21 ¹³C incorporation

22 Abstract

23 Coral reefs are constructed by calcifiers that precipitate calcium carbonate to build
24 their shells or skeletons through the process of calcification. Accurately assessing coral
25 calcification rates is crucial to determine the health of these ecosystems and their response to
26 major environmental changes such as ocean warming and acidification. Several approaches
27 have been used to assess rates of coral calcification, but there is a real need to compare these
28 approaches in order to ascertain that high quality and intercomparable results can be
29 produced. Here, we assessed four methods (total alkalinity anomaly, calcium anomaly, ^{45}Ca
30 incorporation and ^{13}C incorporation) to determine coral calcification of the reef-building coral
31 *Stylophora pistillata*. Given the importance of environmental conditions on this process, the
32 study was performed under two starting pH levels (ambient: 8.05 and low: 7.2) and two light
33 (light and dark) conditions. Under all conditions, calcification rates estimated using the
34 alkalinity and calcium anomaly techniques as well as ^{45}Ca incorporation were highly
35 correlated. Such a strong correlation between the alkalinity anomaly and ^{45}Ca incorporation
36 techniques has not been observed in previous studies and most probably results from
37 improvements described in the present paper. The only method which provided calcification
38 rates significantly different from the other three techniques was ^{13}C incorporation.
39 Calcification rates based on this method were consistently higher than those measured using
40 the other techniques. Although reasons for these discrepancies remain unclear, the use of this
41 technique for assessing calcification rates in corals is not recommended without further
42 investigations.

43 1. Introduction

44 Calcification is the fundamental biological process by which organisms precipitate
45 calcium carbonate. Calcifying organisms take up calcium and carbonate or bicarbonate ions to
46 build their biomineral structures (aragonite, calcite and/or vaterite) which have physiological,
47 ecological and biogeochemical functions. Moreover, calcium carbonate plays a major role in
48 the services provided by ecosystems to human societies.

49 The ocean has absorbed large amounts of anthropogenic CO₂ since the start of the
50 industrial revolution and is currently sequestering about 22% of CO₂ emissions (average
51 2008-2017; Le Quéré et al., 2018). This massive input of CO₂ in the ocean impacts seawater
52 chemistry with a decrease in seawater pH, carbonate ion concentrations [CO₃²⁻] and an
53 increase in CO₂ and bicarbonate concentrations [HCO₃⁻]. These fundamental changes to the
54 carbonate system are referred to as “ocean acidification” (OA; Gattuso and Hansson, 2011).
55 Models project that the average surface water pH will drop by 0.06 to 0.32 pH units by the
56 end of the century (IPCC, 2014).

57 The effect of OA on the ocean is currently the subject of intense research with
58 particular attention to organisms producing CaCO₃. For instance, coral communities have
59 already proven to be particularly vulnerable to rapidly changing global environmental
60 conditions (e.g. Albright et al., 2018). In order to help project the future of coral reefs,
61 accurate estimates of calcification rates during realistic perturbation experiments are
62 necessary in order to produce high quality and intercomparable results (Cohen et al., 2017;
63 Gazeau et al., 2015; Langdon et al., 2010; Riebesell et al., 2010; Schoepf et al., 2017).

64 Several methods are available to quantify rates of coral calcification. Calcification can
65 be measured as the increase of CaCO₃ mass (e.g. the buoyant weight technique; Jokiel et al.,

66 1978) or following the incorporation of radio-labelled carbon or calcium in the skeleton
67 (Goreau, 1959), but also through the quantification of changes in a seawater constituent that is
68 stoichiometrically related to the amount of CaCO₃ precipitated. For instance, the alkalinity
69 anomaly technique (Smith and Key, 1975) has been widely used to estimate net calcification
70 of organisms and communities, especially of corals and coral reef environments (e.g. Smith
71 and Kinsey, 1978; Gazeau et al., 2015; Albright et al., 2016; Cyronak et al., 2018). Total
72 alkalinity (A_T) is directly influenced by bicarbonate and carbonate ion concentrations together
73 with a multitude of other minor compounds (Wolf-Gladrow et al., 2007). Calcification
74 consumes carbonate or bicarbonate, following the reversible reaction:

76 Calcification consumes two moles of HCO₃⁻, hence decreasing A_T by two moles per
77 mole of CaCO₃ produced (eq. 1). It is possible to derive the rate of net calcification (gross
78 calcification - dissolution) by measuring A_T before and after incubating an organism or a
79 community. This method assumes, however, that calcification is the only biological process
80 influencing A_T (Smith and Key, 1975). Nitrogen assimilation through photosynthetic
81 activities, nitrification as well as aerobic and anaerobic remineralization of organic matter are
82 known to impact A_T through the consumption or release of nutrients (ammonium, nitrate and
83 phosphate) and protons (Wolf-Gladrow et al. 2007). While for some group of species (e.g.
84 bivalves, sea urchins), corrections appear necessary to take into account the effect of nutrient
85 release on A_T , changes in nutrient concentrations during incubations of isolated corals are too
86 low (i.e. several orders of magnitude lower than changes in A_T) to introduce a significant bias
87 in the calculations (Gazeau et al. 2015).

88 In contrast to A_T , the concentration of calcium (Ca²⁺) in seawater is only biologically
89 influenced by net calcification and a 1:1 relationship can be used to derive net calcification

90 rates (eq. 1). The depletion of A_T and Ca^{2+} needs to be corrected for gains of A_T and Ca^{2+}
91 resulting from evaporation. These corrections can be applied through the incubation of
92 seawater in the absence of coral (Schoepf et al., 2017). Both the alkalinity anomaly and
93 calcium anomaly methods are non-destructive and typically show a good agreement
94 (Chisholm and Gattuso, 1991; Murillo et al., 2014; Gazeau et al., 2015).

95 The ^{45}Ca incorporation technique has been used since the 1950's (Goreau and Bowen,
96 1955; Goreau, 1959). While earlier techniques showed low reproducibility, methodological
97 improvements led to a significant reduction of the deviations between replicates (see
98 Tambutté et al., 1995, for more details). The strength of this method is that it is extremely
99 sensitive for measuring short-term variations in gross calcification rates. However, in contrast
100 to the A_T and Ca^{2+} anomaly techniques, it is a sample-destructive method.

101 Previous studies designed to compare calcification rate estimates using the ^{45}Ca
102 incorporation and A_T anomaly methods revealed subtle discrepancies. For example, Smith and
103 Roth in Smith and Kinsey (1978) reported an overestimation of rates based on the ^{45}Ca
104 method. In contrast, Tambutté et al. (1995) and Cohen et al. (2017) reported a decrease in A_T
105 without concomitant incorporation of ^{45}Ca ; therefore, suggesting an overestimation of
106 calcification derived from A_T measurements. However, during these studies, in order to avoid
107 radioactive contamination of laboratory equipment, estimates of calcification were not
108 performed during the same incubations, but rather during incubations performed over two
109 consecutive days.

