13

14 **Abstract**

15 Current peatland models generally treat vegetation as static, although plant community structure
16 is known to alter as a response to environmental change. Because the vegetation structure and
17 ecosystem functioning are tightly linked, realistic projections of peatland response to climate
18 change require including vegetation dynamics in ecosystem models. In peatlands, *Sphagnum*
19 mosses are key engineers. Moss community composition primarily follows habitat moisture
20 conditions. The species known preference along the prevailing moisture gradient might not
21 directly serve as a reliable predictor for future species compositions as water table fluctuation is
22 likely to increase. Hence, modelling the mechanisms that control the habitat preference of
23 *Sphagna* is a good first step for modelling community dynamics in peatlands. In this study, we
24 developed the Peatland Moss Simulator (PMS), simulating community dynamics of the peatland
25 moss layer. PMS is a process-based model that employs a stochastic, individual-based approach
26 simulating competition within peatland moss layer based on species differences in functional
27 traits. At the shoot-level, growth and competition were driven by net photosynthesis, which was
28 regulated by hydrological processes via capitulum water content. The model was tested by
29 predicting the habitat preferences of *S. magellanicum* and *S. fallax*, two key species representing
30 dry (hummock) and wet (lawn) habitats in a poor fen peatland (Lakkasuo, Finland). PMS
31 successfully captured the habitat preferences of the two *Sphagnum* species, based on observed
32 variations in trait properties. Our model simulation further showed that the validity of PMS
33 depended on the interspecific differences in capitulum water content being correctly specified.
34 Neglecting the water content differences led to the failure of PMS to predict the habitat
35 preferences of the species in stochastic simulations. Our work highlights the importance of

36 capitulum water content to the dynamics and carbon functioning of *Sphagnum* communities in
37 peatland ecosystems. Studies of peatland responses to changing environmental conditions thus
38 need to include capitulum water processes as a control on moss community dynamics. Our PMS
39 model could be used as an elemental design for the future development of dynamic vegetation
40 models for peatland ecosystems.

44

45 **1.Introduction**

46 Peatlands have important roles in the global carbon cycle as they store about 30% of the world's
47 soil carbon (Gorham, 1991; Hugelius et al., 2013). Environmental changes, like climate warming
48 and land-use changes, are expected to impact the carbon functioning of peatland ecosystems
49 (Tahvanainen, 2011). Predicting the functioning of peatlands under environmental changes
50 requires models to quantify the interactions among ecohydrological, ecophysiological and
51 biogeochemical processes. These processes are known to be strongly regulated by vegetation
52 (Riutta et al. 2007; Wu and Roulet, 2014), which can change over decadal time scales under
53 changing hydrological conditions (Tahvanainen, 2011). Peatland models have generally
54 considered vegetation structure unrealistically as static component (e.g. Frolking et al., 2002;
55 Wania et al., 2009). The recent regional-scale peatland model developed by Chaudhary et al.
56 (2017) includes dynamic vegetation shifts among a single moss plant functional type (PFT) and
57 four vascular PFTs but to support realistic predictions on peatland functioning and global
58 biogeochemical cycles the mechanisms that drive changes in moss community structure need to
59 be identified and integrated with ecosystem processes.

60 A major fraction of peatland biomass is formed by *Sphagnum* mosses (Hayward and Clymo,
61 1983; Vitt, 2000). Although individual *Sphagnum* species often have narrow habitat niches
62 (Johnson et al., 2015), different *Sphagnum* species replace each other along water table gradient
63 and therefore, as a genus, spread across a wide range of water table conditions (Rydin and
64 McDonald, 1985; Andrus et al. 1986; Rydin, 1993; Laine et al. 2009). The species composition
65 of the *Sphagnum* community strongly affects ecosystem processes such as carbon sequestration
66 and peat formation through interspecific variability in species traits such as photosynthetic
67 potential and litter quality (Clymo, 1970; O'Neill, 2000; Vitt, 2000; Turetsky, 2003). The
68 *Sphagnum* biomass and litter production gradually raises the moss carpet, which feeds back
69 into the species composition (Robroek et al. 2009). Hence, modelling the moss community
70 dynamics is fundamental for predicting temporal changes of peatland vegetation. As the
71 distribution of *Sphagnum* species primarily follows the variability in peatland water table

72 (Andrus 1986; Väliiranta et al. 2007), modelling the habitat preference of *Sphagnum* species
73 along a moisture gradient could be a good first step for predicting moss community dynamics
74 (Blois et al., 2013).

75 For a given *Sphagnum* species, the optimal habitat represents the environmental conditions for
76 it to achieve higher rates of net photosynthesis and shoot elongation than its peers (Titus &
77 Wagner, 1984; Rydin & McDonald, 1985; Rydin, 1997; Robroek et al., 2007a; Keuper et al.,
78 2011). Capitulum water content and water storage, which is determined by the balance between
79 the evaporative loss and water gains from capillary rise and precipitation, represents one of the
80 most important controls on net photosynthesis (Titus & Wagner, 1984; Murray et al. 1989; Van
81 Gaalen et al. 2007; Robroek et al., 2009). To quantify the water processes in mosses,
82 hydrological models have been developed to simulate the water movement between moss carpet
83 and the peat underneath, as regulated by the variations in meteorological conditions and energy
84 balance (Price, 2008; Price and Waddington, 2010). On the other hand, experimental work has
85 addressed the species-specific responses of net photosynthesis to changes in capitulum water
86 content (Titus & Wagner, 1984; Hájek and Beckett, 2008; Schipperges and Rydin, 2009) and
87 light intensity (Rice et al., 2008; Laine et al., 2011; Bengtsson et al., 2016). Net photosynthesis
88 and hydrological processes are linked via capitulum water retention, which controls the response
89 of capitulum water content to water potential changes (Jassey & Signarbieux, 2019). However,
90 these mechanisms have not been integrated with ecosystem processes in modelling.

91 Along with the capitulum water processes, modelling the habitat preference of *Sphagna*
92 requires quantification of the competition among mosses, i.e., the “race for space” (Rydin, 1993;
93 Rydin, 1997; Robroek et al., 2007a; Keuper et al., 2011): *Sphagnum* shoots can form new
94 capitula and spread laterally, if there is space available. This reduces or eliminates the light
95 source for any plant that is buried by its peers (Robroek et al. 2009). As the competition occurs
96 between neighboring shoots, its modelling requires downscaling water-energy processes from
97 the ecosystem to the shoot level. For that, *Sphagnum* competition needs to be modelled as spatial
98 processes, considering that spatial coexistence and the variations of functional traits among shoot
99 individuals may impact the community dynamics (Bolker et al., 2003; Amarasekare, 2003).
100 However, coexistence generally relies on simple coefficients to describe the interactions among
101 individuals (e.g. Czárán and Iwasa, 1998; Anderson and Neuhauser, 2000; Gassmann et al.,
102 2003; Boulangeat et al., 2018), thus being decoupled from environmental fluctuation or the
103 stochasticity of biophysiological processes.

104 This study aims to develop and test a model, the Peatland Moss Simulator (PMS), to simulate
105 community dynamics within the peatland moss layer that results in realistic habitat preference of
106 *Sphagnum* species along a moisture gradient. In PMS, community dynamics is driven by
107 *Sphagnum* photosynthesis. Photosynthesis in turn is regulated by capitulum water retention
108 through capitulum moisture content. Therefore, we hypothesize that water retention of the

109 capitula is the mechanism driving moss community dynamics. We test the model validity using
110 data from an experiment based on two *Sphagnum* species with different positions along moisture
111 gradient in the same peatland site. If our hypothesis holds, the model will (1) correctly predict
112 the competitiveness of the two species in wet and dry habitats; and (2) fail to predict
113 competitiveness if the capitulum water retention and water content of the two species are not
114 correctly specified.

115

116 **2. Materials and methods**

117 **2.1 Study site**

118 The peatland site being modelled is located in Lakkasuo, Orivesi, Finland (61° 47' N; 24° 18'
119 E). The site is a poor fen fed by mineral inflows from a nearby esker (Laine et al 2004). Most of
120 the site is formed by lawns dominated by *Sphagnum recurvum* complex (*Sphagnum fallax*,
121 accompanied by *Sphagnum flexuosum* and *Sphagnum angustifolium*) and *Sphagnum papillosum*.
122 Less than 10% of surface is occupied by hummocks, with *Sphagnum magellanicum* and
123 *Sphagnum fuscum*, being 15-25 cm higher than the lawn surfaces. Both microforms are covered
124 by continuous *Sphagnum* carpet with a sparse cover of vascular plants (projection cover of *Carex*
125 12% on average), which spread homogeneously over the topography. The annual mean water
126 table was 15.6 ± 5.0 cm deep at lawn surface (Kokkonen et al., 2019). More information about
127 the site can be found in Kokkonen et al. (2019).

128

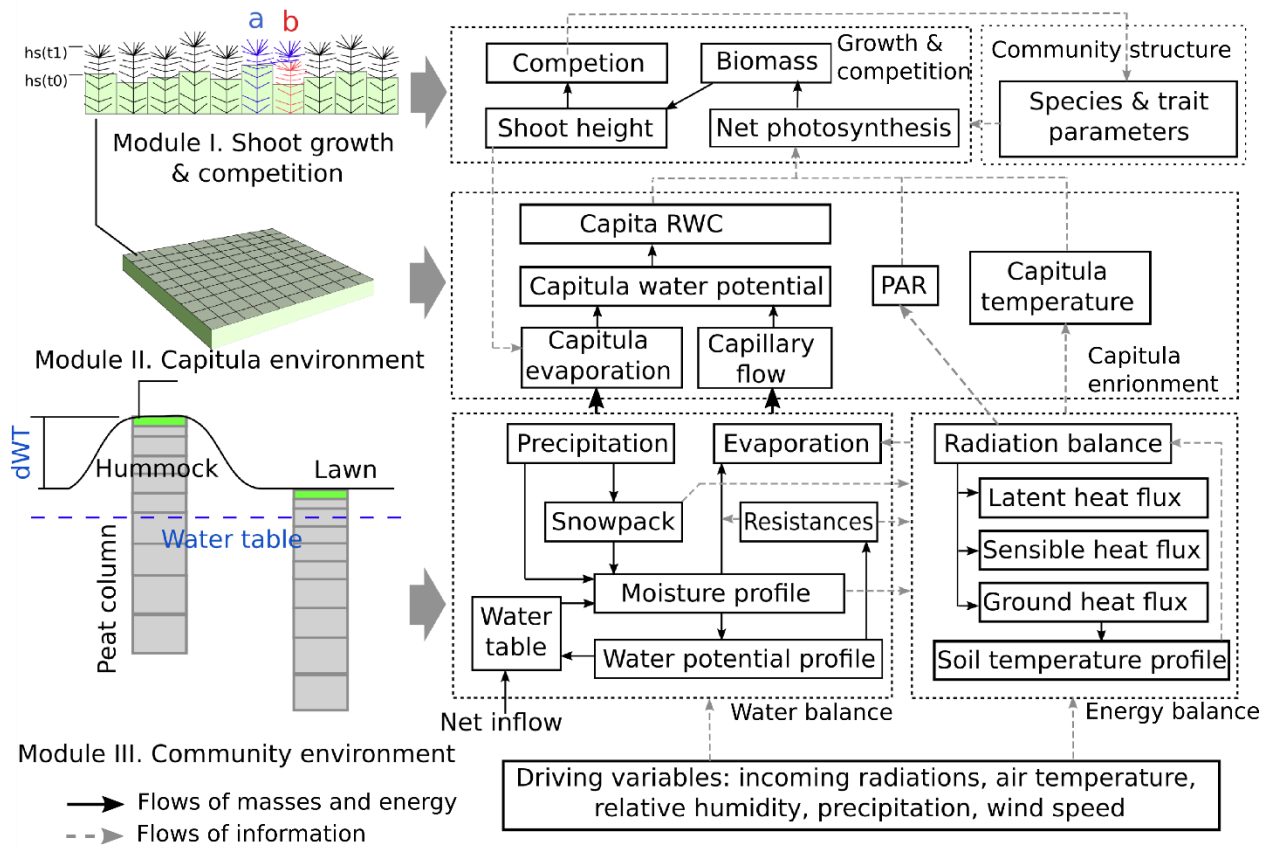

129 **2.2 Model outline**

130 The Peatland Moss Simulator (PMS) is a process-based, stochastic model, which simulates the
131 temporal dynamics of *Sphagnum* community as driven by variations in precipitation, irradiation,
132 and energy flow with individual-based interactions (Fig. 1). In PMS, the studied ecosystem is
133 seen as a dual-column system consisting of hydrologically connected habitats of hummocks and
134 lawns (community environment in Fig. 1). For each habitat type, the community area is
135 downscaled to two-dimensional cells representing the scale of individual shoots (i.e. 1 cm²).
136 Each grid cell can be occupied by one capitulum from a single *Sphagnum* species. The
137 community dynamics, i.e. the changes in species abundances, are driven by the growth and
138 competition of *Sphagnum* shoots at the grid-cell level (Module I in Fig. 1). These processes were
139 regulated by the grid-cell-specific conditions of water and energy (Module II in Fig. 1), which
140 are derived from the community environment (Module III in Fig. 1).

