**Abstract.** Hypolimnetic anoxia in eutrophic lakes can delay lake recovery to lower trophic states via the release of sediment phosphorus (P) to surface waters on short time scales. However, the long-term effects of hypolimnetic redox conditions and eutrophication on sedimentary P-fraction retention in deep lakes are not clear yet. Hypolimnetic withdrawal of P-rich water is predicted to reduce sedimentary P and seasonal P recycling from the lake hypolimnion. Nevertheless, there is a lack of evidence from well-dated sediment cores, in particular, from deep lakes, about the long-term impact of hypolimnetic withdrawal on sedimentary P retention. In this study, long-term sedimentary P-fraction data since the early 1900s from Lake Burgäschi provides information on the potential availability and retention of sediment-P under the influences of increasing lake primary productivity (sedimentary green-pigments proxy), variable hypolimnion oxygenation regimes (Fe/Mn ratio proxy), and hypolimnetic withdrawal restoration since 1977. Results show that, before the operation of hypolimnetic withdrawal (during the early 1900s to 1977), redox-sensitive Fe/Mn-P fraction comprised ~50% of total P in the sediment profile. Meanwhile, long-term retention of total P and labile P-fractions in sediments was predominantly affected by past hypolimnetic redox conditions, and P retention increased in sedimentary Fe- and Mn enriched layers when the hypolimnetic had better seasonally oxic conditions. However, from 1977-2017, eutrophication-induced persistent anoxic conditions in the hypolimnion and hypolimnetic withdrawal both contributed to considerably decreased retention and net burial rates of total P and labile P fractions in surface sediments. By contrast, refractory Ca-P fraction retention was primarily related to lake primary production. Due to the lake restoration since 1977, Ca-P fraction became the primary P fraction in sediments (representing ~39% of total P), indicating a lower P bioavailability of surface sediments. Our study implies that in seasonally-stratified eutrophic deep lakes (like Lake Burgäschi), hypolimnetic withdrawal can effectively reduce P retention in sediments and potentials of sediment-P release (internal P loads). However, more than 40 years of hypolimnetic syphoning have not improved the lake trophic state or decreased lake productivity. The findings of this study are relevant regarding management of deep eutrophic lakes with mixing regimes typical for temperate zones.

## 39 **1 Introduction**

40 Phosphorus (P) eutrophication in freshwater lakes is a global problem and has been a matter of concern to the  
41 public for several decades. In lakes where the external P loading has been reduced, internal P loading (sediment-  
42 P release to surface waters) is widely recognized as the key factor affecting lake trophic status and delaying lake  
43 recovery from eutrophication (Burley et al., 2001; Trolle et al., 2010). Considerable work has been done on  
44 sediment-P speciation to evaluate sediment-P release potentials and implications for lake restoration management  
45 (Gonsiorczyk et al., 1998; Ribeiro et al., 2008).

46 The paradigm that oxygen levels control the sediment-P release via reductive dissolution of Fe-P fraction in surface  
47 sediments has been accepted as the classical model for a long time (Einsele, 1936, 1938; Moosmann et al., 2006).  
48 Under anoxic conditions, P bound to redox-sensitive Fe and Al/Fe (oxyhydr)oxides can be potentially released  
49 from surface sediments into lake water (Burley et al., 2001), which was supported by numerous short-term (days  
50 or seasonal) laboratory or in-situ studies (Chen et al., 2018). Based on this paradigm, it was assumed that an oxic  
51 sediment–water interface might limit the release of Fe-P from sediments and, therefore, improve P retention in  
52 lake sediments. However, the restoration measures with artificial hypolimnetic oxygenation/aeration applied in  
53 eutrophic lakes proved to have only short-lasting effects but no direct effects on internal P loading and redox-  
54 dependent sediment-P retention on longer terms (Gächter, 1987; Gächter and Wehrli, 1998; Moosmann et al., 2006;  
55 Hupfer and Lewandowski, 2008). Gächter and Müller (2003) and Moosmann et al. (2006) further argued that, on  
56 multi-decadal or longer time scales, P retention in lake sediments might eventually primarily depend on the P-  
57 binding capacity of anoxic sediments and sediment composition (e.g. Fe, Mn, Al, and Ca contents). Nevertheless,  
58 until now, there is a lack of evidence from well-dated sediment cores, and there is still a need to know which  
59 processes may have a dominant influence on sediment P-fraction retention on longer time scales (e.g., decades or  
60 more). This information is crucial for predicting and, ultimately, managing sediment-P release, especially in deep  
61 lakes, because hypolimnetic anoxia in deep lakes can lead to large loads of sediment-P release. In contrast to the  
62 well-established studies about sediment-P speciation in shallow polymictic lakes (e.g. Kaiserli et al., 2001;  
63 Søndergaard et al., 2001; Cavalcante et al., 2008), there are only a few studies available from seasonally-stratified  
64 deep lakes. Furthermore, eutrophication has been demonstrated to affect sediment-P release via controlling  
65 hypolimnetic anoxia and lake mixing regime in seasonally stratified deep lakes (Tu et al., 2019). It is not yet fully  
66 understood whether and how lake trophic levels and hypolimnetic anoxia can influence the long-term behavior of  
67 sedimentary P-fraction retention in deep lakes.