110 In contrast to the ^{45}Ca incorporation method, to the best of our knowledge, no studies
111 have used carbon-based incorporation techniques to estimate coral calcification rates in the
112 framework of ocean acidification. Past studies that compared carbon and calcium
113 incorporation rates in coral skeletons based on a double labelling technique with $H^{14}CO_3$ and

114 ^{45}Ca showed that only a minor proportion of the labelled seawater carbon is incorporated in
115 the skeleton (e.g. Marshall and Wright, 1998) and that the major source of dissolved inorganic
116 carbon for calcification is metabolic CO_2 (70–75% of the total CaCO_3 deposition; Furla et al.,
117 2000). Consequently, under both light and dark conditions, the rate of ^{45}Ca deposition appears
118 greater than the rate of ^{14}C incorporation (Furla et al., 2000). To the best of our knowledge,
119 only one study estimated calcification rates of a benthic calcifier (coralline algae) using a
120 stable carbon isotopic technique through addition of ^{13}C -labelled bicarbonate (McCoy et al.,
121 2016). The present study aimed at comparing calcification rates measured using the alkalinity
122 and calcium anomaly methods, as well as the ^{45}Ca and ^{13}C incorporation techniques, under
123 different pH and light conditions.

124 2. Material and Methods

125 Colonies of the reef-building coral *Stylophora pistillata* were incubated in the
126 laboratory, both in the light and dark, under ambient and lowered pH conditions. At ambient
127 pH (experiment conducted in July-August 2017), two sets of incubations were performed
128 using either ^{45}Ca or ^{13}C additions and calcification rates based on these techniques were
129 compared to those derived, during the same incubations, by the alkalinity and calcium
130 anomaly techniques. At lowered pH (experiment conducted in August 2018), no incubations
131 with ^{13}C addition were conducted and only the three other techniques were compared.

132 2.1. Biological material and experimental set-up

133 Specimens used in this experiment originated from colonies of the coral *Stylophora*
134 *pistillata* (Esper 1797) initially sampled in the Gulf of Aqaba (Red Sea, Jordan) and
135 transferred to the Scientific Centre of Monaco where they were cultivated under controlled
136 conditions for several years. In June 2017, 40 terminal portions branches of *S. pistillata*, free
137 of boring organisms, were cut from four different parent colonies (10 branches per parent
138 colony) and suspended by nylon lines to allow tissues to fully cover the exposed skeleton for
139 at least five weeks (Tambutté et al., 1995; Houlbrèque et al., 2015). The nubbins were fed
140 with rotifers (once a day) and artemia nauplii (twice a week; ca. 1 nauplius mL^{-1}) and kept in
141 70 L aquaria (water renewal: 2 L min^{-1}) under an irradiance of 200 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$
142 (12:12 light:dark photoperiod, light banks: HQI 250W Nepturion - BLV (Germany) / 200
143 $\mu\text{mol photons m}^{-2} \text{s}^{-1}$), a seawater temperature of 25 ± 0.5 °C and a salinity of 38 ± 0.5 . Water
144 motion was provided by a submersible pump (Minijet MN 606; RENA©). Before the start of
145 the experiment, specimens were transferred to the International Atomic Energy Agency

146 (IAEA). For the second set of experiments in 2018, nubbins were prepared in June 2018 and
147 cultured, under the conditions described above, at IAEA except that colonies were fed twice a
148 week with newly hatched brine shrimp nauplii (ca. 1 nauplius mL⁻¹). Biometrics parameters
149 (size, weight) of the biological material are shown in Table 1.

150 Different types of incubations were conducted. In July-August 2017, one set of
151 incubations was performed under ambient pH conditions with the addition of radioactive
152 calcium dichloride (⁴⁵CaCl₂). During the same period, another set of incubations was
153 performed, under ambient pH conditions, with addition of labelled ¹³C-sodium bicarbonate
154 (¹³C-NaHCO₃ 99%). Finally, in August 2018, one set of incubations was performed under
155 lowered pH conditions (see thereafter for more details) with the addition of ⁴⁵CaCl₂. For all
156 sets of incubations, organisms were incubated for 5 to 11 hours (Table 1), both in the light
157 and dark, in 500 mL polyethylene beakers equipped with a magnetic stirrer (Fig. 1). Six and
158 five replicates were used, respectively, at ambient and low pH. Furthermore, for all sets of
159 incubations, one beaker was incubated, under the same conditions as the other beakers,
160 without coral and served as a control.

161 For each set of incubations, 2.4 L of seawater, pumped continuous from offshore of
162 the IAEA Monaco premises at 60 m depth, were filtered onto 0.2 µm (GF/F, 47 mm). For
163 incubations performed at lowered pH condition, pure CO₂ was bubbled in the 2.4 L initial
164 seawater batch using an automated pH-stat system (IKS Aquastar©) until the target pH was
165 reached. The pH electrode from the pH-stat system was inter-calibrated using a glass
166 combination electrode (Metrohm, Ecotrode Plus) calibrated on the total scale using a TRIS
167 buffer solution with a salinity of 35 (provided by A. Dickson, Scripps Institution of
168 Oceanography, San Diego). Initial pH_T (total scale) levels were set to ~7.2. It must be stressed
169 that pH levels were not regulated during the incubations. For ⁴⁵Ca-incubations, this initial

170 batch was spiked with $^{45}\text{CaCl}_2$ to reach a nominal activity of $\sim 15 \text{ Bq mL}^{-1}$. As we anticipated
171 lower calcification rates during the set of experiments conducted at low pH, initial nominal
172 activity was set to $\sim 30 \text{ Bq mL}^{-1}$. Before distributing seawater to the experimental beakers, a
173 one-milliliter aliquot of seawater was removed for the precise determination of the initial
174 activity. Samples were stored, in the dark, in high-performance glass vials for 24 h before
175 counting. For ^{13}C -incubations, to determine seawater background isotopic level ($\delta^{13}\text{C}$) of the
176 dissolved inorganic carbon pool ($\delta^{13}\text{C}-C_T$), three 27 mL samples were collected and gently
177 transferred to glass vials avoiding bubbles. Then, $\sim 8.95 \text{ mg}$ of $^{13}\text{C}-\text{NaHCO}_3$ were added to the
178 batch of filtered ambient seawater to increase $\delta^{13}\text{C}-C_T$ to ca. 1,500‰. For the determination
179 of $\delta^{13}\text{C}-C_T$ after enrichment, two 27 mL samples were handled as described above. The vials
180 were then sealed after being poisoned with $10 \mu\text{L}$ of saturated mercuric chloride (HgCl_2) and
181 stored upside-down at room temperature in the dark for subsequent analysis.