141 In this study, we focused on developing Module I and II (Section 2.3) and employed an
142 available soil-vegetation-atmosphere transport (SVAT) model (Gong et al., 2013a, 2016) to
143 describe the water-energy processes for Module III (Appendix A). We assumed that the temporal

144 variation in water table was similar in lawns and hummocks, and the hummock-lawn differences
 145 in water table (dWT in Fig. 1) followed their difference in surface elevations (Wilson, 2012). At
 146 the grid cell level, the photosynthesis of capitula drove the biomass growth and elongation of
 147 shoots, which led to the competition between adjacent grid cells. The net photosynthesis rate was
 148 controlled by capitulum water content (W_{cap}), which was defined by the capitulum water
 149 retention in relation to water potential (h) (Section 2.4). The values for functional traits that
 150 regulate the growth and competition processes were randomly selected within their normal
 151 distribution measured in the field (Section 2.4). Unknown parameters that related the lateral
 152 water flows of the site are estimated using a machine-learning approach (Section 2.5). Finally,
 153 Monte-Carlo simulation was used to support the analysis on the habitat preferences of *Sphagnum*
 154 species and hypothesis tests (Section 2.6). The list of used symbols is given in Table 1.

155

161 *Calculation of Sphagnum growth*

162 To model grid cell biomass production and height increment, we assumed that capitula were the
163 main parts of shoots responsible for photosynthesis and production of new tissues, instead of the
164 stem sections underneath. We employed a hyperbolic light-saturation function (Larcher, 2003) to
165 calculate the net photosynthesis, which was parameterized based on empirical measurements
166 made from the target species collected from the study site (see Appendix B for materials and
167 methods):

$$168 \quad A_{20} = \left(\frac{Pm_{20} * PPF D}{\alpha_{PPFD} + PPF D} - R_{S20} \right) * B_{cap} \quad (1)$$

169 where subscript 20 denotes the variable value measured at 20 °C; R_s is the mass-based
170 respiration rate ($\mu\text{mol g}^{-1} \text{s}^{-1}$); Pm is the mass-based rate of maximal gross photosynthesis (μmol
171 $\text{g}^{-1} \text{s}^{-1}$); $PPFD$ is the photosynthetic photon flux density ($\mu\text{mol m}^{-2} \text{s}^{-1}$); B_{cap} is the capitulum
172 biomass; and α_{PPFD} is the half-saturation point ($\mu\text{mol m}^{-2} \text{s}^{-1}$) for photosynthesis.

173 By adding multipliers for capitula water content (f_w) and temperature (f_T) to Eq. (1), the net
174 photosynthesis rate A ($\mu\text{mol m}^{-2} \text{s}^{-1}$) was calculated as following:

$$175 \quad A = \left[\frac{Pm_{20} * PPF D}{\alpha_{PPFD} + PPF D} f_T(T) - R_{S20} f_R(T) \right] * B_{cap} * f_w(W_{cap}) \quad (2)$$

176 where $f_w(W_{cap})$ describes the responses of A to capitulum water content, W_{cap} ; $f_T(T)$ describes
177 the responses of Pm to capitulum temperature T (Korrensalo et al., 2017). $f_w(W_{cap})$ was estimated
178 based on the empirical measurements (Appendix B; see Section 2.4). The temperature response
179 $f_R(T)$ is a Q_{10} function that describes the temperature sensitivity of R_s (Frolking et al., 2002):

$$180 \quad f_R(T) = Q_{10}^{(T - T_{opt})/10} \quad (3)$$

181 where Q_{10} is the sensitivity coefficient; T is the capitulum temperature (°C); T_{opt} (20 °C) is the
182 reference temperature of respiration.

183 The response of A to W_{cap} ($f_w(W_{cap})$, Eq. 2) was described as a second-order polynomial
184 function):

$$185 \quad f_w(W_{cap}) = a_{w0} + a_{w1} * W_{cap} + a_{w2} * W_{cap}^2 \quad (4)$$

186 where a_{w0} , a_{w1} and a_{w2} are coefficients.

187 Plants can store carbohydrates as nonstructural carbon (NSC, e.g. starch and soluble sugar) to
188 support fast growth in spring or post-stress periods, like after drought events (Smirnoff et al.,
189 1992; Martínez-Vilalta et al., 2016; Hartmann and Trumbore, 2016). We linked the production of
190 shoot biomass to the immobilization of NSC storage (modified from Eq. 10 in Asaeda and
191 Karunaratne, 2000). The change in NSC storage depends on the balance between net
192 photosynthesis and immobilization:

193 $M_B = s_{imm} * NSC * k_{imm} \alpha_{imm}^{T-20}$
 194 (5)

195 $\partial NSC / \partial t = A - M_B, NSC \in [0, NSC_{max}]$ (6)

196 where M_B is the immobilized NSC to biomass production during a time step (g); k_{imm} is the
 197 specific immobilization rate (g g⁻¹) (Asaeda and Karunaratne 2000); α_{imm} is the temperature
 198 constant; s_{imm} is the multiplier for temperature threshold, where $s_{imm} = 1$ when $T > 5$ °C but $s_{imm} =$
 199 0 if $T \leq 5$ °C. NSC_{max} is the maximal NSC concentration in *Sphagnum* biomass (Turetsky et al.,
 200 2008). Timing of growth is controlled by a temperature threshold and NSC availability. Growth
 201 occurs when $T > 5$ °C and NSC is above zero. The dynamics of NSC storage are related to WC
 202 through net photosynthesis.

203 The increase in shoot biomass drove the shoot elongation:

204 $\partial Hc / \partial t = \frac{M_B}{H_{spc} S_c}$ (7)

205 where Hc is the shoot height (cm); H_{spc} is the biomass density of *Sphagnum* stems (g m⁻² cm⁻¹)
 206 and S_c is the area of a cell (m²).

207

208 *Calculation of Sphagnum competition and community dynamics*

209 To simulate the competition among *Sphagnum* shoots, we first compared Hc of each grid cell
 210 (source grid cell, i.e. grid cell *a* in Fig. 1) to its four neighboring cells and marked the one with
 211 lowest position (e.g. grid cell *b* in Fig. 1) as the target of spreading. The spreading of shoots from
 212 a source to a target grid cell occurred when the following criteria were fulfilled: i) the height
 213 difference between source and target grid cells exceeded a threshold value; ii) NSC accumulation
 214 in the source grid cell was large enough to support the growth of new capitula in the target grid
 215 cell; iii) the capitula in the source grid cell can split at most once per year.

216 The threshold of height difference in rule i) was set equal to the mean diameter of capitula in
 217 the source cell, based on the assumption that the shape of a capitulum was spherical. When
 218 shoots spread, the species type and model parameters in the target grid cell were overwritten by
 219 those in the source grid cell, assuming the mortality of shoots originally in the target cell. During
 220 the spreading, NSC storage was transferred from the source cell to the target cell to form new
 221 capitula. In cases where spreading did not take place, establishment of new shoots from spores
 222 could maintain the continuity of *Sphagnum* carpet at the site. During the establishment from
 223 spores, which was rare and occurred during the first years of simulation, the traits of *Sphagnum*
 224 species were randomized within their normal distribution measured in the field.

225

226 2.3.2 Calculating grid cell-level dynamics of environmental factors (Module II)

227 Module II computes grid-cell values of W_{cap} , $PPFD$ and T for Module I. The cell-level $PPFD$
228 and T were assumed to be equal to the community means, which were solved by the SVAT
229 scheme in Module III (Appendix A.). The community level evaporation rate (E) was partitioned
230 to cell-level (E_i) as following:

$$231 \quad E_i = E * \left(\frac{Sv_i}{r_{bulk,i}} \right) / \sum \left(\frac{Sv_i}{r_{bulk,i}} \right) \quad (8)$$

232 where $r_{bulk,i}$ is the bulk surface resistance of cell i , which is as a function ($r_{bulk,i} = fr(h_i)$) of grid-
233 cell-based water potential h_i , capitulum biomass (B_{cap}) and shoot density (D_s) based on the
234 empirical measurements (Appendix B); Sv_i was the evaporative area, which was related to the
235 height differences among adjacent grid cells:

$$236 \quad Sv_i = Sc_i + lc \sum_j (Hc_i - Hc_j) \quad (9)$$

237
238 where lc is the width of a grid cell (cm); and subscript j denotes the four-nearest neighbouring
239 grid cells. In this way, changes in the height difference between the neighboring shoots feeds
240 back to affect the water conditions of the grid cells, via alteration of the evaporative surface area.

241 The grid cell-level changes in capitula water potential (h_i) were driven by the balance between
242 the evaporation (E_i) and the upward capillary flow to capitula:

$$243 \quad \partial h_i = \frac{K_m}{C_i} \left[\frac{(h_i - h_m)}{0.5z_m} - 1 - E_i \right] \quad (10)$$

244 where h_m is the water potential of the living moss layer, solved in Module III (Appendix A.); z_m
245 is the thickness of the living moss layer ($z_m=5$ cm); K_m is the hydraulic conductivity of the moss
246 layer and that is set to be the same for each grid cell; C_i is the cell-level specific water uptake
247 capacity ($C_i = \partial W_{cap,i} / \partial h_i$). $\partial W_{cap,i} / \partial h_i$ could be derived from the capitulum water retention
248 function $h_i = f_h(W_{cap})$. W_{cap} can be then calculated from the estimated from h_i and affect the
249 calculation of net photosynthesis through $f_w(W_{cap})$ (Eq. 2).

250

251 2.4 Model parameterization

252 Selection of *Sphagnum* species

253 We chose *S. fallax* and *S. magellanicum*, which form 63% of total plant cover at the study site at
254 Lakkasuo (Kokkonen et al., 2019), as the target species representing the lawn and hummock
255 habitats respectively. These species share a similar niche along the gradients of soil pH and
256 nutrient richness (Wojtuń et al., 2003), but are discriminated by their preferences of water table
257 level (Laine et al., 2004). While *S. fallax* is commonly found close to the water table (Wojtuń et

258 al., 2003), *S. magellanicum* can occur along a wider range of a dry-wet gradient, from
 259 intermediately wet lawns up to dry hummocks (Rice et al., 2008; Kyrkjeeide, et al., 2016;
 260 Korresalo et al., 2017). The transition from *S. fallax* to *S. magellanicum* along the wet-dry
 261 gradient thus indicates the decreasing competitiveness of *S. fallax* against *S. magellanicum* with
 262 a lowering water table.

263 *Parameterization of morphological traits, net photosynthesis and capitulum water retention*

264 We empirically quantified the morphological traits capitulum density (D_s , shoots cm^{-2}), biomass
 265 of capitula (B_{cap} , g m^{-2}), biomass density of living stems (H_{spe} , $\text{g cm}^{-1} \text{m}^{-2}$), net photosynthesis
 266 parameters (Pm_{20} , Rs_{20} and α_{PPFD}) and the water retention properties (i.e., $f_h(W_{cap})$ and $fr(h)$, Eqs.
 267 8 and 10) for the two *Sphagnum* species (see Appendix B for methods). The values (mean \pm SD)
 268 of the morphological parameters, the photosynthetic parameters and polynomial coefficients
 269 (a_{w0} , a_{w1} and a_{w2} , Eq. 3) are listed in Table 2. For each parameter, a random value was
 270 initialized for each cell based on the measured means and SD, assuming the variation of
 271 parameter values is normally distributed.

272 We noticed that the fitted $f_w(W_{cap})$ was meaningful when W_{cap} was below the optimal water
 273 content for photosynthesis ($W_{opt} = -0.5 a_{w1} / a_{w2}$). If $W_{cap} > W_{opt}$, photosynthesis decreased
 274 linearly with increasing W_{cap} , as being limited by the diffusion of CO_2 (Schipperges and Rydin,
 275 1998). In that case, $f_w(W_{cap})$ was calculated following Frolking et al. (2002):

$$276 \quad f_w(W_{cap}) = 1 - 0.5 \frac{W_{cap} - W_{opt}}{W_{max} - W_{opt}}$$

277 (11)

278 where W_{max} is the maximum water content of capitula.

279 It is known that W_{max} is around 25-30 g g^{-1} (e.g. Schipperges and Rydin, 1998), or about 0.31 -
 280 0.37 $\text{cm}^3 \text{cm}^{-3}$ in term of volumetric water content (assuming 75 g m^{-2} capitula biomass and 0.6
 281 cm height of capitula layer). This range is broadly lower than the saturated water content of moss
 282 carpet ($> 0.9 \text{ cm}^3 \text{cm}^{-3}$, McCarter and Price, 2014). Consequently, we used the following
 283 equation to convert volumetric water content to capitula RWC, when h_i was higher than the
 284 boundary value of -10^4 cm:

$$285 \quad W_{cap} = \min(W_{max}, \theta_m / (H_{cap} * B_{cap} * 10^{-4}))$$

286 (12)

287 where W_{max} is the maximum water content that set to 25 g g^{-1} for both species; θ_m is the
 288 volumetric water content of moss layer; H_{cap} is the height of capitula and is set to 0.6 cm (Hájek
 289 and Beckett, 2008).

290

291 **2.5 Model calibration for lateral water influence**

292 We used a machine-learning approach to estimate the influence of upstream area on the water
 293 balance of the site. The rate of net inflow (I , see Eq. A18 in Appendix A.) was described as a
 294 function of Julian day (JD), assuming the inflow was maximum after spring thawing and then
 295 decreased linearly with time:

$$296 \quad I_j = (a_N * JD + b_N) * Ks_j, JD > JD_{thaw} \quad (11)$$

297 where subscript j denotes the peat layers under water table; Ks is the saturated hydraulic
 298 conductivity; JD_{thaw} is the Julian day that thawing completed; and a_N and b_N are parameters.