68 The restoration technique of hypolimnetic withdrawal has been frequently applied in seasonally stratified lakes in  
69 Europe (Kucklantz and Hamm, 1988; Nürnberg, 2007), whereby P-enriched water from the hypolimnion is  
70 discharged directly into the lake outflow. This restoration technique has been shown to efficiently reduce P  
71 concentrations in lake waters (Nürnberg, 2007). Hypolimnetic withdrawal was also expected to reduce P retention  
72 in sediments and seasonal P recycling from the lake hypolimnion to the upper waters, for example, in Lake Mauen,  
73 a shallow, eutrophic lake (maximum depth 6.8 m; Gächter, 1976). However, there is lack of empirical evidence  
74 from sedimentary P-fraction data, which provides valuable information on possible sediment-P release

75 characteristics and potentials of internal P loadings. Furthermore, for deep lakes, the long-term influence of this  
76 restoration on sedimentary P release potentials is unclear.

77 The objectives of this study were to (1) explore the main factors controlling long-term changes of P-fraction  
78 retention in sediments of deep lakes, (2) investigate how sediment P-fraction retention responds to changes in lake  
79 eutrophication and hypolimnetic anoxia of the past prior to anthropogenic eutrophication, (3) examine the long-  
80 term effects of lake hypolimnetic withdrawal restoration on sedimentary P-fraction retention in seasonally-  
81 stratified deep lakes, and (4) evaluate with sediment-P data the predictions from Gächter (1976) that hypolimnetic  
82 withdrawal should result in reduced total P contents in sediments and sediment-P release to lake water. To achieve  
83 these objectives, we investigated short sediment cores from Lake Burgäschi, a deep and eutrophic lake on the  
84 Swiss Plateau. Sedimentary green-pigments (chlorophylls and diagenetic products) inferred from hyperspectral  
85 imaging (HSI) scanning and XRF-inferred Fe/Mn ratios primarily reflect lake trophic state evolution (aquatic  
86 primary productivity) and hypolimnetic oxygenation, respectively. A sequential P-extraction with five P fractions  
87 was performed to uncover P fractionation in sediment profiles. We combined all data to identify the dominant  
88 factors responsible for temporal changes in P-fraction retention. Changes in P-fraction records for the periods  
89 before and during the restoration were also investigated.

90 Lake Burgäschi is an excellent study site because there were substantial changes in lake trophic levels and possibly  
91 lake-mixing regimes since the last century (Guthruf et al., 1999; Van Raden, 2012), and exceptionally long  
92 historical and limnological survey data are available for most of the last 50 years. Hypolimnetic withdrawal  
93 restoration has operated in the lake since 1977.

94

## 95 **2 Study site**

96 Lake Burgäschi (47°10'8.5"N, 7°40'5.9"E) is a small lake located on the Swiss Plateau (Fig. 1a). It has a very  
97 restricted catchment (3.2 km<sup>2</sup>). The catchment area geologically belongs to the Molasse Basin, and mostly consists  
98 of carbonate-rich sandstones and mudstones (Schmid et al., 2004). The kettle hole lake was formed after the retreat  
99 of the Rhone glacier (ca. 19 k yr. BP; Rey et al., 2017). Currently the maximum water depth is ~31 m, which is  
100 quite deep in contrast to the small surface area of 0.21 km<sup>2</sup> (Guthruf et al., 1999). The mean retention time of the  
101 lake water is ~1.4 year (Nürnberg, 1987). The lake has several small inflows in the southwest (Rey et al., 2017)  
102 and one outflow in the north (Fig. 1c).