182 For all sets of incubations, samples for the measurements of pH_T , A_T (200 mL), and
183 Ca^{2+} concentrations (50 mL) were taken before distributing seawater to the experimental
184 beakers. While pH_T was measured immediately after sampling, samples for A_T measurements
185 were poisoned with $40 \mu\text{L}$ of 50% saturated HgCl_2 and stored in the dark at $4 \text{ }^\circ\text{C}$ pending
186 analysis less than two weeks later. Samples for $[\text{Ca}^{2+}]$ measurements were not poisoned and
187 stored in the dark at $4 \text{ }^\circ\text{C}$ pending analysis less than two weeks after sampling.

188 Gravimetrically determined amounts of filtered seawater (ca. 300 g) were transferred
189 to the incubation containers which were placed in a temperature-controlled (IKS Aquastar©)
190 water bath maintained at $25 \pm 0.5 \text{ }^\circ\text{C}$. Coral nubbins were suspended with a nylon line in the
191 experimental beakers 5 cm below the water level covered with transparent film to limit
192 evaporation (Fig. 1). During the low pH incubations conducted in 2018, to avoid
193 physiological stress, coral nubbins were acclimated by gradually lowering pH to the target

194 levels during 24 h. This acclimation was performed in an open-flow 20 L aquarium (one full
195 water renewal per hour) using a pH-stat system as previously described and with a pH
196 decrease of ca. 0.03 units h⁻¹.

197 Incubations in the light were performed at an irradiance of 200 μmol photons m⁻² s⁻¹
198 during daytime whereas dark incubations were conducted at night. Incubation times were not
199 fixed based on scientific considerations and differed between the different incubations due to
200 practical constrains (i.e. access to the lab etc...). Before the beginning of the incubations, all
201 beakers (containing corals) were precisely weighed at ± 0.01 g (Sartorius BP 310S).

202 At the conclusion of the incubations, all beakers were precisely weighed to evaluate
203 evaporation and seawater samples were analyzed for pH_T, A_T and [Ca²⁺] as well as for ⁴⁵Ca
204 activity or δ¹³C-C_T depending on the type of incubations. pH_T was measured immediately and
205 samples for A_T and [Ca²⁺] determinations were filtered onto 0.2 μm (GF/F, Ø 47 mm),
206 poisoned with saturated HgCl₂ (only for A_T) and stored in the dark at 4 °C pending analysis
207 (within two weeks). The corals were then removed from the beakers for the analysis of
208 incorporated ⁴⁵Ca or ¹³C. Three additional corals which were not incubated were processed
209 for carbon isotopic composition of the previously accreted calcium carbonate (see section
210 “2.3. Computations and statistics”).

211 2.2. Analytical techniques

212 Immediately after sampling, pH_T was measured on a Metrohm 826 mobile pH-logger
213 and a glass electrode (Metrohm, Ecotrode Plus) calibrated on the total scale using a TRIS
214 buffer of salinity 35 (provided by A. Dickson, Scripps University, USA). A_T was determined
215 in triplicate 50 mL subsamples by potentiometric titration on a titrator Titrand 888
216 (Metrohm) coupled to a glass electrode (Metrohm, Ecotrode Plus) and a thermometer

217 (pt1000). The pH electrode was calibrated before every set of measurements on the total scale
218 using a TRIS buffer of salinity 35 (provided by A. Dickson, Scripps University, USA).
219 Measurements were carried out at a constant temperature of 25 °C and A_T was calculated as
220 described in Dickson et al. (2007). Certified reference material (CRM; batches 143 and 156)
221 provided by A. Dickson (Scripps University, USA) were used to check precision (standard
222 deviation within measurements of the same batch) and accuracy (deviation from the certified
223 nominal value). Over the six series of A_T measurements performed during the experiment,
224 mean accuracy and precision (\pm SD) were respectively 7.2 ± 1.2 and $1.2 \pm 0.2 \mu\text{mol kg}^{-1}$.
225 $[\text{Ca}^{2+}]$ was determined in triplicate using the ethylene glycol tetra acetic acid (EGTA)
226 potentiometric titration (Lebel and Poisson, 1976). About 10 g of sampled seawater and 10 g
227 of HgCl_2 solution (ca. 1 mmol L^{-1}) were accurately weighed out. Then, about 10 g of a
228 concentrated EGTA solution (ca. 10 mmol L^{-1} , also by weighing) was added to completely
229 complex Hg^{2+} and to complex nearly 95% of Ca^{2+} . After adding 10 mL of borate buffer
230 ($\text{pH}_{\text{NBS}} \sim 10$) to increase the pH of the solution, the remaining Ca^{2+} was titrated by a diluted
231 solution of EGTA (ca. 2 mmol L^{-1}) using a titrator (Titrand 888, Metrohm) coupled to an
232 amalgamated silver combined electrode (Metrohm Ag Titrode). Following Cao and Dai
233 (2011), the volume of EGTA necessary to titrate the remaining ca. 5% of Ca^{2+} were obtained
234 by manually fitting a polynomial function to the first derivative of the titration curve using the
235 function “loess” of the R software¹. The EGTA solution was calibrated prior to each
236 measurement series using International Association for the Physical Sciences of the Oceans
237 (IAPSO) standard seawater (salinity = 38.005). Mean $[\text{Ca}^{2+}]$ precision obtained using this
238 technique was $2.9 \mu\text{mol kg}^{-1}$ ($n = 40$), corresponding to a coefficient of variation (CV) of
239 0.026%.

¹The R Development Core Team, R.: A language and environment for statistical computing, 2018.

240 To determine the specific activity in radio-labelled seawater, the 1 mL aliquots were
241 transferred to 20 mL glass scintillation vials and mixed in proportion 1:10 (v:v) with
242 scintillation liquid Ultima Gold™ XR. According to a method adapted from Tambutté et al.
243 (1995), at the end of incubation sampled nubbins were immersed for 30 min in beakers
244 containing 300 mL of unlabelled seawater to achieve isotopic dilution of the ⁴⁵Ca contained in
245 the gastrovascular cavity. Constant water motion was provided in the efflux medium by
246 magnetic stirring bars. Tissues were then dissolved completely in 1 mol L⁻¹ NaOH at 90 °C
247 for 20 min. The skeleton was rinsed twice in 1 mL NaOH and twice in 5 mL in MilliQ water.
248 It was then dried for 72 h at 60 °C, precisely weighed at ± 0.01 g using a Sartorius BP 310S
249 (referred thereafter to as skeleton dry weight), and dissolved in 12 N HCl. Three 200 µL
250 aliquots from each skeleton dissolution were transferred to 20 mL glass scintillation vials and
251 mixed with 10 mL scintillation liquid Ultima Gold™ XR. Radioactive samples were
252 thoroughly mixed to homogenize the solution and kept in the dark for 24 h before counting.
253 The radioactivity of ⁴⁵Ca was counted using a Tri-Carb 2900 Liquid Scintillation Counter.
254 Counting time was adapted to obtain a propagated counting error of less than 5% (maximal
255 counting duration was 90 min). Radioactivity was determined by comparison with standards
256 of known activities and measurements were corrected for counting efficiency and physical
257 radioactive decay.