299 We simulated water table changes using climatic scenarios from the Weather Generator
 300 (Appendix A). During the calibration, the community compositions were set constant, such that
 301 *S. magellanicum* fully occupied the hummock habitat whereas *S. fallax* fully occupied the lawn
 302 habitat. The simulated multi-year means of weekly water table values were compared to the
 303 weekly mean water table obtained observed at the site during years 2001, 2002, 2004 and 2016.
 304 The cost function for the learning process was based on the sum of squared error (SE) of the
 305 simulated water table:

$$306 \quad SE = \Sigma(WTs_k - Wtm_k)^2 \quad (12)$$

307 where Wtm is the measured multi-year weekly mean of water table; WTs is the simulated multi-
 308 year weekly mean of water table; and subscript k denotes the week of year when the water table
 309 was sampled.

310 The values of a_N and b_N were estimated using the Gradient Descent approach (Ruder, 2016),
 311 by minimizing SE in above Eq. (19):

$$312 \quad X_N(j) := X_N(j) - \Gamma \frac{\partial SE}{\partial X_N(j)} \quad (13)$$

313 where Γ is the learning rate ($\Gamma = 0.1$). Appendix D shows the simulated water table with the
 314 calibrated inflow term I , as compared against the measured values from the site.

315

316 **2.6 Model-based analysis**

317 First, we examined the ability of model to capture the preference of *S. magellanicum* for the
 318 hummock environment and *S. fallax* for the lawn environment (Test 1). For both species, the
 319 probability of occupation was initialized as 50% in a cell, and the distribution of species in the
 320 communities were randomly patterned. Monte-Carlo simulations (40 replicates) were carried out,
 321 with a time step of 30 minutes. A simulation length of 15 years was selected based on
 322 preliminary studies, in order to cover the major interval of change and to ease computational
 323 demand. Biomass growth, stem elongation and the spreading of shoots were simulated on a daily
 324 basis. The establishment of new shoots in deactivated cells was calculated at the end of each

325 simulation year. We then assessed if the model could capture the dominance of *S. magellanicum*
326 in the hummock communities and the dominance of *S. fallax* in lawn communities. The
327 simulated annual height increments of mosses were compared to the values measured for each
328 community type. To measure moss height growth in the field, we deployed 20 cranked wires on
329 *S. magellanicum* dominated hummocks and 15 on *S. fallax* dominated lawns in 2016. Each
330 cranked wire was a piece of metal wire attached with plastic brushes at the side anchored into the
331 moss carpet (e.g. Clymo 1970, Holmgren et al., 2015). Annual height growth (dH) was
332 determined by measuring the change in the exposed wire length above moss surface from the
333 beginning to the end of growing season.

334 Second, we tested the robustness of the model to the uncertainties in a set of parameters (Test
335 2-4). In test 2, we focused on parameters that closely linked to hydrology and growth
336 calculations, but were roughly parameterized (e.g., k_{imm} , r_{aero}) or adopted as a prior from other
337 studies (e.g., K_{sat} , α , n , NSC_{max} ; see Table 3). One at a time, each parameter value was adjusted
338 by +10 % or -10. 40 Monte-Carlo simulations were run using the same runtime settings as in
339 Test 1. The simulated means of cover were then compared to those calculated without the
340 parameter adjustment.

341 Tests 3-4 were then carried out to test whether the model could correctly predict
342 competitiveness of the species in dry and wet habitats, if the species-specific trends of capitulum
343 water content were not correctly specified. For both species, we set the values of parameters
344 controlling the water retention (i.e. B_{cap} and D_s , Appendix B) and the water-stress effects on net
345 photosynthesis (i.e. W_{cap} , Eq. 4) to be the same as those in *S. magellanicum* (Test 3) or same as
346 those in *S. fallax* (Test 4). Our hypothesis would be supported if removing the interspecific
347 differences in RWC responses led to the failure to predict the habitat preferences of the species.

348 We implemented Tests 5-6 to test the importance of parameters that directly control the species
349 ability to overgrow another species with more rapid height increment (i.e. Pm_{20} , RS_{20} , α_{PPFD} and
350 H_{spec}) in lawn and hummock conditions. We eliminated the species differences in the parameter
351 values to be same as those in *S. magellanicum* (Test 5) and same as those in *S. fallax* (Test 6).
352 The effects of the manipulation were compared against those from Tests 3-4. For each of Tests
353 3-6, 80 Monte-Carlo simulations were run using the setups described in Test 1.

354 Test 7-8 were implemented to separate the effects of photosynthetic water-response
355 parameters from the effects of the water retention of capitula. We set the photosynthetic water-
356 response parameters to be the same as those in *S. magellanicum* (Test 7) and same as those in *S.*
357 *fallax* (Test 8). As our model aimed to couple the environmental fluctuations and stochasticity of
358 ecosystem processes, we further tested the model responses to the absences of environmental
359 fluctuations (Test 9) or the absence of stochasticity in model parameters (Test 10). In Test 9,
360 monthly mean values of meteorological variables were used to drive the model simulation. In
361 Test 10, we removed the stochasticity of model parameters, and assigned average value to each

362 parameter of grid cells. For each of Tests 7-10, 40 Monte-Carlo simulations were run using the
363 setups described in Test 1.

364

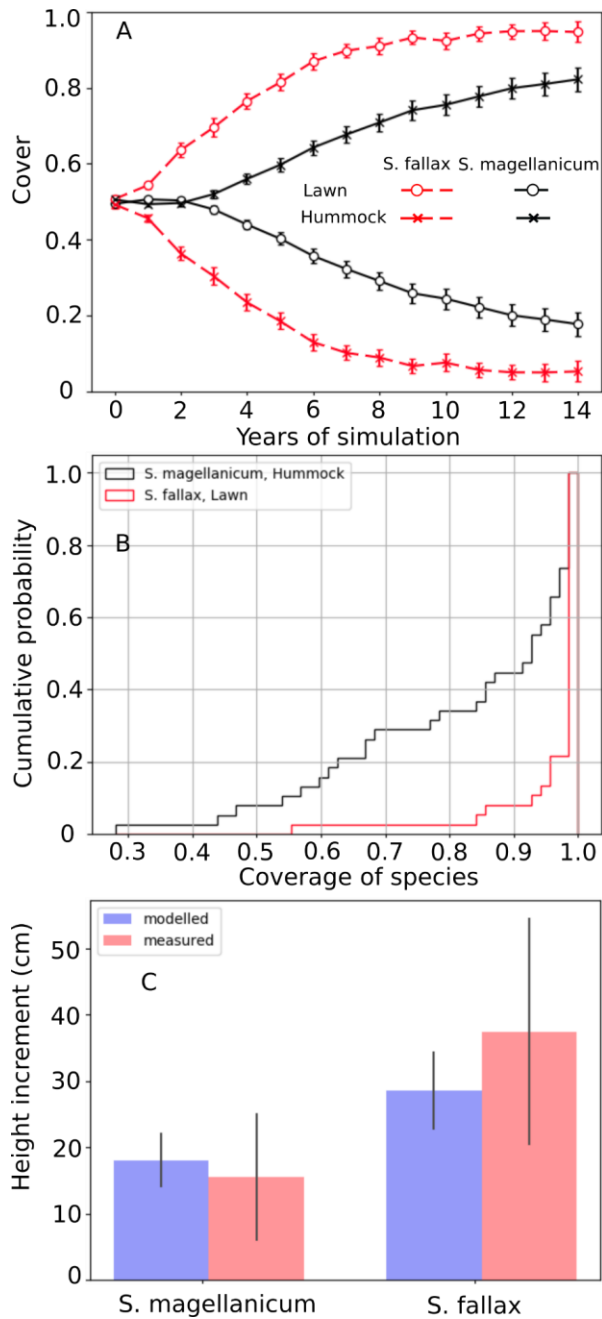

365

366 3 Results

367 3.1 Simulating the habitat preferences of *Sphagnum* species as affected by water content 368 traits of capitulum

369 Test 1 demonstrated the ability of model to capture the preference of *S. magellanicum* for the
370 hummock environment and *S. fallax* for the lawn environment (Fig. 2A). The simulated annual
371 changes in species covers were greater in lawn than in hummock habitats during the first 5
372 simulation years. The changes in lawn habitats slowed down around year 10 and the cover of *S.*
373 *fallax* plateaued at around $95 \pm 2.8\%$ (mean \pm standard error). In contrast, the cover of *S.*
374 *magellanicum* on hummocks continued to grow until the end of simulation and reached
375 $83 \pm 3.1\%$. In the lawn habitats, the cover of *S. fallax* increased in all Monte-Carlo simulations
376 and the species occupied all grid cells in 70% of the simulations. In the hummock habitats, the
377 cover of *S. magellanicum* increased in 91% of Monte-Carlo simulations, and formed
378 monocultural community in 16% of simulations (Fig. 2B). The height growth of *Sphagnum*
379 mosses was significantly greater at lawns than at hummocks ($P < 0.01$). The ranges of simulated
380 height growths agreed well with the observed values from field measurement for both species
381 (Fig. 2C).

382

383

384 Figure 2. Testing the ability of PMS to predict habitat preference of *Sphagnum magellanicum*
 385 and *S. fallax* (Test 1). The hummock and lawn habitats were differentiated by water table depth,
 386 surface energy balances and capitulum water potential in modelling. In the beginning of
 387 simulation, the cover of the two species was set equal and it was allowed to develop with time.
 388 (A) Annual development of the relative cover (mean and standard error) of the two species in
 389 hummock and lawn habitats, (B) the cumulative probability distribution of the cover of the two
 390 species at the end of the 15-year period based on 40 Monte-Carlo simulations, and (C) the
 391 simulated and measured means of annual height growth of *Sphagnum* surfaces in their natural
 392 habitats in hummock and lawn habitats.

393

394 3.2 Testing model robustness

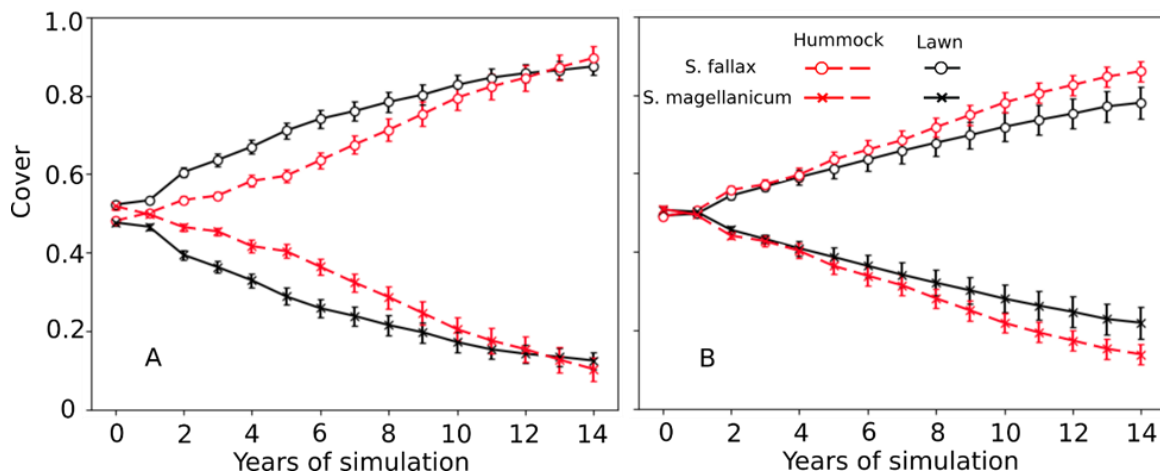

395 Test 2 addressed the model robustness to the uncertainties in several parameters that closely
396 linked to hydrology and growth calculations. Modifying most of the parameter values by +10%
397 or -10% yielded marginal changes in the mean cover of species in either hummock or hollow
398 habitat (Table 4). Reducing the moss carpet and peat hydraulic parameter n had stronger impacts
399 on *S. fallax* cover in hummocks than in lawns. Nevertheless, changes in simulated cover that
400 were caused by parameter manipulations were generally smaller than the standard deviations of
401 the means i.e. fitting into the random variation.

402

403 3.3 Testing the controlling role of capitulum water content for community dynamics

404 In Tests 3 and 4, the model incorrectly predicted the competitiveness of two species when the
405 interspecific differences of capitulum water content were eliminated. In both tests, *S. fallax*
406 became dominant in all habitats. The use of water responses characteristic to *S. magellanicum* for
407 both species (Test 3) led to faster development of *S. fallax* cover and higher coverage at the end
408 of simulation (Fig. 3A), as compared with the simulation results where the water responses
409 characteristic to *S. fallax* were used for both species (Test 4, Fig. 3B). The pattern was more
410 pronounced in hummock than in lawn habitats.

411

412

413 Figure 3. Testing the importance of capitulum water content to the habitat preference of *S.*
414 *magellanicum* and *S. fallax*. The development of the relative cover (mean and standard error)
415 were simulated in hummock and lawn habitats over a 15-year time frame for the two species. For
416 both species, parameter values for the capitulum water content, capitulum biomass (B_{cap}) and
417 density (D_s) were set to be the same as those from (A) *S. magellanicum* (Test 3) or (B) *S. fallax*
418 (Test 4).