103 Since the 19<sup>th</sup> century, the lake's water level was lowered several times to create agricultural lands, with the most  
104 recent lowering (up to 2 m) during 1943-1945 (Guthruf et al., 1999). Agricultural area currently covers ~55% of  
105 the lake catchment, followed by ~29% area of forests. The lake region experiences a warm humid continental  
106 climate (Dfb; Köppen-Geiger classification). The mean annual temperature is 9 °C and the warmest month is July  
107 (mean temperature 19 °C).

108 Lake Burgäschi has been highly productive (eutrophic to highly eutrophic state) since the 1970s with high algal-  
109 biomass production and anoxic conditions in the hypolimnion (Guthruf et al., 1999, 2013). The eutrophication in  
110 Lake Burgäschi has been linked to increased agricultural P inputs via drainage into the lake in the second half of  
111 the 20<sup>th</sup> century (Guthruf et al., 1999). To mitigate the eutrophication, hypolimnetic withdrawal restoration has

112 been applied in Lake Burgäschi since 1977, and the lake water has been monitored twice a year for more than 30  
113 years for various parameters, such as pH, oxygen content, phosphorus concentrations, phytoplankton biomass, etc.  
114 Despite a sharp decline in hypolimnetic phosphorus concentrations due to the restoration, a high production of  
115 algae biomass continues today (GSA, 2007). Additionally, hypolimnetic oxygenation conditions and the lake  
116 trophic state have been stabilized but not fundamentally improved (GBL, 1995; Guthruf et al., 2013).

117

### 118 **3 Materials and methods**

#### 119 **3.1 Core collection and sampling**

120 In September 2017, two 75-cm-long sediment cores (Burg17-B and Burg17-C) were retrieved from the deepest  
121 point of Lake Burgäschi (water depth ~31 m) (47°10'8.6"N, 07°40'5.3"E; coring site in Fig. 1c) using a UWITEC  
122 gravity corer. After the collection, the cores were stored in a dark cold room (~4 °C). After opening and splitting  
123 lengthwise, core-half A of Burg17-B was continuously subsampled at 2-cm resolution from 0 to 60 cm for <sup>210</sup>Pb  
124 and <sup>137</sup>Cs dating. The oxidized surface of core-half B (Burg17-B) was visually described (Schnurrenberger et al.,  
125 2003) before non-destructive XRF core and HSI scanning. After the opening, one-half of core Burg17-C was  
126 transferred immediately into a glove box with an anoxic atmosphere where it was continuously subsampled at 2-  
127 cm resolution from 0 to 72 cm. The fresh sediments from each sample slice were homogenized and used for  
128 sequential P extraction. Afterwards, the remaining sediment was freeze-dried and homogenized for bulk element  
129 analyses.

#### 130 **3.2 Chronology**

131 The chronology of the core Burg17-B is based on <sup>210</sup>Pb and <sup>137</sup>Cs activity profiles. The freeze-dried and  
132 homogeneous samples were stored dry and dark until analysis. The <sup>210</sup>Pb, <sup>137</sup>Cs and <sup>226</sup>Ra radiometric activities  
133 were measured by gamma spectrometry at the University of Bern Department of Chemistry and Biochemistry.  
134 1.3-5.1 g of the freeze-dried samples were encapsulated into polystyrene petri dishes (68 mm O.D., 11 mm height;  
135 Semadeni, Ostermundigen, Switzerland) together with a polystyrene disk to fill in the headspace above the sample  
136 material, and the petri dishes were vacuum-sealed into a gas-tight aluminum foil for equilibration. <sup>210</sup>Pb (46.5 keV),  
137 <sup>241</sup>Am (59.5 keV), <sup>226</sup>Ra progenies <sup>214</sup>Pb and <sup>214</sup>Bi (295.2, 351.9 and 609.3 keV), as well as <sup>137</sup>Cs (661.7 keV) were  
138 measured using a Broad Energy Germanium (BEGe) detector (Canberra GmbH, Rüsselsheim, Germany). This  
139 system is composed of a high-purity germanium crystal of 50 cm<sup>2</sup> area and 30 mm thickness with a 0.6 mm thick  
140 carbon epoxy window, which shows high absolute full-energy peak efficiencies for close on-top geometries of >20%  
141 and ~5% for <sup>210</sup>Pb and <sup>137</sup>Cs, respectively. Low integrated background count rates of 0.20 s<sup>-1</sup> (energy range of 30-  
142 1800 keV) were achieved by application of low-background materials, installation in third underground floor (~10  
143 m of water-equivalent overburden), passive shielding (outside to inside: 10 cm low-background lead, 3 mm ancient  
144 lead with negligible <sup>210</sup>Pb content, 2 mm cadmium), flushing of the shield interior with nitrogen gas and an active  
145 anti-cosmic shield (plastic scintillator panels of totally 1 m<sup>2</sup> area mounted directly above the passive shielding).  
146 Supported <sup>210</sup>Pb in each sample was assumed to be in equilibrium with the in-situ <sup>226</sup>Ra (equilibration time 4  
147 weeks). Unsupported <sup>210</sup>Pb activity was calculated by subtracting <sup>226</sup>Ra activity from total <sup>210</sup>Pb activity level-by-  
148 level. The correction for the total unsupported <sup>210</sup>Pb missing inventory followed Tylmann et al. (2016).