258 The analyses of seawater $\delta^{13}\text{C}-C_T$ as well as of the ¹³C signature of coral calcified
259 tissues were performed at Leuven University. For $\delta^{13}\text{C}-C_T$ analyses, a helium headspace (5
260 mL) was created in the vials and samples were acidified with 2 mL of phosphoric acid
261 (H₃PO₄, 99%). Samples were left to equilibrate overnight to transfer all C_T to gaseous CO₂.
262 Samples were injected in the carrier gas stream of an EA-IRMS (Thermo EA1110 and Delta
263 V Advantage), and data were calibrated with NBS-19 and LSVEC standards (Gillikin and

264 Bouillon, 2007). Corals were treated following the same protocol as for ^{45}Ca incorporation
 265 measurements and powdered. Triplicate subsamples of carbonate powder ($\sim 100 \mu\text{g}$) were
 266 placed into gas-tight vials, flushed with helium, and converted into CO_2 with H_3PO_4 . After 24
 267 h, subsamples of the released CO_2 were injected into the EA-IRMS system as described
 268 above. Data were calibrated with NBS-19 and LSVEC. Carbon isotope data are expressed in
 269 the delta notation (δ) relative to Vienna Pee Dee Belemnite (VPDB) standard and were
 270 calculated as:

$$271 \quad R_{\text{sample}} = \frac{\delta^{13}\text{C}_{\text{sample}}}{1000 + 1} \cdot R_{\text{VPDB}} \quad (2)$$

272 2.3. Computations and statistics

273 The carbonate chemistry was assessed using pH_T and A_T and the R package seacarb².
 274 Propagation of errors on computed parameters was performed using the new function “error”
 275 of the package seacarb (Orr et al., 2018) on the R software, considering errors associated to
 276 the estimation of A_T as well as errors on dissociation constants.

277 Estimates of coral calcification rates based on changes in A_T and $[\text{Ca}^{2+}]$ during
 278 incubations were computed following equations (3) and (4), respectively. As shown in these
 279 equations, initial levels of A_T and $[\text{Ca}^{2+}]$ are not necessary to compute calcification rates and
 280 only final values in the incubations with corals and without corals (controls) were used:

$$281 \quad G_{AT} = -\frac{(A_{T2} - A_{T1}) - (A_{T2c} - A_{T1})}{2t} \cdot \frac{W_w}{W_c} = -\frac{(A_{T2} - A_{T2c})}{2t} \cdot \frac{W_w}{W_c} \quad (3)$$

$$282 \quad G_{Ca} = -\frac{(Ca_2 - Ca_1) - (Ca_{2c} - Ca_1)}{t} \cdot \frac{W_w}{W_c} = -\frac{(Ca_2 - Ca_{2c})}{t} \cdot \frac{W_w}{W_c} \quad (4)$$

²seacarb: seawater carbonate chemistry with R. Gattuso, J.-P., J. M. Epitalon, H. Lavigne, J. C. Orr, B. Gentili, M. Hagens, A. Hofmann, A. Proye, K. Soetaert and J. Rae, 2018. <https://cran.r-project.org/package=seacarb>

283 where A_{T1} and Ca_1 are A_T and Ca^{2+} concentrations at the start of the incubations (in $\mu\text{mol kg}^{-1}$;
 284 not used in the computations), A_{T2}/A_{T2c} and Ca_2/Ca_{2c} are A_T and Ca^{2+} concentrations at the end
 285 of the incubations, respectively with and without corals, t is the incubation duration in h, W_w
 286 and W_c are respectively the mass of seawater (average between initial and final weights) and
 287 the coral skeleton dry weight (g; DW). G_{AT} and G_{Ca} are therefore expressed in $\mu\text{mol CaCO}_3 \text{ g}$
 288 $\text{DW}^{-1} \text{ h}^{-1}$. Error propagation was used to estimate errors:

$$289 \quad SE_{G_{AT}} = \frac{\sqrt{SE_{AT_2}^2 + SE_{AT_{2c}}^2}}{2t} \cdot \frac{W_w}{W_c} \quad (5)$$

$$290 \quad SE_{G_{Ca}} = \frac{\sqrt{SE_{Ca_2}^2 + SE_{Ca_{2c}}^2}}{t} \cdot \frac{W_w}{W_c} \quad (6)$$

291 where $SE_{AT_2}/SE_{AT_{2c}}$ and $SE_{Ca_2}/SE_{Ca_{2c}}$ correspond to standard errors associated with the
 292 measurement of three analytical replicates per sample for A_T and Ca^{2+} at the end of the
 293 incubations, respectively with and without corals, t is the incubation duration in h, W_w and W_c
 294 are respectively the mass of seawater (average between initial and final weights) and the coral
 295 skeleton dry weight (g DW).

296 Coral calcification rates based on ^{45}Ca incorporation were estimated using measured
 297 seawater activity and activity recorded in the skeleton digest. Rates were then normalized per
 298 g skeleton dry weight using the formula:

$$299 \quad G_{^{45}\text{Ca}} = \frac{\text{Activity}_{\text{sample}} \cdot \frac{\text{Ca}}{\text{Activity}_{\text{seawater}}}}{W_c \cdot t} \quad (7)$$

300 where $\text{Activity}_{\text{sample}}$ is the average of counts per minute (CPM) of three 200 μL
 301 aliquots from the dissolved skeleton sample, $\text{Activity}_{\text{seawater}}$ is the total CPM in the 1 mL
 302 seawater samples, Ca is the $[\text{Ca}^{2+}]$ measured in the corresponding samples (average between
 303 initial and final values, $\mu\text{mol kg}^{-1}$) and further converted to $\mu\text{mol L}^{-1}$ considering a

304 temperature of 25 °C and a salinity of 38, W_c is the skeleton dry weight (in g) and t the
 305 incubation duration (h). G_{45ca} is therefore expressed in $\mu\text{mol CaCO}_3 \text{ g DW}^{-1} \text{ h}^{-1}$. The standard
 306 errors for these calcification rate estimates were propagated based on standard errors
 307 associated with the measurements of triplicate samples for both $\text{Activity}_{\text{sample}}$ and $[\text{Ca}^{2+}]$.