419

420 In Tests 5 and 6, the species differences in the growth-related parameters were eliminated.
421 However, the model still predicted the dominances of *S. fallax* and *S. magellanicum* in lawn and
422 hummock habitats, respectively (Fig. 4). The increase in the mean cover of *S. magellanicum* was
423 especially fast in hummock habitat in comparison to the results of the unchanged model from
424 Test 1 (Fig. 2A). In lawns, the use of *S. fallax* growth parameters for both species gave stronger
425 competitiveness to *S. magellanicum* (Fig. 4B) than using the *S. magellanicum* parameters (Fig.
426 4A). In Test 7 and 8, ignoring the interspecific differences in the photosynthetic water-response
427 parameters did not change the simulated habitat preferences of *S. fallax* and *S. magellanicum*
428 (Table 5). Using the water response parameters of *S. fallax* decreased the mean cover of *S. fallax*
429 in lawns but increased the cover of *S. magellanicum* on hummocks. In contrast, using the water
430 response parameters of *S. magellanicum* increased the mean cover of *S. fallax* in lawns but
431 decreased the cover of *S. magellanicum* on hummocks.

432

433

434

435 Figure 4. Testing the importance of parameters regulating net photosynthesis and shoot
436 elongation to the habitat preference of *S. magellanicum* and *S. fallax*. Annual development of the
437 relative cover (mean and standard error) of the two species were simulated for hummock and
438 lawn habitats over a 15-year time frame. For both species, the parameter values (i.e. Pm_{20} , Rs_{20} ,
439 α_{PPFD} and H_{spec}) were set to be the same as those from (A) *S. magellanicum* (Test 5) or (B) *S.*
440 *fallax* (Test 6).

441

442 **3.4 Testing the effects of environmental fluctuations and stochasticity of ecosystem**
443 **processes on community dynamics**

444 In Tests 9, the model failed to simulate the preference of *S. magellanicum* to hummocks (Table
445 5) if the environmental fluctuation was ignored. However, the simulated cover of *S. fallax* in
446 lawns was higher as compared to unchanged condition (i.e. Test 1). Using mean value for each
447 model parameters led to mono output, i.e. *S. magellanicum* occupied 100% hummock area
448 whereas *S. fallax* took over lawns completely.

449

450

451 **4 Discussion**

452 In peatland ecosystems, *Sphagna* are keystone species distributed primarily along the
453 hydrological gradient (e.g. Andrus et al. 1986; Rydin, 1986). In a context where substantial
454 change in peatland hydrology is expected under a changing climate in northern areas (e.g. longer
455 snow-free season, lower summer water table and more frequent droughts), there is a pressing
456 need to understand how peatland plant communities could react and how *Sphagnum* species
457 could redistribute under habitat changes. In this work, we developed the Peatland Moss
458 Simulator (PMS), a process-based stochastic model, to simulate the competition between *S.*
459 *magellanicum* and *S. fallax*, two key species representing dry (hummock) and wet (lawn)
460 habitats in a poor fen peatland. We empirically showed that these two species differed in
461 characteristics that likely affect their competitiveness along a moisture gradient.

462 Capitulum water retention for the lawn-preferring species (*S. fallax*) was weaker than that for the
463 hummock-preferring species (*S. magellanicum*). Compared to *S. magellanicum*, the capitula of *S.*
464 *fallax* held less water at saturation and water content decreased more rapidly with dropping water
465 potential. Hence, *S. fallax* would dry faster than *S. magellanicum* under the same rate of water
466 loss. Moreover, water content in *S. fallax* capitula was less resistant to evaporation. These
467 differences indicated that it is harder for *S. fallax* capitula to buffer evaporative water loss and
468 thereby avoid or delay desiccation. Similar differences between hummock and hollow species
469 have been found earlier (Titus & Wagner, 1984; Rydin & McDonald, 1985). In addition, the net
470 photosynthesis of *S. fallax* is more sensitive to changes in capitulum water content than *S.*
471 *magellanicum*, as seen in a steeper decline in photosynthesis with decreasing water content (Fig.
472 B2C). Consequently, the growth of *S. fallax* is more likely to be slowed down by dry periods,
473 when the capillary water cannot fully compensate the evaporative loss (Robroek et al., 2007b)
474 making it less competitive in habitats prone to desiccation.

475 The PMS successfully captured the habitat preferences of the two *Sphagnum* species (Test 1):
476 starting from a mixed community with equal probabilities for both species, the lawn habitats
477 with shallower water table were eventually dominated by the typical lawn species *S. fallax*,
478 whereas hummock habitats, which were 15 cm higher than the lawn surface, were taken over by
479 *S. magellanicum*. The low final cover of *S. magellanicum* simulated in lawn habitats agreed well

480 with field observation from our study site, where *S. magellanicum* cover was less than 1% in
481 lawns (Kokkonen et al., 2019). On the other hand, *S. fallax* was outcompeted by *S. magellanicum*
482 in the hummock habitats. This result is consistent with previous findings that hollow-preferring
483 *Sphagna* are less likely to survive in hummock environments with greater drought pressure (see
484 Rydin 1985; Rydin et al. 2006; Johnson et al., 2015). The simulated annual height increments of
485 mosses also agreed well with the observed values for both habitat types. Our simulation for lawn
486 habitat shows that the looser stem structure of *S. fallax* allows it to allocate more of its produced
487 biomass into height growth, and thereby overgrow *S. magellanicum*, in which new biomass
488 forms a compact stem, packed with thick fascicles. This finding indicates that PMS can capture
489 key mechanisms in controlling the growth and competitive interactions of the *Sphagnum* species.

490 Parameter sensitivity testing showed the robustness of PMS regarding the uncertainties in
491 parameterization, as the simulated changes in the mean species cover, under 10% changes in
492 several parameters, were generally less than the standard deviations of the means. Decreasing the
493 value of the hydraulic parameter n (Table 3, Eq. A5) increased the presence of *S. fallax* in the
494 hummock habitats. This was expected as n is a scaling factor and therefore its changes get
495 magnified: a lower n value will lead to higher water content in the unsaturated layers above the
496 water table (van Genuchten, 1978), which allows wet-adapted *Sphagna* to survive dry conditions
497 (Hayward and Clymo, 1982; Robroek et al., 2007b; Rice et al., 2008). In contrast, the response
498 of *Sphagnum* cover to the changes in other hydraulic parameters (i.e. α , n , K_h) was limited in
499 lawn habitats. This could be due to the relatively shallow water table in lawns, which was able to
500 maintain sufficient capillary rise to the moss carpet and capitula. Decreasing the values of the
501 specific immobilization rate ($kimm$) and maximal NSC concentration in *Sphagnum* biomass
502 (NSC_{max}) mainly decreased the cover of *S. fallax* in lawn habitats, consistent with the importance
503 of biomass production to *Sphagna* in high moisture environment (e.g. Rice et al., 2008; Laine et
504 al., 2011). In addition, the SVAT modelling for hummocks and lawns (Module III, Fig. 1)
505 employed same hydraulic parameter values obtained from *S. magellanicum* hummocks
506 (McCarter and Price, 2014). For lawns, this could overestimate K_m but underestimate n , as the
507 lawn peat would be less efficient in holding high water content and generating capillary-flow
508 than hummock peat (Robroek et al., 2007b; Branham and Strack, 2014). As the decrease in K_m
509 and increase in n showed counteracting effects on the simulated species covers (Table 4), the
510 biases in the parameterization of K_m and n may not critically impact model performance.

511 Both our empirical measurements and PMS simulations indicate the importance of capitulum
512 water content as a mechanism controlling the moss community dynamics in peatlands. It has
513 long been hypothesized and experimentally studied that *Sphagnum* niche is defined by two
514 processes. Firstly, dry, high elevation habitats such as hummocks physically select species with
515 ability to remain moist (Rydin, 1993). If the interspecific differences in water retention and
516 water-stress effects were correctly specified (Test 1, Fig. 2) our model predicted this phenomena
517 of stronger competitiveness of *S. magellanicum* against *S. fallax* in hummock habitats correctly.

518 Alternatively, the model failed to predict the distribution of *S. magellanicum* on hummocks, if
519 these interspecific differences in the water processes were neglected (Test 3 and Test 4, Fig. 3).
520 During low water table periods in summer capillary rise may not fully compensate for high
521 evaporation (Robroek et al., 2007b; Nijp et al., 2014). In such circumstances, capitulum water
522 potential could drop rapidly towards the pressure defined by the relative humidity of air
523 (Hayward and Clymo, 1982). Consequently, the ability of capitula to retain cytoplasmic water is
524 particularly important for the hummock-preferring species, as was also shown by Titus &
525 Wagner (1984).

526 Secondly, in habitats with more persistently high moisture content such as lawns and hollows,
527 interspecific competition becomes important: it is well acknowledged that species from such
528 habitats generally have higher growth rates and photosynthetic capacity compared to hummock
529 species (e.g. Laing et al., 2014; Bengtsson et al., 2016). Our results also agreed on this, as setting
530 the growth-related parameters (i.e. Pm_{20} , Rs_{20} , α_{PPFD} and H_{spec}) of *S. magellanicum* to be the
531 same as those of *S. fallax* decreased the *S. fallax* cover in both hummock and lawn habitats (Test
532 6, Fig. 4B). However, such changes didn't impact the simulated habitat preferences for the tested
533 species. Based on this, the growth-related parameters seem to be less important than those water-
534 related ones. Further on, our Tests 7 and 8 showed that when interspecific differences in the
535 water-stress effects on photosynthesis were removed, the model still predicted the correct habitat
536 preferences of *S. magellanicum* and *S. fallax*. Therefore, the interspecific differences in
537 capitulum water retention could be the main determinant on the habitat preferences of the tested
538 species.

539

540 There have been growing concerns about the shift of peatland communities from *Sphagnum*-
541 dominated towards more vascular-abundant under a drier and warmer climate (Wullschleger et
542 al., 2014; Munir et al. 2015; Dieleman et al. 2015). Nevertheless, the potential of *Sphagnum*
543 species composition to adjust to this forcing remains poorly understood. Particularly in
544 oligotrophic fens, where the vegetation is substantially shaped by lateral hydrology
545 (Tahvanainen, 2011; Turetsky et al., 2012), plant communities can be highly vulnerable to
546 hydrological changes (Gunnarsson et al. 2002; Tahvanainen, 2011). Based on the validity and
547 robustness of PMS, we believe PMS could serve as one of the first mechanistic tools to
548 investigate the direction and rate of change in *Sphagnum* communities under environmental
549 forcing. The hummock-lawn differences showed by Test 1 imply that *S. magellanicum* could
550 outcompete *S. fallax* within a decade in a poor fen community, if the water table of habitats like
551 lawns was lowered by 15 cm (Test 1). Although this was derived from a simplified system with
552 only the two species, it highlighted the potential of rapid turnover of *Sphagnum* species: the
553 hummock-lawn difference of water table in simulation was comparable to the expected water
554 table drawdown in fens under the warming climate (Whittington and Price, 2006; Gong et al.,

555 2013b). The effect traits of mosses, while studied less than those of vascular plant traits, have far
556 reaching impacts on biogeochemistry of ecosystems such as peatlands, where mosses form the
557 most significant plant group (Cornelissen et al. 2007). Because of the large interspecific
558 differences of traits such as photosynthetic potential, hydraulic properties and litter chemistry
559 (Laiho 2006; Straková et al., 2011; Korrensalo et al., 2017; Jassey & Signarbieux, 2019), change
560 in *Sphagnum* community composition is likely to impact long-term peatland stability and
561 functioning (Waddington et al., 2015). Turnover between hummock and wetter habitat species
562 would feedback to climate as they differ in their decomposability (Straková et al. 2012;
563 Bengtsson et al. 2016). As hummock species produces more calcitrant litter the carbon bind into
564 the system would take longer to get released back to atmosphere. In addition, the replacement of
565 wet adapted moss species with hummock species is likely to result in higher ability to maintain
566 carbon sink under periods of drought (Jassey, & Signarbieux, 2019).

567 Although efforts have been made on analytical modelling to obtain boundary conditions for
568 equilibrium states of moss and vascular communities in peatland ecosystems (Pastor et al.,
569 2002), the dynamic process of peatland vegetation has not been well-described or included in
570 earth system models (ESMs). Existing ecosystem models usually consider the features of
571 peatland moss cover as “fixed” (Sato et al., 2007; Wania et al., 2009; Euskirchen et al., 2014), or
572 change directionally following a projected trajectory (Wu and Roulet, 2014). Chaudhury et al.
573 (2017) have a dynamic peatland vegetation model, with a single moss PFT and four vascular
574 PFTs, so moss productivity relative to vascular plants can vary, however moss characteristics are
575 fixed to a single set of values. Our modelling approach provided a way to incorporate the
576 environmental fluctuation and the mechanisms of dynamic moss cover into peatland carbon
577 modelling. PMS employed an individual-based approach where each grid cell carries a unique
578 set of trait properties, so that shoots with favorable trait combinations in prevailing environment
579 are thus able to replace those whose trait combinations are less favorable. Moreover, the model
580 included the spatial interactions of individuals, which can impact the sensitivity of coexistence
581 pattern to environmental changes (Bolker et al., 2003; Sato et al., 2007; Tatsumi et al., 2019).
582 This mimics the stochasticity in plant responses to environmental fluctuations, which is essential
583 to community assembly and trait filtering under environmental forcing (Clark et al., 2010). The
584 importance of incorporating environmental fluctuations with the stochasticity of biophysiological
585 processes is supported by our Test 9 and 10. If the monthly mean climate conditions were used
586 as input, our model failed to predict the dominance of *S. magellanicum* on hummocks. If the
587 stochasticity of model parameters were omitted and only mean values were used, the model
588 generated only single output disregarding the randomness of environmental conditions. As these
589 features are considered essential to the “next generation” DVMs (Scheiter et al., 2013), our PMS
590 could be considered as an elemental design for future DVM development.

