the spatial distribution of planktonic foraminifera species. In
657 particular, the lower temperatures south of the SAF seem to favour the development of
658 *Neogloboquadrina pachyderma* sin. and *Turborotalita quinqueloba* as indicated by the
659 high abundance of these species in the PFZ (> 80% of the annual integrated flux for both
660 species together; King and Howard, 2003). Additionally, the dramatically different algal
661 communities dwelling in each zonal system may also play a role in planktonic
662 foraminifera species distributions. In particular, diatoms can account for a major part of
663 the diet of some foraminifera species, including *N. pachyderma* (Schiebel and Hemleben,

664 2017). Therefore, it is likely that the preferential grazing on diatoms of some foraminifera
665 species may play an important role in the increase of foraminifera CaCO₃ production
666 moving poleward.

667

668 **4.5 Future predictions of coccolithophore community response to environmental** 669 **change in the subantarctic zone**

670 The response of *E. huxleyi* to environmental change has been extensively studied
671 in laboratory experiments (Meyer and Riebesell, 2015; Müller et al., 2015; Feng et al.,
672 2017) and the available information is sufficient to propose possible changes of its niche
673 and calcification in the Southern Ocean, as discussed in detail in Trull et al. (2018) and
674 Krumhardt et al. (2017). Due to the ubiquity and abundance of *E. huxleyi*, the
675 ecophysiology of this species is often regarded as typical of all coccolithophores.
676 However, *E. huxleyi* is rather different from most other coccolithophore species in that its
677 physiological adaptations place it in the upper limit of the *r-K* ecological gradient of these
678 organisms (i.e. an opportunistic species), while most of the other species are located at
679 the opposite end of the spectrum (i.e. conservative or K-selected species) (Probert and
680 Houdan, 2004). Our results demonstrate that *E. huxleyi* plays an important, but not
681 dominant role in CaCO₃ export, with other species such as *C. leptoporus*, *H. carteri* or *C.*
682 *pelagicus* making a larger contribution to the annual CaCO₃ export in the SAZ (Fig. 3).
683 Therefore, it is of critical importance to evaluate how these other biogeochemically
684 important coccolithophore species will respond to projected climate-induced changes in
685 the Southern Ocean. Here, we now assess the response of large coccolithophore species
686 to projected changes in temperature and carbonate chemistry, that have been highlighted
687 among the most important environmental stressors expected to impact Southern Ocean
688 coccolithophore physiological rates (Müller et al., 2015; Charalampopoulou et al., 2016;
689 Feng et al., 2017; Trull et al., 2018).

690 The Southern Ocean is warming rapidly (Gille, 2002; Böning et al., 2008), largely
691 due to the southward migration of the ACC fronts (Sokolov and Rintoul, 2009). Only
692 between 1992 and 2007 the position of Southern Ocean fronts shifted by approximately
693 60 km to the south (Sokolov and Rintoul, 2009) and this trend may continue throughout
694 the next century. Therefore, it is likely that any further southward migration of ACC
695 fronts will be coupled with an expansion of subantarctic coccolithophore species towards
696 higher latitudes. The poleward expansion of *E. huxleyi* geographic range has already been

697 suggested in the Southern Ocean (Cubillos et al., 2007; Winter et al., 2014;
698 Charalampopoulou et al., 2016) and it also appears to be occurring in the North Atlantic
699 (Rivero-Calle et al., 2015; Neukermans et al., 2018). Given the important contribution of
700 large subantarctic coccolithophore species to CaCO₃ export, the expansion of their
701 ecological niche could result in a substantial increase in CaCO₃ production and export in
702 the Southern Ocean. However, this may not be the future scenario for the SAZ southeast
703 on New Zealand, where bathymetry strongly controls the location of ocean fronts
704 (Fernandez et al., 2014; Chiswell et al., 2015). If the fronts are bathymetrically ‘locked’,
705 then the SAZ will not expand in areal extent, although the region is still predicted to
706 undergo significant physical, biogeochemical and biological changes (Law et al., 2017)
707 that will have likely flow-on effects on coccolithophore productivity and export
708 (Deppeler and Davidson, 2017).