308 The precipitation of calcium carbonate minerals (G) during the incubation interval was
 309 also estimated using measured $\delta^{13}\text{C}$ values and isotope mass balance calculations [eq. (8) and
 310 (9) below]. The CO_2 released during phosphoric acid digestion is derived from two sources:
 311 new coral CaCO_3 and previously accreted skeletal carbonate mineral. The new carbon
 312 acquired in each measured nubbins ($\delta^{13}\text{C}_N$) was assumed to have the same carbon isotope
 313 composition as the labelled seawater C_T (average between initial and final level, $\delta^{13}\text{C}-C_T \sim$
 314 1,400-1,700‰). The previously accreted skeletal material was assumed to have a $\delta^{13}\text{C}$ value
 315 equal to the measured value for the background sample ($\delta^{13}\text{C}_P$). The $\delta^{13}\text{C}$ value ($\delta^{13}\text{C}_M$),
 316 representing the mixture of new calcified material and previously accreted carbonate mineral,
 317 is then calculated the following mixing equation:

$$318 \quad \delta^{13}\text{C}_M = f_G \cdot \delta^{13}\text{C}_N + (1 - f_G) \cdot \delta^{13}\text{C}_P \quad (8)$$

319 where f_G is the fraction of the calcium carbonate mineral precipitated during the experiment,
 320 and $\delta^{13}\text{C}_N$ and $\delta^{13}\text{C}_P$ are the carbon isotope compositions of the newly precipitated and
 321 previously accreted calcium carbonate, respectively. Equation (8) was solved for f_G to
 322 determine the calcium carbonate precipitated during the incubation using:

$$323 \quad G_{13C} = \frac{f_G}{t \cdot M_{\text{CaCO}_3}} \cdot 1e^6 \quad (9)$$

324 where M_{CaCO_3} is the molar mass of calcium carbonate (g mol^{-1}) and t is the incubation
325 duration in h. $G_{13\text{C}}$ are therefore expressed in $\mu\text{mol CaCO}_3 \text{ g DW}^{-1} \text{ h}^{-1}$. The standard errors for
326 these calcification rate estimates were calculated based on standard errors associated with the
327 triplicate measurements of $\delta^{13}\text{C}_\text{P}$ and $\delta^{13}\text{C}_\text{N}$.

328 Model-II linear regressions (Sokal and Rohlf, 1995) were used to compare net
329 calcification rates obtained with the different methods. All regressions were performed using
330 function “lmodel2” of the package lmodel2³ on the R software.

³lmodel2: Model II Regression, Legendre P. and J. Oksanen, 2018. <https://cran.r-project.org/package=lmodel2>

331 3. Results

332 Environmental conditions at the start of the different incubations are shown in Table 2.
333 All values in Table 2 as well as in the text below correspond to the average between replicates
334 (or incubations) \pm standard deviation (SD). All incubations performed under ambient pH_T
335 (~ 8.05) were conducted under carbonate chemistry favorable to calcification with saturation
336 states with respect to aragonite (Ω_a) well above 1 (average of 4.0 ± 0.1 over the four
337 incubations). In contrast, during experiments at low pH_T (initial $\text{pH}_T \sim 7.2$), seawater was
338 corrosive with respect to aragonite ($\Omega_a \sim 0.75$). However, as pH was not regulated during the
339 incubations (see previous section), it increased, at lowered pH, to an average of 7.75 ± 0.03 (n
340 = 5) in dark conditions and to an average of 7.84 ± 0.03 in light conditions ($n = 5$). Evolution
341 of pH in control beakers (final pH_T of 7.78 and 7.48; $n = 1$ for both in the light and in the
342 dark, respectively) showed that the observed increase in beakers with corals was due to the
343 additive effects of biological control (photosynthesis minus respiration and calcification) and
344 exchanges at the interface in the light, and mostly due to CO_2 exchange with air during the
345 much longer incubations performed in the dark. Assuming linear variations with time, the
346 average conditions of the carbonate chemistry in the lowered pH experiments were slightly
347 favorable to aragonite production ($\Omega_a = 1.4 \pm 0.2$ in the dark, $n = 5$ and 1.6 ± 0.05 in the light,
348 $n = 5$). Under ambient pH conditions (both for ^{45}Ca and ^{13}C incubations), pH did not change
349 during incubations in the light (average final pH_T of 8.05 ± 0.03 , $n = 12$, data not shown)
350 while it decreased in the dark, due to respiration and calcification, to reach an average pH_T
351 level of 7.62 ± 0.07 , $n = 12$, data not shown). In control beakers under ambient pH, pH_T
352 slightly increased in the light (8.09 , $n = 2$) and did not change in the dark (8.05 , $n = 2$).

353 ^{45}Ca activities in seawater did not change during the incubations, reaching a final
354 activity of 16.1 ± 1.2 ($n = 12$) and 28.5 ± 0.6 ($n = 10$) Bq mL^{-1} under ambient and lowered pH
355 conditions, respectively (including both dark and light incubations, data not shown).
356 Furthermore, for all incubations, these values were similar to those measured in beakers
357 without corals (control, data not shown). Under ambient pH levels (no incubation at lowered
358 pH), seawater was enriched in ^{13}C ($\delta^{13}\text{C}-C_T$) from a background level of $0.26 \pm 0.05\text{‰}$ ($n = 3$)
359 to $1,740 \pm 4.7\text{‰}$ ($n = 2$) and $1,634 \pm 11\text{‰}$ ($n = 2$) in the light and dark, respectively. During
360 light condition incubations, $\delta^{13}\text{C}-C_T$ levels decreased to an average of $1,636 \pm 10\text{‰}$ ($n = 6$,
361 data not shown) while they decreased to an average of $1,466 \pm 24\text{‰}$ in dark conditions ($n = 6$,
362 data not shown). Incubations in control beakers (without corals) showed that the majority of
363 $\delta^{13}\text{C}-C_T$ loss for both types of incubations (light and dark) was due to ^{13}C incorporation by
364 corals with a minor effect of gas exchanges at the interface (data not shown).

365 Both A_T and $[\text{Ca}^{2+}]$ declined in all incubations as a consequence of coral calcification
366 (Table 3). Changes in A_T during incubations in control beakers (data not shown) were
367 comprised between 0.1 and 1.1% of the initial level. Similar results were observed for $[\text{Ca}^{2+}]$
368 with a relative change comprised between 0.05 and 1.15% of the initial value. These minimal
369 changes were corroborated with no measurable changes in seawater weight between the start
370 and the end of all incubations (data not shown), showing that evaporation, if any, was
371 minimal using our experimental set-up over the considered incubation times. At ambient pH
372 levels, decreases in A_T and $[\text{Ca}^{2+}]$ (average of -380 ± 97 and $-194 \pm 51 \mu\text{mol kg}^{-1}$ for both
373 parameters, respectively, $n = 24$ including both ^{45}Ca and ^{13}C incubations) were roughly
374 similar under light and dark conditions although coral specimen used for dark incubations
375 were ca. 166% heavier (skeleton dry weight, see Table 1). Incubations performed under
376 lowered pH levels showed much lower A_T and $[\text{Ca}^{2+}]$ net consumption rates than under

377 ambient pH levels. Under these pH conditions, an extremely high A_T consumption rate was
378 observed in one beaker (dark incubation, see Table 3) while no changes in $[Ca^{2+}]$ was
379 observed in a total of three beakers (see Table 3). These estimates ($n = 4$) have been
380 considered as outliers, marked with an asterisk in Table 3 and not included in the following
381 analyses.