591 We see PMS as an elemental design for the future development of dynamic vegetation models
592 for peatland ecosystems, yet there are certain uncertainties and features that should be developed

593 further. We used a gas-exchange-based method to quantify the simultaneous changes in capitula
594 water potential, water content and carbon uptake of *Sphagnum* moss capitula. It should be noted
595 that, the measurements mainly covered the changes from RWC_{opt} towards RWC_{cmp} (Table 1 and
596 Fig. 3). However, capitula water content could be higher than RWC_{opt} at saturation (e.g. about
597 25-30 g g⁻¹; Schipperges and Rydin, 1998). When RWC is high, vapor diffusion may occur
598 mainly from the capitula surface or macropores, instead of the inside capitula. Hence, our
599 methodology may not be suitable to reflect the water potential changes under near-saturation
600 conditions. In our modelling, we used the volumetric water content of moss carpet to estimate
601 RWC as an approximation for wet conditions (Eq. 17). The accuracy of such approximation for
602 high RWC conditions remains ambiguous and more information is still required.

603 We assumed that tissue structure did not change during the measurement process, and that the
604 aerodynamic resistance (r_a , Eq. 3) for vapor to diffuse from the inner capitula to the headspace
605 was constant. However, capitula drying may change leaf curvature, especially in species with
606 slim and sparsely spread leaves (Laine et al., 2018). Such changes in the branch-leaf structure
607 could expose the more of the leaf surface to evaporation and reduce the value of r_a .
608 Consequently, PMS could underestimate capitula water potential towards the drying end for
609 those species, if a constant r_a is derived from the maximal evaporation rate (E_m , Eq. 5; Fig 3C).

610 The water-retention relationship in PCM may not sufficiently capture water potential changes at
611 wet and dry extremes (e.g., *S. magellanicum* in Fig. 4C). Water retention functions developed
612 for mineral soils (e.g., Clapp and Hornberge, 1978; van Genuchten, 1980) may not be well
613 parameterized for peat soils and moss (non-vacular) vegetation, particularly under very dry or
614 wet conditions. Hence, further studies are needed to improve the description of the nonlinearity
615 of capitula water content, as influenced by capitula morphology (e.g. capitula biomass and shoot
616 density) and structural changes of branch leaves.

617 PMC lacks horizontal (lateral) water transport that may allow individuals of lawn species to be
618 present in hummocks (Rydin 1985). With additional experimental data, such as species-specific
619 hydraulic conductivity, the current model could be improved to also quantify the horizontal
620 water transport among neighboring grid cells.

621 To conclude, PMS could successfully capture the habitat preferences of the modelled *Sphagnum*
622 species. In this respect, PMS could provide fundamental support for the future development of
623 dynamic vegetation models for peatland ecosystems. Based on our findings, capitulum water
624 processes should be considered as a control on vegetation dynamics in future impact studies on
625 peatlands under changing environmental conditions.

628 We are grateful to Harri Strandman (University of Eastern Finland) for the coding of Weather

629 Generator. The project was funded by Academy of Finland (Project number 287039). AML
630 acknowledges support from the Kone Foundation and SF from grant #1802825 from the US
631 National Science Foundation, and the Fulbright-Finland and Saastamoinen Foundations.

632

633 *Code and data availability.* The data and the code to reproduce the analysis is available upon
634 request to the corresponding author.

635 *Author contributions.* JG and EST designed the study. JG, AML and NK conducted the
636 experiment and analysis. JG, EST, NR and SF designed the model. JG coded the model and
637 conducted the model simulation and data analysis. JG and EST wrote the manuscript with
638 contributions from all co-authors.

639 *Competing interests.* The authors declare that they have no conflict of interest.

912 Table. 1 List of symbols and abbreviations

Symbol	Description	Unit
A	Net photosynthesis rate	$\mu\text{mol m}^{-2} \text{s}^{-1}$
A_m	Maximal net photosynthesis rate	$\mu\text{mol m}^{-2} \text{s}^{-1}$
α_{imm}	Temperature constant for NSC immobilization	
α_{PPFD}	Half-saturation point of PPFD for photosynthesis.	$\mu\text{mol m}^{-2} \text{s}^{-1}$
B_{cap}	Capitulum biomass	g m^{-2}
C_T	Specific heat	$\text{J K}^{-1} \text{kg}^{-1}$
D_S	Capitulum density	shoots cm^{-2}
dH	Annual height growth of <i>Sphagnum</i> mosses	cm
dWT	Hummock-lawn differences in water table	cm
E	Rate of evaporation	cm timestep ⁻¹
f_w	Water content multiplier on photosynthesis rate	
f_T	Temperature multiplier on photosynthesis rate	
h	Water potential	cm
H_c	Shoot height of <i>Sphagnum</i> mosses	cm
H_{cap}	Height of capitula	cm
H_{spc}	Biomass density of living <i>Sphagnum</i> stems	$\text{g m}^{-2} \text{cm}^{-1}$
I	Rate of net inflow water	cm
k_{imm}	Specific immobilization rate	g g^{-1}
JD_{thaw}	Julian day when thawing completed	
K_h	Hydraulic conductivity of peat layer	cm s^{-1}
K_m	Hydraulic conductivity of moss layer	cm s^{-1}

K_{sat}	Saturated hydraulic conductivity	cm s^{-1}
K_T	Thermal conductivity	$\text{W m}^{-1} \text{K}^{-1}$
lc	Width of a grid cell in simulation	cm
M_B	Immobilized NSC to biomass production	g
NSC_{max}	Maximal NSC concentration in <i>Sphagnum</i> biomass	g g^{-1}
P	Precipitation	cm
Pm	Mass-based rate of maximal gross photosynthesis	$\mu\text{mol g}^{-1} \text{s}^{-1}$
$PPFD$	Photosynthetic photon flux density	$\mu\text{mol m}^{-2} \text{s}^{-1}$
ρ_{bulk}	Bulk density of peat	g cm^{-3}
r_{aero}	Aerodynamic resistance	s m^{-1}
r_{bulk}	Cell-level bulk surface resistance	s m^{-1}
r_{ss}	Bulk surface resistance of community	s m^{-1}
Rh	Relative humidity	$\%$
Rs	Mass-based respiration rate	$\mu\text{mol g}^{-1} \text{s}^{-1}$
R_s	Incoming shortwave radiation	W m^{-2}
R_l	Incoming longwave radiation	W m^{-2}
S_c	Area of a cell in model simulation	m^2
S_{imm}	Multiplier for temperature threshold	
Sv_i	Evaporative area of a cell i	cm^2
T	Capitulum temperature	$^{\circ}\text{C}$
Ta	Air temperature	$^{\circ}\text{C}$
T_{opt}	reference temperature of respiration (20 $^{\circ}\text{C}$)	$^{\circ}\text{C}$
u	Wind speed	m s^{-1}

W_{cap}	Capitulum water content	g g^{-1}
W_{cmp}	Capitulum water content at the compensation point	g g^{-1}
W_{max}	Maximum water content of capitula	g g^{-1}
W_{opt}	Optimal capitulum water content for photosynthesis	g g^{-1}
W_{cf}	field-water contents of <i>Sphagnum</i> capitulum	g g^{-1}
W_{sf}	field-water contents of <i>Sphagnum</i> stem	g g^{-1}
WTm	Measured multi-year mean of weekly water table	cm
WTs	Simulated multi-year mean of weekly water table	cm
z_m	Thickness of the living moss layer	cm
θ_m	Volumetric water content of moss layer	
θ_r	permanent wilting point water content	
θ_s	saturated water content	

Abbreviations:

915 Table. 2 Species-specific values of morphological and photosynthetic parameters for *S.*
 916 *magellanicum* and *S. fallax*. The parameters include: capitulum density (D_S), capitulum biomass
 917 (B_{cap}), specific height of stem (H_{spc}), maximal gross photosynthesis rate at 20 °C (Pm_{20}),
 918 respiration rate at 20 °C (Rs_{20}), half-saturation point of photosynthesis (α_{PPFD}), and polynomial
 919 coefficients (a_{w0} , a_{w1} and a_{w2}) for the responses of net photosynthesis to capitulum water
 920 content. Parameter values are given as mean \pm standard deviation.
 921

Parameter	Unit	<i>S. magellanicum</i>	<i>S. fallax</i>	Equation
D_S	cm ⁻²	0.922±0.289	1.46±0.323	- ^a
B_{cap}	g m ⁻²	75.4±21.5	69.2±19.6	- ^a
H_{spc}	g ⁻¹ cm ⁻¹	45.4 ± 7.64	32.6±6.97	(7)
Pm_{20}	μmol g ⁻¹ s ⁻¹	0.0189±0.00420	0.0140±0.00212	(2)
Rs_{20}	μmol g ⁻¹ s ⁻¹	0.00729±0.00352	0.00651±0.00236	(2)
α_{PPFD}	μmol m ⁻² s ⁻¹	101.4±14.1	143±51.2	(2)
a_{w0}	unitless	-1.354±0.623	-1.046±0.129	(4)
a_{w1}	unitless	0.431±0.197	0.755±0.128	(4)
a_{w2}	unitless	-0.0194±0.0119	-0.0751±0.0223	(4)

922 ^a the parameter was used in the linear models predicting the log₁₀-transformed capitulum water
 923 potential (h) and bulk resistance (r_{bulk}) for *S. fallax* and *S. magellanicum*. The capitulum density
 924 and photosynthetic parameter values measured here are well within the range of those reported in
 925 literature for these species (McCarter & Price, 2014; Laing et al. 2014; Bengtsson et al. 2016;
 926 Korrensalo et al. 2016).

927 Table 3. Parameters values for SVAT simulations (Module III). The parameters include:
 928 saturated hydraulic conductivity (K_{sat}), water retention parameters of water retention curves (α
 929 and n), saturated water content (θ_s), permanent wilting point water content (θ_r), snow layer
 930 surface albedos (a_s , a_l), the thermal conductivity (K_T), specific heat (C_T), maximal nonstructural
 931 carbon (NSC) concentration (NSC_{max}).

Parameter	Value	Equation	Source
K_{sat}	162	A6	McCarter and Price, 2014
n	1.43	A5	McCarter and Price, 2014
α	2.66	A5	McCarter and Price, 2014
θ_s	0.95 ^a	A5	Päivänen, 1973
θ_r	0.071 ^b	A5	Weiss et al., 1998
a_s	0.15	A9	Runkle et al., 2014
a_l	0.02	A10	Thompson et al., 2015
$K_{T,water}$	0.57	A4	Letts et al., 2000
$K_{T,ice}$	2.20	A4	Letts et al., 2000
$K_{T,org}$	0.25	A4	Letts et al., 2000
$C_{T,water}$	4.18	A3	Letts et al., 2000
$C_{T,ice}$	2.10	A3	Letts et al., 2000
$C_{T,org}$	1.92	A3	Letts et al., 2000
NSC_{max}	0.045	6	Turetsky et al., 2008

932 ^a The value was calculated from bulk density (ρ_{bulk}) as $\theta_s = 97.95 - 79.72\rho_{bulk}$ following Päivänen
 933 (1973); ^b The value was calculated as $\theta_r = 4.3 + 67\rho_{bulk}$ following Weiss et al. (1998).

934 Table 4. Results from the Test 2 addressing the robustness of the model to the uncertainties in a
 935 set of parameters. Each parameter was increased or decreased by 10%. Model was run for *S.*
 936 *magellanicum* and *S. fallax* in their preferential habitats. Difference in mean cover between
 937 simulations under changed and unchanged parameter values are given with the standard
 938 deviations (SD) of the means in brackets. The parameters include: specific immobilization rate
 939 (*kimm*), maximal nonstructural carbon (NSC) concentration (*NSC_{max}*), hydraulic conductivity of
 940 moss layer (*K_m*), hydraulic conductivity of peat layer (*K_h*), water retention parameters of water
 941 retention curves (α and n), snow layer surface albedo (a_s) and aerodynamic resistance (r_{aero}).