709 The available carbonate chemistry manipulation experiments with *C. leptoporus*
710 have come to different conclusions. While some studies identified an increase in coccolith
711 malformations with increasing CO₂ concentrations (Langer et al., 2006; Langer and Bode,
712 2011; Diner et al., 2015), another study (Fiorini et al., 2011) reported no changes in the
713 calcification of *C. leptoporus* at elevated *p*CO₂. Interestingly, *C. leptoporus* did not
714 experience changes in its photosynthesis rates over the tested CO₂ range in any of the
715 aforementioned studies. The most likely explanation for the different results between the
716 studies is a strain-specific variable responses to changing carbonate chemistry (Diner et
717 al., 2015). Strain-specific variability in response to changing carbonate chemistry has
718 been previously reported in other coccolithophores, such as *E. huxleyi* (Langer et al.,
719 2009; Müller et al., 2015), and therefore it is likely that this also occurs in other species.
720 Given the fact that Southern Ocean fronts act as barriers for species distributions and gene
721 flows (Medlin et al., 1994; Patarnello et al., 1996; Thornhill et al., 2008; Cook et al.,
722 2013), it is possible that the subantarctic *C. leptoporus* populations exhibit a different
723 ecophysiology than those used in the above mentioned laboratory experiments. Prediction
724 of the responses of *H. carteri* and *C. pelagicus* is even more challenging due to the lack
725 of experiments testing the response of these species to changing seawater carbonate
726 chemistry. The only available insights in the response of one of these species to ocean
727 acidification are found in the fossil record. Both Gibbs et al. (2013) and O’Dea et al.
728 (2014) reconstructed the evolution of *C. pelagicus* populations during the Palaeocene-
729 Eocene Thermal Maximum (PETM), a period arguably regarded as the best geological
730 approximation of the present rapid rise in atmospheric CO₂ levels and temperatures.

731 These studies concluded that *C. pelagicus* most likely reduced its growth rates and
732 calcification during this period. This limited number of studies suggest that the ongoing
733 ocean acidification in the Southern Ocean could potentially have a negative impact on the
734 physiological rates of *C. leptoporus* and *C. pelagicus* while the effect on *H. carteri* is
735 unknown. Physiological response experiments (e.g. Müller et al., 2015) with Southern
736 Ocean strains of *C. leptoporus*, *H. carteri* and *C. pelagicus* are, therefore, urgently needed
737 to be able to quantify the effect of projected changes in oceanic conditions in the SAZ on
738 their physiological rates and consequent effects on carbon cycling in the Southern Ocean.

739 Our synthesis suggests opposing influence of environmental stressors on
740 subantarctic coccolithophore populations. Poleward migration of fronts will likely
741 increase coccolithophore CaCO₃ production in the Southern Ocean, while changes in
742 carbonate chemistry speciation will reduce growth rates of subantarctic coccolithophores.
743 It seems possible that coccolithophores will initially expand southward as waters warm
744 and fronts migrate, but then eventually diminish as acidification overwhelms those
745 changes.

746

747 **Acknowledgments**

748 This project has received funding from the European Union's Horizon 2020 research and
749 innovation programme under the Marie Skłodowska-Curie grant agreement number
750 748690 – SONAR-CO2 (ARH, JAF and FA). The SOTS mooring work was supported
751 by IMOS, the ACE CRC, and the Australian Marine National Facility. The work at SAM
752 was supported by funding provided by the New Zealand Ministry of Business, Innovation
753 and Employment and previous agencies, and most recently by NIWA's Strategic Science
754 Investment Fund. NIWA is acknowledged for providing capital grants for mooring
755 equipment purchases, and thanks to all the NIWA scientists, technicians and vessels staff,
756 who participated in the New Zealand biophysical moorings programme (2000-12).
757 Cathryn Wynn-Edwards (IMAS) provided support in sample splitting/processing and
758 laboratory analysis. Satellite Chlorophyll-*a* and PIC data sets were produced with the
759 Giovanni online data system, developed and maintained by the NASA GES DISC. We
760 thank Griet Neukermans and Alex Poulton for their constructive comments and
761 suggestions that helped improve and clarify this manuscript.

762

763 **Author contributions**

764 TWT, SDN, DMD and LN planned and performed the field experiment. ARH led the
765 coccolithophore study and performed sample processing and microscopy and image
766 analyses. AMB and ARH performed SEM analyses. ARH and SN performed numerical
767 analyses. ARH wrote the paper with feedback from all authors.

768 **Competing interests**

769 The authors declare no competing interests.

770

771 **Data Availability**

772 Morphometric data of major coccolithophore species generated during the current study are listed
773 in Table 1, while species relative abundance and species fluxes (plotted in Supplement Figure 1)
774 can be accessed in the following link:

775 https://data.aad.gov.au/metadata/records/Coccolithophore_Fluxes_SAZ_2009-2012.