382 ^{45}Ca activities in coral skeleton reached maximum levels under ambient pH and light
383 conditions (average of 87.5 ± 9.1 Bq, $n = 6$). Although seawater was more enriched in ^{45}Ca at
384 the lower pH levels (see above), ^{45}Ca activity in corals incubated under these conditions were
385 much lower with lowest values measured in the dark (average of 19.6 ± 9.1 Bq, $n = 5$). $\delta^{13}C$
386 levels measured in coral skeletons (-3.69 to 8.92%) showed significant enrichment as
387 compared to background levels ($-3.97 \pm 0.35\%$, $n = 9$).

388 Calcification rates using the different techniques were higher in the light than in the
389 dark and much lower rates were estimated at lowered pH (Table A1, Figs. 2, 3 and 4). The
390 rates measured by alkalinity anomaly (G_{AT}) and calcium anomaly (G_{Ca}) techniques were
391 highly correlated (Fig. 2; $R^2 = 0.98$, $p < 0.01$, $n = 34$). No significant difference was observed
392 between rates measured by the two methods (see Table 4 for the 95% confidence intervals of
393 the slope and intercept). The ^{45}Ca method provided also very similar rates than the two
394 previous approaches (Fig. 3; G_{Ca} vs. $G_{^{45}Ca}$ not shown) although the slope and the intercept of
395 the geometric regression between G_{AT} and $G_{^{45}Ca}$ were significantly different from 1 and 0,
396 respectively. Finally, the only approach that did not provide similar rates to the others was the
397 ^{13}C incorporation technique. Calcification rates based on this method were systematically
398 higher than those measured using the other three techniques (see Table 4), and rates were not
399 always significantly related (e.g. $R^2 = 0.33$, $p > 0.05$, $n = 12$ for G_{AT} vs $G_{^{13}C}$, see Fig. 4; other
400 relationships not shown).

401 4. Discussion

402 Under all experimental conditions (ambient pH vs low pH, light vs dark), significant
403 consumption rates of A_T and Ca^{2+} as well as significant incorporation rates of ^{45}Ca and ^{13}C
404 were observed in the zooxanthellate coral *Stylophora pistillata*. For all methods, calcification
405 rates were lower in dark than in light conditions. Such trends are expected as it has long been
406 established that calcification rates increase in zooxanthellate corals during periods in which
407 photosynthesis is occurring (Yonge, 1931), a process known as light-enhanced calcification
408 (e.g. Gattuso et al., 1999). Even under lowered pH conditions, at pH levels far below those
409 predicted to occur in the next decades (starting pH_T of ca. 7.2, average pH_T during incubations
410 of ca. 7.5), all corals appeared to produce calcifying structures under both light and dark
411 conditions. The organisms selected for this experiment were fully coated with tissues with no
412 exposed calcareous structures which can explain the absence of observable net dissolution
413 such as reported by Cohen et al. (2017) in a similar study. Since our experimental protocol
414 was not designed to address the potential impact of decreasing pH levels on calcification rates
415 of this species (no control of carbonate chemistry during incubations, no acclimation of the
416 organisms etc.), we will not discuss further the observed decrease of calcification rates
417 identified by the three techniques used at these pH levels.

418 Under all experimental conditions, rates of calcification calculated using the alkalinity
419 and the calcium anomaly techniques were highly correlated with a slope of 1 and no
420 significant intercept. These results are consistent with previously published data on colonies
421 of *Pocillopora damicornis* (Chisholm and Gattuso, 1991), *Cladocora caespitosa* (Gazeau et
422 al., 2015) and several other coral species (Murillo et al. 2014). Although the precision
423 obtained on Ca^{2+} measurements is among the highest reported to date (Gazeau et al., 2015),

424 the alkalinity anomaly technique appears as the most appropriate to estimate calcification
425 rates of isolated corals (better precision, stronger signals). As observed by Murillo et al.
426 (2014), this is not true when an entire community including sediment is investigated. The
427 occurrence of several processes in the sediment that can impact A_T prevents the use of this
428 technique. It is therefore recommended to use the calcium anomaly technique when working
429 in natural settings, assuming that Ca^{2+} concentrations are measured with an analytical
430 technique as precise as the one used in our study ($CV < 0.05\%$). Similarly, although
431 corrections are possible when applying the alkalinity anomaly technique on organisms that
432 significantly release nutrients (echinoderms, bivalves etc.), the use of the calcium anomaly
433 technique is highly recommended instead (Gazeau et al., 2015).

434 Calcification rate estimates based on changes of A_T or Ca^{2+} were highly correlated
435 with estimates based on ^{45}Ca incorporation in corals. These results are not consistent to those
436 reported by Smith and Roth (in Smith and Kinsey, 1978), Tambutté et al. (1995) and Cohen et
437 al. (2017). These studies revealed discrepancies between the alkalinity anomaly and the ^{45}Ca
438 incorporation techniques. Smith and Roth found that rates measured with the ^{45}Ca method
439 were higher than those measured using the alkalinity anomaly technique (significant ^{45}Ca
440 incorporation at $\Delta A_T = 0$). Results from both Tambutté et al. (1995) and Cohen et al. (2017)
441 suggested the opposite with a decrease in A_T consumption without any concomitant ^{45}Ca
442 incorporation. A number of reasons may explain these discrepancies. First, the present study
443 is the first one comparing these techniques in the same incubations, in contrast to the other
444 ones in which incubations for A_T anomaly and ^{45}Ca incorporation were performed over two
445 consecutive days (due to radioactive contamination issues). Second, calcification expressed as
446 absolute changes in A_T during incubations, measured during our experiment, were at least one
447 order of magnitude higher than measured during these studies (44,200 to 745,600 nmol vs

448 less than 4,000 nmol in previous experiments). Cohen et al. (2017) have shown that such
449 discrepancies were much higher at very low rates and that the ratio between rates estimated
450 based on ^{45}Ca incorporation and A_T consumption were getting closer to 1 with increasing
451 calcification rates. Nevertheless, even at the highest levels of calcification computed during
452 these studies, ^{45}Ca -based rates were still significantly different from ΔA_T -based rates, which is
453 in contrast with our results.