Change in parameter value	Equation	Changes in simulated cover, % (SD)	
		<i>S. magellanicum</i> (hummock)	<i>S. fallax</i> (lawn)
<i>kimm</i> +10%	5	-1.2 (3.5)	-3.5 (3.8)
<i>kimm</i> -10%		+2.7 (0.4)	-5.0 (3.4)
<i>NSC_{max}</i> +10%	6	+4.5 (2.9)	+0.7 (3.0)
<i>NSC_{max}</i> -10%		-0.7 (4.0)	-4.8 (4.5)
<i>K_m</i> +10%	10	+1.0 (3.1)	-1.7 (2.3)
<i>K_m</i> -10%		-1.7 (2.7)	+4.1 (4.3)
<i>K_h</i> +10%	A1	-1.1 (3.0)	+1.1 (2.0)
<i>K_h</i> -10%		-1.8 (3.1)	-0.5 (2.7)
n +10%	A5	-1.6 (3.2)	-3.2 (3.2)
n -10%		-9.4 (3.6)	-0.3 (2.9)
α +10 %	A5	-0.5 (2.9)	-0.3 (2.3)
α -10 %		-1.3 (3.6)	+3.2 (1.0)
a_s +10%	A9	-2.2 (3.8)	+0.6 (2.1)
a_s -10%		+3.3 (3.4)	+1.2 (1.8)
r_{aero} +10%	A14, A15	-2.1 (3.4)	+0.3 (2.1)
r_{aero} -10%		-3.8 (4.4)	+2.3 (1.1)

942 Table 5. Result from the Test 7-10 addressing the importance of meteorological fluctuations,
 943 stochasticity of model parameters and the photosynthetic water-response. In Test 7, monthly
 944 mean values of meteorological variables were used to drive the model simulation. In Test 8, the
 945 stochasticity of model parameters was removed, and average values were used to parameters at
 946 grid cell level. In Test 9-10, the photosynthetic water-response parameters (i.e. a_{w0} , a_{w1} and a_{w2} .
 947 See Table 2) were set to be the same as those in *S. magellanicum* (Test 9) and same as those in *S.*
 948 *fallax* (Test 10). The mean cover of *S. magellanicum* on hummocks and *S. fallax* on lawns after
 949 the simulation of 15 year periods are listed in the table.

950

Test	<i>S. magellanicum</i> (hummock)	<i>S. fallax</i> (lawn)
7	73%	96%
8	90%	72%
9	14 %	100 %
10	100 %	100 %

951

952

953 **Appendix A. Calculating community SVAT scheme (Module III)**

954 *Transport of water and heat in peat profile*

955 Simulating the transport of water and heat in the peat profiles was based on Gong et al. (2012,
956 2013). Here we list the key algorithms and parameters. Ordinary differential equations governing
957 the vertical transport of water and heat in peat profiles were given as:

$$958 \quad C_h \frac{\partial h}{\partial t} = \frac{\partial}{\partial z} \left[K_h \left(\frac{\partial h}{\partial z} + 1 \right) \right] + S_h$$

959 (A1)

$$960 \quad C_T \frac{\partial T}{\partial t} = \frac{\partial}{\partial z} \left(K_T \frac{\partial T}{\partial z} \right) + S_T \quad (A2)$$

961 where t is the time step; z is the thickness of peat layer; h is the water potential; T is the
962 temperature; C_h and C_T are the specific capacity of water (i.e. $\partial\theta/\partial h$) and heat; K_h and K_T are the
963 hydraulic conductivity and thermal conductivity, respectively; and S_h and S_T are the sink terms
964 for water and energy, respectively.

965 C_T and K_T were calculated as the volume-weighted sums from components of water, ice and
966 organic matter:

$$967 \quad C_T = C_{water}\theta_{water} + C_{ice}\theta_{ice} + C_{org}(1 - \theta_{water} - \theta_{ice})$$

968 (A3)

$$969 \quad K_T = K_{water}\theta_{water} + K_{ice}\theta_{ice} + K_{org}(1 - \theta_{water} - \theta_{ice}) \quad (A4)$$

970 where C_{water} , C_{ice} and C_{org} are the specific heats of water, ice and organic matter, respectively;
971 K_{water} , K_{ice} and K_{org} are the thermal conductivities of water, ice and organic matter, respectively;
972 and θ_{water} and θ_{ice} are the volumetric contents of water and ice, respectively.

973 For a given h , $C_h = \partial\theta(h)/\partial h$ was derived from the van Genuchten water retention model (van
974 Genuchten, 1980) as:

$$975 \quad \theta(h) = \theta_r + \frac{(\theta_s - \theta_r)}{[1 + (\alpha|h^n|)^m]} \quad (A5)$$

976 where θ_s is the saturated water content; θ_r is the permanent wilting point water content; α is a
977 scale parameter inversely proportional to mean pore diameter; n is a shape parameter; and $m=1-$
978 $1/n$.

979 Hydraulic conductivity (K_h) in an unsaturated peat layer was calculated as a function of θ by
980 combining the van Genuchten model with the Mualem model (Mualem, 1976):

$$981 \quad K_h(\theta) = K_{sat} S_e^{Le} \left[1 - \left(1 - S_e^{1/m} \right)^m \right]$$

982 (A6)

983 where K_{sat} is the saturated hydraulic conductivity; S_e is the saturation ratio and $S_e = (\theta - \theta_r) / (\theta_s - \theta_r)$;
 984 and L_e is the shape parameter ($L_e=0.5$; Mualem, 1976).

985

986 *Boundary conditions and surface energy balance*

987 A zero-flow condition was assumed at the lower boundary of the peat column. The upper
 988 boundary condition was defined by the surface energy balance, which was driven by net
 989 radiation (Rn). The dynamics of Rn at surface x ($x=0$ for vascular canopy and $x=1$ for moss
 990 surface) was determined by the balance between incoming and outgoing radiation components:

$$991 \quad Rn_x = Rsn_{b,x} + Rsn_{d,x} + Rln_x \quad (A7)$$

992 where $Rsn_{b,x}$ and $Rsn_{d,x}$ are the absorbed energy from direct and diffuse radiation; Rln_x is the
 993 absorbed net longwave radiation.

994 Algorithms for calculating the net radiation components were detailed in Gong et al. (2013), as
 995 modified from the methods of Chen et al. (1999). Canopy light interception was determined by
 996 the light-extinction coefficient (k_{light}), leaf area index (Lc) and solar zenith angle. The
 997 partitioning of reflected and absorbed irradiances at ground surface was regulated by the surface
 998 albedos for the shortwave (a_s) and longwave (a_l) components, and the temperature of surface x
 999 (T_x) also affects net longwave radiation:

$$1000 \quad Rn_x = Rsn_{b,x} + Rsn_{d,x} + Rln_x \quad (A8)$$

$$1001 \quad Rsn_{d,x} = Rsid,x(1 - a_s) \quad (A9)$$

$$1002 \quad Rln_x = Rli,x(1 - a_l) - \varepsilon \delta T_x^4$$

1003 (A10)

1004 where $Rsid$, $Rsid$, Rli are the incoming beam, diffusive and longwave radiations; ε is the emissivity
 1005 ($\varepsilon = 1 - a_l$); δ is the Stefan Boltzmann's constant ($5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$).

1006 Rn_x was partitioned into latent heat flux (λE_x), sensible heat flux (H_x) and ground heat flux (for
 1007 canopy $G_l=0$):

$$1008 \quad Rn_x = H_x + \lambda E_x + G_x$$

1009 (A11)

$$1010 \quad G_1 = K_T (T_x - T_s) / (0.5z) \quad (A12)$$

1011 where T_s is the temperature of the moss carpet; z is the thickness of the moss layer ($z = 5 \text{ cm}$).

1012 The latent heat flux was calculated by the “interactive scheme” (Daamen and McNaughton,
 1013 2000; see also in Gong et al., 2016), which is a K-theory-based, multi-source model:

$$1014 \quad \lambda E_x = \frac{(\Delta/\gamma)A_x r_{sa,x} + \lambda VPD_b}{r_{b,x} + (\Delta/\gamma)r_{sa,x}} \quad (A13)$$

1015 where Δ is the slope of the saturated vapor pressure curve against air temperature; λ is the latent
 1016 heat of vaporization; E is the evaporation rate; VPD_b is the vapor pressure deficit at z_b ; $r_{b,x}$ is the
 1017 total resistance to water vapor flow, the sum of boundary layer resistance ($r_{sa,x}$) and surface
 1018 resistance (r_{ss}); and A is the available energy for evapotranspiration and $A_x = Rn_x - G_x$.

1019 The calculations of γ , λ and VPD_b require the temperature (T_b) and vapor pressure (e_b) at the
 1020 mean source height (z_b). These variables were related to the total of latent heat ($\sum \lambda E_x$) and
 1021 sensible heat ($\sum H_x$) from all surfaces using the Penman-type equations:

$$1022 \quad \Sigma \lambda E_x = \rho_a C_p (e_b - e_a) / (r_{aero} \gamma) \quad (A14)$$

$$1023 \quad \Sigma H_x = \rho_a C_p (T_b - T_a) / r_{aero}$$

$$1024 \quad (A15)$$

1025 where $\rho_a C_p$ is the volumetric specific heat of air; r_{aero} is the aerodynamic resistance between z_b
 1026 and the reference height z_a , and was a function of T_b accounting for the atmospheric stability
 1027 (Choudhury and Monteith, 1988); and γ is the psychrometric constant ($\gamma = \rho_a C_p / \lambda$).

1028 Changes in the energy balance affect the surface temperature (T_x) and vapor pressure (e_x), which
 1029 further feed back to the energy availability (Eq. A10, A12), the source-height temperature, VPD
 1030 and the resistance parameters (e.g., r_{aero}). The values of T_x and e_x were solved iteratively by
 1031 coupling the energy balance equations (eqs. A11–A15) with the Penman-type equations (see also
 1032 Appendix B in Gong et al., 2016):

$$1033 \quad \lambda E_x = \rho_a C_p (e_x - e_b) / (r_{sa,x} \gamma) \quad (A16)$$

$$1034 \quad H_x = \rho_a C_p (T_x - T_b) / r_{sa,x} \quad (A17)$$

1035 where the boundary-layer resistance for ground surface ($r_{sa,l}$) and canopy ($r_{sa,0}$) were calculated
 1036 following the approaches of Choudhury and Monteith (1988).

1037

1038 *Sink terms of transport functions for water and heat*

1039 The sink term $S_{h,i}$ (see Eq. A11) for each soil layer i was calculated as:

$$1040 \quad S_{h,i} = E_i - P_i - W_{melt,i} - I_i \quad (A18)$$

1041 where E_i is the evaporation loss of water from the layer; P_i is rainfall ($P_i = 0$ if the layer is not
 1042 topmost, i.e. $i > 1$); $W_{melt,i}$ is the amount of melt water added to the layer; I_i is the net water inflow
 1043 and was calibrated in Section 2.5.

1044 The value of E_i was calculated as:

1045 $E_i = f_{top}E_0 + f_{root}(i)E_1$ (A19)

1046 where E_0 and E_1 are the evaporation rate from ground surface and canopy (Eq. A13); f_{top} is the
 1047 location multiplier for the topmost layer ($f_{top} = 0$ in cases $i > 1$); and $f_{root}(i)$ is the fraction of fine-
 1048 root biomass in layer i .

1049 The value of $W_{melt,i}$ was controlled by the freeze-thaw dynamics of soil water and snow pack,
 1050 which were related to the heat diffusion in soil profile (Eq. A2). We set the freezing point
 1051 temperature to 0 °C, and the temperature of a soil layer was held constant (0 °C) during freezing
 1052 or melting. For the i th soil layer, the sink term (S_T) in heat transport equation (Eq. A2) was
 1053 calculated as:

1054 $S_{T,i} = f_{phase} \max(|T_i| C_{T,i}, W_{phase} \lambda_{melt})$ (A20)

1055 where $C_{T,i}$ is specific heat of soil layer (Eq. A13); W_{phase} is the water content for freezing (W_{phase}
 1056 = θ_w) or melting ($W_{phase} = \theta_{ice}$); λ_{melt} is the latent heat of freezing; f_{phase} is binomial coefficient that
 1057 denotes the existence of freezing or thawing. For each time step t , we computed $T_i(t)$ with a prior
 1058 assumption that $S_{T,i} = 0$. Then f_{phase} was determined by whether the temperature changed across
 1059 the freezing point, i.e. $f_{phase} = 1$ if $T_i(t) * T_i(t-1) \leq 0$, otherwise $f_{phase} = 0$.

1060

1061 *Parameterization of SVAT processes*

1062 For the calculation of surface energy balance, we set the height and leaf area of vascular
 1063 canopy to 0.4 m and 0.1 m² m⁻², consistent with the scarcity of vascular canopies at the site. The
 1064 aerodynamic resistance (r_{aero} , Eq. A14, Appendix A) for surface energy fluxes was calculated
 1065 following Gong et al. (2013a). The bulk surface resistance of community (r_{ss} , Eq. A13, Appendix
 1066 A) was summarized from the cell-level values of $r_{bulk,i}$, that $1/r_{ss} = \sum(1/r_{bulk,i})$. To calculate the
 1067 peat hydrology and water table, peat profiles of hummock and lawn communities were set to 150
 1068 cm deep and stratified into horizontal layers of depths varying from 5cm (topmost) to 30cm
 1069 (deepest). For each peat layer, the thermal conductivity (K_T) of fractional components, i.e. peat,
 1070 water and ice, were evaluated following Gong et al. (2013a). The bulk density of peat (ρ_{bulk}) was
 1071 set to 0.06 g cm⁻³ below acrotelm (40 cm depth, Laine et al., 2004), and decreased linearly
 1072 toward the living moss layer. The saturated hydraulic conductivity (K_{sat} , Eq. A6, Appendix A)
 1073 and water retention parameters (i.e. α and n , Eq. A5, Appendix A) of water retention curves were
 1074 calculated as functions of ρ_{bulk} and the depth of peat layer following Päivänen (1973). K_{sat} , α and
 1075 n for the living moss layer were adopted from the values measured by McCarter and Price (2014)
 1076 from *S. magellanicum* carpet. The parameter values for SVAT processes are listed in Table 3.

1077 *Calculation of snow dynamics*

1078 In boreal and arctic regions, the amount and timing of snow melt has crucial impact on moisture

1079 conditions, especially at fen peatlands. Therefore, to have realistic spring conditions we
1080 introduced a snow-pack model, SURFEX v7.2 (Vionnet et al., 2007), into the SVAT modelling.
1081 The snow-pack model simulates snow accumulation, wind drifting, compaction and changes in
1082 metamorphism and density. These processes influenced the heat transport and freezing-melting
1083 processes (i.e. S_h and S_T , see Eq. A1-A2, Appendix A). In this modelling, we calculate the snow
1084 dynamics on a daily basis in parallel to the SVAT simulation. Daily snowfall was converted into
1085 a snow layer and added to ground surface. For each of the day-based snow layers (D-layers), we
1086 calculated the changes in snow density, particle morphology and layer thicknesses. At each time
1087 step, D-layers were binned into layers of 5-10 cm depths (S-layers) and placed on top of the peat
1088 column for SVAT modelling. With a snow layer present, surface albedos (i.e. a_s , a_l) were
1089 modified to match those of the topmost snow layer (see Table 4 in Vionnet et al., 2007). If the
1090 total thickness of snow was less than 5 cm, all D-layers were binned into one S-layer. The
1091 thermal conductivity (K_T), specific heat (C_T), snow density, thickness and water content of each
1092 S-layer were calculated as the mass-weighted means from the values of D-layers. Melting and
1093 refreezing tended to increase the density and K_T of a snow layer but decrease its thickness (see
1094 Eq. 18 in Vionnet et al., 2007). The fraction of melted water that exceeded the water holding
1095 capacity of a D-layer (see Eq. 19 in Vionnet et al., 2007) was removed immediately as
1096 infiltration water. If the peat layer underneath was saturated, the infiltration water was removed
1097 from the system as lateral discharge.

1098 *Boundary conditions and driving variables*

1099 A zero-flow boundary was set at the bottom of peat. At peat surface the boundary conditions of
1100 water and energy were defined by the ground surface temperature (T_0 , see Eq. A10-A15 in
1101 Appendix A) and the net precipitation (P minus E). The profiles of layer thicknesses, ρ_{bulk} and
1102 hydraulic parameters were assumed to be constant during simulation. Lateral boundary
1103 conditions were used to calculate the spreading of *Sphagnum* shoots among cells along the edge
1104 of the model domain so that shoots can spread across the edge of simulation area and invade into
1105 the grid cell at the boarder of the opposite side.

1106 The model simulation was driven by climatic variables of air temperature (T_a), precipitation
1107 (P), relative humidity (Rh), wind speed (u), incoming shortwave radiation (R_s) and longwave
1108 radiation (R_l). To support the stochastic parameterization of the model and Monte-Carlo
1109 simulations, Weather Generator (Strandman et al., 1993) was used to generate randomized
1110 scenarios based on long-term weather statistics (period of 1981-2010) from the four closest
1111 weather stations of the Finnish Meteorological Institute. This generator had been intensively
1112 tested and applied under Finnish conditions (Kellomäki and Väisänen, 1997; Venäläinen et al.,
1113 2001; Alm et al., 2007). We also compared the simulated meteorological variables against 2-year
1114 data measured from Siikaneva peatland site (61°50 N; 24°10 E), located 10 km away from our
1115 study site (Appendix C).

1117 **Appendix B. Methods and results of the empirical study on *Sphagnum capitula* water**
1118 **retention as a controlling mechanism for peatland moss community dynamics**

1119

1120 *Measurement of morphological traits*

1121 To quantify morphological traits, samples of *S. fallax* and *S. magellanicum* were collected at the
1122 end of August 2016 with a core (size d 7cm, area 50 cm², height at least 8 cm) maintaining the
1123 natural density of the stand. Samples were stored in plastic bags at cool room (4 °C) until
1124 measurements. Eight replicates were collected for each species. For each sample, capitulum
1125 density (D_s , shoots cm⁻²) was measured and ten moss shoots were randomly selected and
1126 separated into capitula and stems (5 cm below capitula). The capitula and stems were moistened
1127 and placed on top of a tissue paper for 2 minutes to extract free-moving water, before weighing
1128 them for water-filled fresh weight. The samples were dried at 60 °C for at least 48h to measure
1129 the dry masses. The field-water contents of capitula (W_{cf} , g g⁻¹) and stems (W_{sf} , g g⁻¹) were then
1130 calculated as the ratio of water to dry mass for each sample. The biomass of capitula (B_{cap} , g m⁻²)
1131 and living stems (B_{st} , g m⁻²) were calculated by multiplying the dry masses with the capitulum
1132 density (D_s). Biomass density of living stems (H_{spc} , g cm⁻¹ m⁻²) was calculated by dividing B_{st}
1133 with the length of stems.

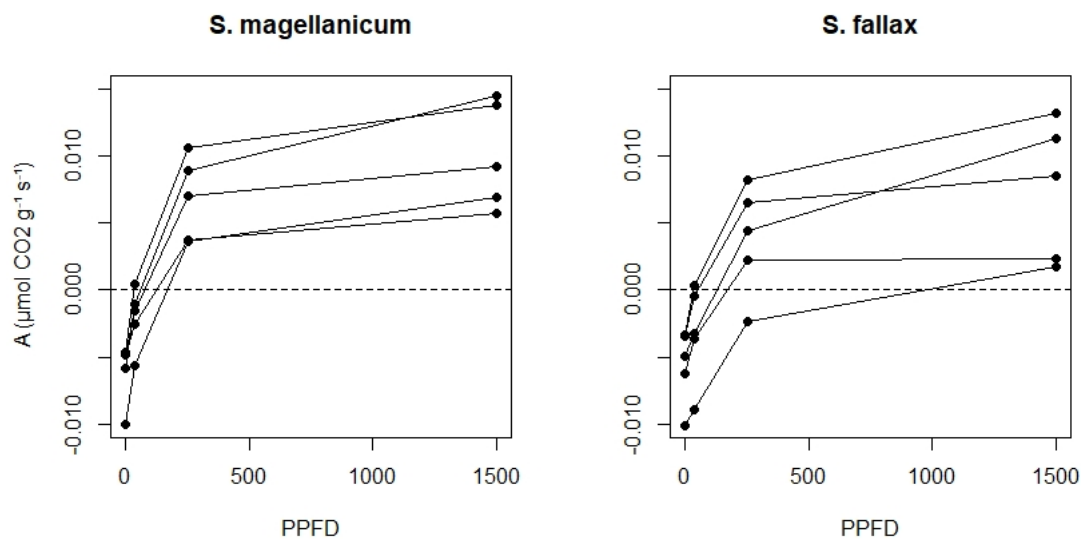

1134 *Measurement of photosynthetic traits*

1135 We measured the photosynthetic light response curves for *S. fallax* and *S. magellanicum* with
1136 fully controlled, flow-through gas-exchange fluorescence measurement systems (GFS-3000,
1137 Walz, Germany; Li-6400, Li-Cor, US) under varying light levels. In 2016, measurements on
1138 field-collected samples were done during May and early June, which is a peak growth period for
1139 *Sphagna* (Korrensalo et al. 2017). Samples were collected from the field site each morning and
1140 were measured the same day at Hyytiälä field station. Samples were stored in plastic containers
1141 and moistened with peatland water to avoid changes in plant status during the measurement.
1142 Right before the measurement we separated *Sphagnum* capitula from their stems and dried them
1143 lightly using tissue paper before placing an even layer of them in a custom-made cuvette by
1144 retaining the same density as naturally at field (Korrensalo et al. 2017). Net photosynthesis rate
1145 (A , μmol g⁻¹ s⁻¹) was measured at 1500, 250, 35, and 0 μmol m⁻² s⁻¹ photosynthetic photon flux
1146 density (PPFD) (Fig 1B). The light levels were chosen based on previous investigation by Laine
1147 et al. (2011, 2015), which showed increasing A until PPFD at 1500 and no photoinhibition even
1148 at high values of 2000 μmol m⁻² s⁻¹. The samples were allowed to adjust to cuvette conditions
1149 before the first measurement and after each change in the PPFD level until the CO₂ rate had
1150 reached a steady level, otherwise the cuvette conditions were kept constant (temperature 20°C,
1151 CO₂ concentration 400 ppm, flow rate 500 μmol s⁻¹, impeller at level 5 and relative humidity of
1152 inflow air 60%, yet the relative humidity remained on average 81% during the measurements).
1153 The time required for a full measurement cycle varied between 60 and 120 minutes. Each sample

1154 was weighed before and after the gas-exchange measurement, then dried at 40°C for 48 h to
 1155 determine the biomass of capitula (B_{cap}). For each species, five samples were measured as
 1156 replicates and were made to fit a hyperbolic light-saturation curve (Larcher, 2003):

$$1157 \quad A_{20} = \left(\frac{Pm_{20} * PPF D}{\alpha_{PPFD} + PPF D} - R_{S_{20}} \right) * B_{cap} \quad (B1)$$

1158 where subscript 20 denotes the variable value measured at 20 °C; R_s is the mass-based dark
 1159 respiration rate ($\mu\text{mol g}^{-1} \text{s}^{-1}$); Pm is the mass-based rate of maximal gross photosynthesis (μmol
 1160 $\text{g}^{-1} \text{s}^{-1}$); and α_{PPFD} is the half-saturation point ($\mu\text{mol m}^{-2} \text{s}^{-1}$), i.e., PPF D level where half of Pm is
 1161 reached. The measured morphological and photosynthetic traits are listed in Table 2.

1162
 1163 Figure B1. Measured light response curves for *S. magellanicum* and *S. fallax*.

1164
 1165 *Drying experiment*

1166 To link the water retention and photosynthesis of *Sphagnum* capitula, we performed a drying
 1167 experiment using a GFS-3000 system to measure co-variations of capitulum water potential (h ,
 1168 cm water), water content (W_{cap} , g g^{-1}) and A ($\mu\text{mol g}^{-1} \text{s}^{-1}$). For both species, four mesocosms
 1169 were collected in August 2018 and transported to laboratory in UEF Joensuu, Finland. Capitula
 1170 were harvested and wetted by water from the mesocosms. The capitula were then placed gently
 1171 on a piece of tissue paper for 2 minutes and then placed into the same cuvette as used in the
 1172 previous photosynthesis measurement. The cuvette was then placed into GFS and measured
 1173 under constant conditions of PPF D (1500 $\mu\text{mol m}^{-2} \text{s}^{-1}$), temperature (293.2K), inflow air (700
 1174 $\mu\text{mol s}^{-1}$), CO_2 concentration (400 ppm) and relative humidity (40%). Measurement was stopped
 1175 when A dropped to less than 10% of its maximum. Each measurement lasted between 120
 1176 and 180 minutes. Each sample was weighed before and after the gas-exchange measurement, then

1177 dried at 40°C for 48 h to determine the biomass of capitula (B_{cap}).

1178 The GFS-3000 records the vapor pressure (e_a , kPa) and the evaporation rate (E , g s⁻¹)
1179 simultaneously with A at every second (Heinz Walz GmbH, 2012). The changes in W_{cap} with
1180 time (t) was calculated as following:

$$1181 \quad RWC(t) = (W_{pre} - B_c - \sum_{t=0}^t E(t)) / B_c \quad (B2)$$

1182 We assumed that the vapor pressure at the surface of water-filled cells equaled the saturation
1183 vapor pressure (e_s), and the vapor pressure in the headspace of cuvette equaled that in the
1184 outflow (e_a). The vapor pressure in capitula pores (e_i) thus can be calculated based on following
1185 gradient-transport function (Fig. B2A):

$$1186 \quad \lambda E(t) = \frac{\rho_a c_p (e_i(t) - e_a(t))}{\gamma r_a(t)} = \frac{\rho_a c_p (e_s - e_i(t))}{\gamma r_s(t)} \quad (B3)$$

1187 where λ is the latent heat of vaporization; γ is the slope of the saturation vapor pressure -
1188 temperature relationship; r_a is the aerodynamic resistance (m s⁻¹) for vapor transport from inter-
1189 leaf volume to headspace; r_s is the surface resistance of vapor transport from wet leaf surface to
1190 inter-leaf volume. The bulk resistance for evaporation (r_{bulk}) was thus calculated as $r_a + r_s$.

1191 We assumed that the structures of tissues and pores did not change during the drying process
1192 and assumed r_a to be constant during each measurement. A tended to increase with time t until it
1193 peaked (A_m) and then decreased (Fig. 2B). The point $A=A_m$ implied the water content where
1194 further evaporative loss would start to drain the cytoplasmic water, leading to the decrease in A .
1195 The response of A to W_{cap} was fitted as a second-order polynomial function (Robroek et al.,
1196 2009) using data from t_{Am} to t_n :

$$1197 \quad f_A(W_{cap}) = a_{w0} + a_{w1} * W_{cap} + a_{w2} * W_{cap}^2 \quad (B4)$$

1199 where a_{w0} , a_{w1} and a_{w2} are parameters; and $f_A(W_{cap}) = A/A_m$. For each replicate, the optimal water
1200 content for photosynthesis (W_{opt}) was derived from the peak of fitted curve (Eq. 4). The
1201 capitulum water content at the compensation point W_{cmp} , where the rates of gross photosynthesis
1202 and respiration are equal, can be calculated from the point $A=0$.