454 As already mentioned, although calcification rates of the present study were lower at
455 lowered pH levels, there was still a close to perfect agreement between the different
456 techniques. While the ^{45}Ca labelling technique is thought to provide rates of gross
457 calcification, there is no doubt that both the A_T and Ca^{2+} anomaly techniques allow the
458 estimation of net calcification rates (gross calcification – dissolution). A full agreement of
459 rates computed from these methods further suggest that no dissolution of previously
460 precipitated CaCO_3 structures occurred during our study, even under lowered pH conditions.
461 The corals used in our experiment were fully covered with tissues which is likely the reason
462 why no dissolution was measured.

463 Furthermore, we must note that the protocol for ^{45}Ca incorporation considered in our
464 study differed from the one used in the above-mentioned past studies. A much smaller activity
465 was used ($0.025 \text{ kBq mL}^{-1}$) compared to Tambutté et al. (1995; 40 kBq mL^{-1}) and Cohen et al.
466 (2017; 9 kBq mL^{-1}). Moreover, in contrast to Cohen et al. (2017), rates were not corrected for
467 ^{45}Ca incorporation on the skeleton of dead corals. This choice was motivated by the absence
468 of detectable radioactivity on bare skeletons exposed for 7 h and treated with the same
469 protocol than one used in our study (Lanctôt, pers. comm.).

470 To the best of our knowledge, this is the first study comparing calcification rates
471 measured using the ^{13}C labelling technique to the more widely used alkalinity and calcium

472 anomaly techniques. It shows that ^{13}C -derived rates were systematically higher and much
473 more variable (with large uncertainties) than the ones estimated using the two other
474 techniques. As already mentioned, several studies have shown that most of the carbon
475 precipitated in the skeleton comes from coral and its symbiotic zooxanthellae (e.g. Erez,
476 1978; Furla et al., 2000), leading to an underestimation of calcification rates based on
477 labelled, radioactive carbon incorporation. As there is no reason for ^{13}C to behave differently,
478 our results appear inconsistent with a metabolic source of carbon. As the nubbins were treated
479 following the same protocol as for ^{45}Ca incorporation measurements, it is unclear why much
480 stronger ^{13}C incorporation was obtained and why variability was so high. Before better
481 insights on such discrepancies can be developed, we recommend to avoid this technique to
482 estimate coral calcification rates.

483 Our study was designed to compare different techniques to estimate calcification rates
484 and not to define the best experimental approach to study the effects of ocean acidification on
485 coral species using these different approaches. As such, the chosen experimental protocol
486 (e.g. incubation times) was not optimal and led, in some cases, to significant changes in the
487 carbonate chemistry during incubations. However, our results provide some insights that we
488 further discuss in the following section. Measuring and comparing calcification rates of
489 organisms under varying pH conditions requires the careful choice of a volume and a time
490 interval such that the precision of the calcification rate measurement is large enough to
491 observe significant signals and that the change in carbonate chemistry parameters between the
492 beginning and end of the incubation is small compared to the range of these parameters in the
493 different treatments (Langdon et al. 2010). Table 5 illustrates the incubation time necessary to
494 obtain measurable changes for each method (t_{min}) considering the ratio between incubation
495 volume and coral size chosen for our study. As the ^{13}C incorporation method did not provide

496 reliable rates, this technique was not considered in this analysis. The threshold for significant
497 signals was set at 10-fold the analytical precision of the instruments (Langdon et al. 2010) for
498 A_T and Ca^{2+} measurements (1.2 and 2.9 $\mu\text{mol kg}^{-1}$, respectively) and above the detection limit
499 of 15 cpm for ^{45}Ca activity estimated. Maximum incubation times are more difficult to
500 estimate. Langdon et al. (2010) and Riebesell et al. (2010) recommend considering incubation
501 times short enough to maintain A_T and C_T within an acceptable range (ΔA_T and $\Delta C_T < 10\%$).
502 As it is more difficult to estimate what changes in pH are acceptable, we have arbitrarily
503 considered a maximal change in pH of 0.06, corresponding to the lowest change in global
504 surface ocean pH projected for 2100 (IPCC, 2014). Maximal incubation times, as presented in
505 Table 5 (t_{max}), correspond then to incubation times that should not be exceeded in order to
506 maintain acceptable conditions of the carbonate chemistry ($\Delta\text{pH}_T < 0.6$ and $\Delta A_T < 10\%$ and
507 $\Delta C_T < 10\%$).

508 Under light and ambient pH conditions, even if the ratio between incubation volume
509 and nubbin size is much higher than for previous similar studies (e.g. Cohen et al. 2017), all
510 methods would allow a precise estimation of calcification rates over very short incubation
511 times (~15 min to 1 h, depending on the method) while leading to moderate changes in
512 carbonate chemistry. In the dark, and under ambient pH conditions, in the absence of pH
513 increase due to photosynthesis, the decrease of pH due to respiration, narrows the possible
514 incubation period to 1.3 h. While this is still larger than the incubation time allowing to obtain
515 a significant signal with the alkalinity anomaly technique (~20 min), the other two methods
516 necessitate longer incubation times to obtain precise estimates (> 1.5 h). At lower pH, both
517 under light and dark conditions, and using open systems without a continuous pH regulation
518 as in our study, it is obvious that all techniques are not well adapted to this experimental
519 protocol. Indeed, as a consequence of lower calcification rates at lower pH and significant

520 CO₂ degassing, incubation times necessary to obtain significant signals using these techniques
521 are too large to maintain the carbonate parameters within an acceptable range. This is not
522 insurmountable as a continuous regulation of pH using for instance pure CO₂ bubbling or
523 incubations performed in a closed container (i.e. without contact to the atmosphere) would
524 alleviate these problems.

525 In conclusion, the present study is the first one allowing a direct (i.e. during the same
526 incubations) comparison of three methods used to estimate coral calcification rates, the
527 calcium and alkalinity anomaly techniques and the ⁴⁵Ca incorporation technique. These
528 methods provided very consistent calcification rates of the coral *Stylophora pistillata*
529 independently of the conditions set for the incubations (light vs dark, ambient vs low pH).
530 Among these three methods, the alkalinity anomaly and the ⁴⁵Ca incorporation techniques
531 appear to be the most sensitive allowing the quantification of coral calcification rates without
532 significant changes in targeted environmental conditions. In contrast, the ¹³C incorporation
533 technique did not provide reliable calcification rates and its use is not recommended until
534 further investigations clarify the discrepancies. Finally, this study was restricted to a single
535 coral species and used nubbins fully covered with tissues. Conducting similar comparison
536 studies with other coral species as well as other major calcifying groups widely studied in the
537 context of ocean acidification (e.g. coralline algae, molluscs etc...) would be necessary for a
538 better understanding of ocean acidification impacts on ecosystem services provided by
539 calcifying organisms.