1203

1204

1205

1206

1207

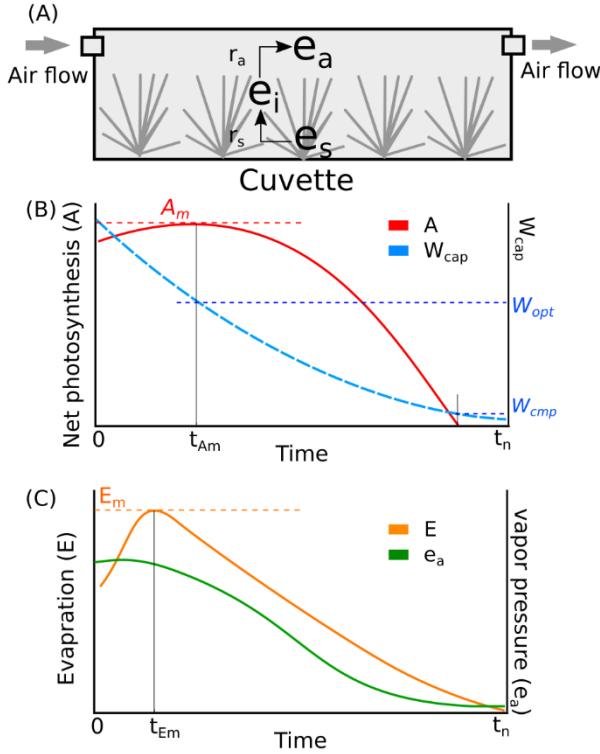

Figure B2. Conceptual schemes of (A) cuvette setting and resistances, (B) the co-variations of net photosynthesis and W_{cap} , and (C) the co-variations of evaporation and vapor pressure in headspace during a measurement. Meanings of symbols: e_a , vapor pressure in headspace of cuvette (kPa); e_i , vapor pressure in branch-leaf structure of capitula; e_s , vapor pressure at the surface of wet tissues; r_a , aerodynamic resistance of vapor diffusion from inner capitula to headspace; r_s , surface resistance of vapor diffusion from wet tissue surface to inner capitula space; A , net photosynthesis rate ($\mu\text{mol m}^{-2} \text{s}^{-1}$); A_m , maximal net photosynthesis rate ($\mu\text{mol m}^{-2} \text{s}^{-1}$); W_{cap} , water content of capitula (g g^{-1}); W_{opt} , W_{cap} at $A=A_m$; W_{cmp} , W_{cap} at $A=0$; E , evaporation rate (mm s^{-1}).

1225

1226

1227 Similarly, the evaporation rate (E) increased from the start of measurement until maximum
 1228 evaporation E_m , and then decreased (Fig. B2C). The point $E=E_m$ implied the time when the wet
 1229 capitulum tissues were maximally exposed to the air flow. Therefore, r_a was estimated as the
 1230 minimum of bulk resistance using Eq. (B5), by assuming $e_i(t) \approx e_s$ when $E(t) = E_m$:

$$1231 \quad r_a = \frac{\rho_a c_p (e_s - e_a(t))}{\gamma \lambda E_m} \quad (\text{B5})$$

1232 Based on the calculated $e_i(t)$, we were able to derive the capitulum water potential (h)
 1233 following the equilibrium vapor-pressure method (e.g. Price et al, 2008; Goetz and Price, 2015):

$$1234 \quad h = \frac{RT}{Mg} \ln \left(\frac{e_i}{e_s} \right) + h_0 \quad (\text{B6})$$

1235 where R is the universal gas constant ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$); M the molar mass of water (0.018 kg
 1236 mol^{-1}); g is the gravitational acceleration (9.8 N kg^{-1}); e_i/e_s is the relative humidity; h_0 is the
 1237 water potential due to the emptying of free-moving water before measurement (set to 10 kPa
 1238 according to Hayward and Clymo, 1982).

1239

1240 *Statistical analysis*

1241 The light response curve (Eq. B1) and the response function of A/A_m to W_{cap} changes (Eq. B4)
1242 were fitted using nlme package in R (version 3.1). The obtained values of shape parameters a_{w0} ,
1243 a_{w1} and a_{w2} (Eq. 4) were then used to calculate W_{opt} ($W_{opt} = -0.5 a_{w1} / a_{w2}$) and W_{cmp} ($W_{cmp} = 0.5$
1244 $[-a_{w1} - (a_{w1}^2 - 4a_{w0} a_{w2})^{0.5}] / a_{w2}$). We then applied ANOVA to compare *S. magellanicum* against
1245 *S. fallax* for the traits obtained from the field sampling (i.e. structural properties such as B_{cap} , D_S ,
1246 H_{spe} , W_{cf} , W_{sf}) and from the gas-exchange measurements (i.e. Pm_{20} , Rs_{20} , W_{opt} , W_{cmp} and r_{bulk}),
1247 using R (version 3.1).

1248 The measured values of capitulum water potential (h) were \log_{10} -transformed and related to the
1249 variations in W_{cap} , B_{cap} and D_S with a linear model. Similarly, a linear model was established to
1250 quantify the response of bulk resistance for evaporation (r_{bulk}) (\log_{10} -transformed) to the
1251 variations in h , B_{cap} and D_S . The linear regressions were based on statsmodels (version 0.9.0) in
1252 Python (version 2.7), as supported by Numpy (version 1.12.0) and Pandas (version 0.23.4)
1253 packages.

1254

1255 **Results of the empirical measurements**

1256 The two *Sphagnum* species differed in their structural properties (Table B1). Lawn species *S.*
1257 *fallax* had looser structure than hummock species *S. magellanicum* as seen in lower capitulum
1258 density (D_S) and specific height (H_{spe}) in *S. fallax* than in *S. magellanicum* ($P < 0.05$, Table. B1).
1259 Moreover, in conditions prevailing in the study site *S. fallax* mosses were dryer than *S.*
1260 *magellanicum*; the field-water contents of *S. fallax* capitulum (W_{cf}) and stem (W_{sf}) were 40% and
1261 46% lower than *S. magellanicum* ($P < 0.01$, Table. B1), respectively. The different density of
1262 capitulum of the two species differing in their capitulum size led to similar capitulum biomass
1263 (B_{cap}) ($P = 0.682$) between *S. fallax* with small capitulum and *S. magellanicum* with large
1264 capitulum. Unlike the structural properties, maximal CO_2 exchange rates (Pm_{20} and Rs_{20}) did not
1265 differ between the two species (Table B1).

1266 The drying experiment demonstrated how capitulum water content regulated capitulum
1267 processes in both studied *Sphagnum* species (Fig. B3). Decreasing capitulum water content
1268 (W_{cap}) led to decrease in the water potential (h), the responses of h to W_{cap} varied among
1269 replicates (Fig. 3A). The values of W_{cap} for *S. fallax* were generally lower than those for *S.*
1270 *magellanicum* under the same water potentials. The fitted linear models explained over 95% of
1271 the variations in the measured h for both species (Table. B2), although fitted responses of h to
1272 W_{cap} were slightly smoother than the measured ones, particularly for *S. magellanicum* (Fig.
1273 B3A). The responses of h to W_{cap} was significantly affected by the capitulum density (D_S),
1274 capitulum biomass (B_{cap}) and their interactions with W_{cap} (Table. B2).

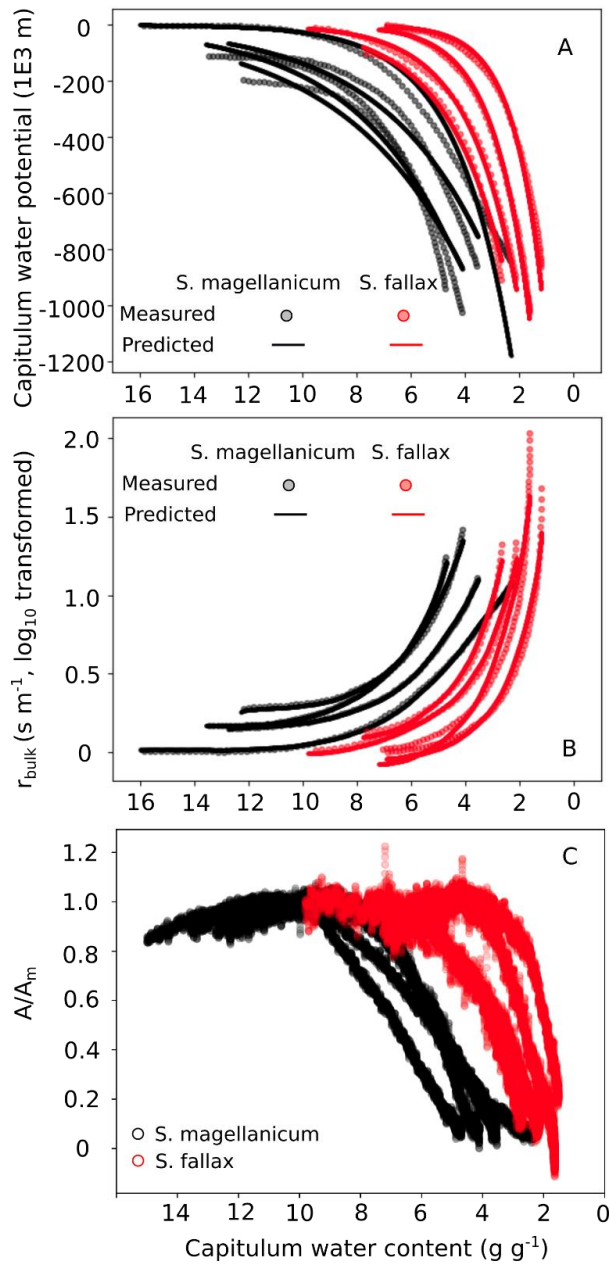

1275 Decreasing capitulum water content (W_{cap}), and water potential (h), were associated with
1276 increasing bulk resistance for evaporation (r_{bulk} , Fig. B3B), although the sensitivity of r_{bulk} to h

1277 changes varied by replicates. The values of r_{bulk} from *S. fallax* were largely lower than those
1278 from *S. magellanicum* when the capitulum water content of the two species were similar. The
1279 fitted linear models explained the observed variations in the measured r_{bulk} well for both species
1280 (Fig. 2B and Table. B3). The variation in the response of r_{bulk} to h was significantly affected by
1281 capitulum density (D_S), capitulum biomass (B_{cap}) and their interactions with h (Table. B3).

1282 Decreasing capitulum water content (W_{cap}) slowed down the net photosynthesis rate (Fig.
1283 B2C), as represented by the decreasing ratio of A/A_m . *S. fallax* required lower capitulum water
1284 content (W_{cap}) than *S. magellanicum* to reach photosynthetic maximum and photosynthetic
1285 compensation point. However, the ranges of capitulum water content from photosynthetic
1286 maximum (W_{opt}) or field capacity (W_{fc}) to that at compensation point (W_{cmp}) were smaller for *S.*
1287 *fallax* than *S. magellanicum*. Hence, *S. fallax* had narrower transition zone for photosynthesis to
1288 respond to drying, compared to *S. magellanicum*.

1289

1290

1291

1292 Figure B3. Responses of (A) capitulum water potential, (B) bulk resistance of evaporation, and
 1293 (C) net photosynthesis to changes in capitulum water content (W_{cap}) of two *Sphagnum* species
 1294 typical to hummocks (*S. magellanicum*, black) and lawns (*S. fallax*, red). As the measured results
 1295 are based on the drying experiment starting with fully wetted capitula characteristic for both
 1296 species, the X-axis is shown from high to low W_{cap} . The values predicted in (B) and (C) are
 1297 based on linear models with parameter values listed in Tables B2 and B3 and predictor values
 1298 from the drying experiment.

1353 **Appendix C. Comparisons of meteorological variables simulated by Weather Generator**
1354 **and those measured from Siikaneva peatland site (ICOS site located in 10 km distance**
1355 **from the study site Lakkasuo)**

1356

1357 Fig. C1 Comparisons of meteorological variables simulated by Weather Generator and those
1358 measured from Siikaneva peatland site. The variables include (A) cumulative precipitation (mm),
1359 (B) incoming shortwave radiation (W m^{-2}), (C) air temperature ($^{\circ}\text{C}$), and (D) relative humidity
1360 (%). These variables were measured and simulated at half-hourly timescale. The measurements
1361 were carried out during 2012-2013. Details about the site and measurements have been described
1362 by Alekseychik et al. (2018). The measured seasonal dynamics of the meteorological variables
1363 were generally in line with the 95% confidence intervals (CI) of the simulated values, which
1364 were calculated based on Monte-Carlo simulations ($n=5$).

1365

1366 **Appendix D. Comparisons of seasonal water table measured from the study site and the**
1367 **values simulated based on calibrated net inflow**

1368

1369 Fig. D1 Comparison of seasonal water table (WT) measured at the Lakkasuo study site and the
1370 values simulated by the calibrated PCS. WT values were sampled weekly from the lawn habitats
1371 both in field and in model output. The weekly mean WT was measured during 2001, 2002, 2004
1372 and 2016. The modelled means and standard deviations (SD) of WT were based on 20 Monte-
1373 Carlo simulations. The simulated seasonality of mean WT generally followed the measured
1374 trends. The calibration reduced the sum of squared error (SE , Eq. 12) from 199.5 ($a_N=b_N=0$) to
1375 117.3. The calibrated values for a_N and b_N were $-5.3575 \cdot 10^{-4}$ and $4.7599 \cdot 10^{-5}$, respectively (Eq.
1376 A18).