659 Table 1. Experimental details for the series of incubations of the coral *Stylophora pistillata* performed under ambient and low pH, and in
 660 the light and dark following ^{45}Ca or ^{13}C labelling. The ratio $W_w:W_c$ corresponds to the ratio between seawater weight (g) and skeletal dry
 661 weight (g). Values represent mean \pm standard deviation (SD); n is the number of true replicates considered for each experiment. All
 662 incubations were conducted at 25 ± 0.5 °C.

pH conditions	Ambient (n = 6)				Lowered (n = 5)	
	^{45}Ca		^{13}C		^{45}Ca	
Added label	Light	Dark	Light	Dark	Light	Dark
Light conditions						
Coral size (mm)	33.2 \pm 1.5	44.7 \pm 1.5	36.3 \pm 2.2	50.2 \pm 1.7	26.0 \pm 1.6	28.9 \pm 1.9
Coral Skeleton dry weight (g)	2.5 \pm 0.5	3.8 \pm 0.7	2.6 \pm 0.5	4.7 \pm 0.5	2.1 \pm 0.2	2.8 \pm 0.4
Ratio $W_w:W_c$	126.4 \pm 25.6	81.9 \pm 14.7	106.9 \pm 24.5	67.8 \pm 7.5	146.5 \pm 14.3	110.0 \pm 12.4
Incubation time (h)	8	8	9.12	9.12	5	11

665 Table 2. Environmental conditions at the start of incubations of the coral *Stylophora pistillata*. pH on the total scale (pH_T), partial pressure
 666 of CO₂ (pCO₂ in μatm), total alkalinity (A_T in $\mu\text{mol kg}^{-1}$), dissolved inorganic carbon (C_T in $\mu\text{mol kg}^{-1}$), saturation states with respect to
 667 aragonite (Ω_a) and calcite (Ω_c) as well as calcium concentrations ([Ca²⁺] in $\mu\text{mol kg}^{-1}$) are presented. Labelled seawater ⁴⁵Ca activity
 668 (Activity_{seawater} in Bq mL⁻¹) and the isotopic level, after enrichment, of the seawater dissolved inorganic carbon pool ($\delta^{13}\text{C-C}_T$ in ‰) are
 669 also shown. Means \pm standard deviation (SD) of analytical triplicates (duplicates for $\delta^{13}\text{C-C}_T$) are shown when available. All incubations
 670 were conducted at 25 ± 0.5 °C.

671

672 Table 3. Changes in total alkalinity (A_T) and calcium concentrations ($[Ca^{2+}]$) during the different types of incubations as compared to

673 control beakers: $\Delta A_T = A_{T2} - A_{T2c}$, $\Delta[Ca^{2+}] = Ca_2 - Ca_{2c}$, both expressed in $\mu\text{mol kg}^{-1}$. Standard errors (SE) have been calculated as

674
$$\sqrt{SE_{A_{T2}}^2 + SE_{A_{T2c}}^2}$$
 and
$$\sqrt{SE_{Ca_2}^2 + SE_{Ca_{2c}}^2}$$
 for A_T and $[Ca^{2+}]$, respectively, where SE correspond to standard errors associated with the

675 measurement of three analytical replicates per sample. ^{45}Ca activity (Activity_{sample} in Bq) and ^{13}C incorporation ($\delta^{13}\text{C}_M$ in ‰) of sampled

676 corals are also shown. Values of ^{45}Ca activity and $\delta^{13}\text{C}$ are mean \pm standard error of the mean (SE) associated with the measurement of

677 three aliquots for each coral. Outliers (n = 4; see text for details) are identified with an asterisk.

684

685 Table 5. Incubation times (t_{\min} ; h) necessary to obtain significant signals using the three methods: the alkalinity anomaly technique (A_T),
686 the calcium anomaly technique (Ca^{2+}) and the ^{45}Ca incorporation techniques (^{45}Ca), see text for calculation procedures. t_{\max} (h) is the
687 maximum incubation time to maintain carbonate chemistry within an acceptable range ($\Delta\text{pH}_T < 0.06$ and $\Delta C_T < 10\%$ and $\Delta A_T < 10\%$). The
688 ratios between incubation volume (in mL) and the size of the nubbins (in cm), considered in our study for the different sets of incubations
689 (Ambient pH vs Low pH; Light vs Dark), are also shown. t_{\min} values are noted in bold when higher than t_{\max} .

	Ratio V:S		t_{\min} (h)		t_{\max} (h)
	A_T	Ca^{2+}	^{45}Ca	^{45}Ca	
Ambient pH – Light	77-95	0.26	1.00	0.6	4.7
Ambient pH – Dark	59-69	0.33	2.10	1.5	1.3
Lowered pH – Light	109-121	1.25	6.15	1.1	0.5
Lowered pH – Dark	95-109	1.60	11.20	3.4	1.3

690

691 Table A1. Calcification rates estimated by the different methods considered in this study: the alkalinity and calcium anomaly techniques
 692 (G_{AT} and G_{Ca} , respectively) as well as the ^{45}Ca and ^{13}C incorporation techniques (G_{45Ca} and G_{13C} , respectively). All rates are mean \pm
 693 standard errors of the mean (SE) and are expressed in $\mu\text{mol CaCO}_3 \text{ g DW}^{-1} \text{ h}^{-1}$.

695 **Figure captions**

696 Fig. 1. Scheme of the polyethylene container in which a coral nubbin is suspended with a
697 nylon line and covered with a transparent film.

698 Fig. 2. Calcification rates estimated based on the alkalinity anomaly technique (G_{AT}) as a
699 function of calcification rates estimated based on the calcium anomaly technique (G_{Ca}). The
700 dashed line represents the 1:1 relationship while the full line represents the model-II
701 regression relationship. Horizontal error bars represent standard errors (SE) associated with
702 the estimation of G_{Ca} . Vertical error bars representing SE associated with the estimation of
703 G_{AT} are too small to be visible. The corresponding dataset can be found in Table A1.

704 Fig. 3. Calcification rates estimated based on the alkalinity anomaly technique (G_{AT}) as a
705 function of calcification rates estimated based on the ^{45}Ca incorporation technique ($G_{45\text{Ca}}$).
706 The dashed line represents the 1:1 relationship while the full line represents the model-II
707 regression relationship. Horizontal error bars represent standard errors (SE) associated with
708 the estimation of $G_{45\text{Ca}}$. Vertical error bars representing SE associated with the estimation of
709 G_{AT} are too small to be visible. The corresponding dataset can be found in Table A1.

710 Fig. 4. Calcification rates estimated based on the alkalinity anomaly technique (G_{AT}) as a
711 function of calcification rates estimated based on ^{13}C incorporation technique ($G_{13\text{C}}$). The
712 dashed line represents the 1:1 relationship while the full line represents the model-II
713 regression relationship. Horizontal error bars represent standard errors (SE) associated with
714 the estimation of $G_{13\text{C}}$. Vertical error bars representing SE associated with the estimation of
715 G_{AT} are too small to be visible. The corresponding dataset can be found in Table A1.