149

150 The  $^{210}\text{Pb}$  chronology of core Burg17-B was determined using the Constant Rate of Supply (CRS) model (Appleby,  
151 2002), which accounts for variation in sediment accumulation rates. We tested two CRS models: CRS-1 model  
152 was unconstrained (i.e. without reference points from the  $^{137}\text{Cs}$  activity). The CRS-2 model was constrained with  
153 the chronologic marker of peak fallout from nuclear weapons testing in 1963 ( $^{137}\text{Cs}$  and  $^{241}\text{Am}$ ). Both models were  
154 then tested and validated with independent time-markers at the onset of nuclear weapons testing in 1953/54 and  
155 the Chernobyl accident in 1986/87 (onset of  $^{137}\text{Cs}$  and peak of  $^{137}\text{Cs}$  and  $^{241}\text{Am}$ , respectively).

156

157 The two sediment cores (Burg 17-B and Burg 17-C) are visually very similar but show a length-offset due to coring  
158 compaction of approximately 2-6 cm (Fig. S1 in Supplementary data). The age-depth stratigraphy of Burg17-C  
159 core was inferred from the dated core Burg17-B by visual stratigraphic correlation from high-resolution core  
160 pictures.

161

### 162 **3.3 Non-destructive geochemical methods**

163 Non-destructive X-ray fluorescence (XRF) core scanning was done using an Avaatech XRF Core Scanner (Richter  
164 et al., 2006) for semi-quantitative element composition measurements at 0.5 mm resolution to capture relative  
165 elemental concentrations of the laminae. The core surface was smoothed and covered with a 4- $\mu\text{m}$ -thick Ultralene  
166 foil prior to the analysis. Elements were measured using a Rhodium anode and a 25  $\mu\text{m}$  Be window. The lighter  
167 elements (e.g. Al, Si, P etc.) were measured for 15 seconds count time at 10 kV with 1500 A, no filter; while the  
168 heavier elements (e.g. Mn, Fe, Br etc.) were exposed for 40 seconds at 30 kV with 2000 A, Pd-thin filter. Element  
169 intensities (semi-quantitative concentrations) of the selected elements (Mg, Si, Al, K, Ti, Rb, P, Fe, Mn, Ca) are  
170 expressed as count rates (counts per second, cps).

171 Following the methodology in Butz et al. (2015), hyperspectral imaging (HSI) scanning was performed using a  
172 Specim Ltd. Single Core Scanner equipped with a visual to near infrared range (VNIR, 400–1000 nm)  
173 hyperspectral linescan camera (Specim PFD-CL-65-V10E). Parameters were set for a spatial resolution of  $\sim 70$   
174  $\mu\text{m}/\text{pixel}$  and a spectral sampling of 1.57 nm (binning of 2). Spectral endmembers were determined using the  
175 “Spectral Hourglass Wizard” of the ENVI 5.5 software package (Exelisvis ENVI, Boulder, Colorado). The relative  
176 absorption band depth (RABD) index calculation was performed following the method in Schneider et al. (2018).  
177 However, based on the spectral end members (Fig. S2), we used the absorption feature between the wavelengths  
178 R590 and R765 (590-765 nm), i.e.  $\text{RABD}_{590-765}$ . Butz et al. (2017) and Schneider et al. (2018) revealed that this  
179 index is well calibrated to absolute green-pigments (chlorophyll *a* + pheophytin *a*) concentrations in sediments.  
180 The sediments in Lake Burgäschi are mostly laminated and organic-rich (Van Raden, 2012), which indicates that  
181 the sediments are anoxic, bioturbation is absent, and sedimentary pigments are well-preserved (Reuss et al., 2005).  
182 Therefore, in our study, the relative concentrations of green-pigments inferred from  $\text{RABD}_{590-765}$  index values  
183 provide a semi-quantitative reconstruction of lake primary productivity (total algal abundance) at sub-annual  
184 resolution, and are suggested to reflect the trophic state evolution of Lake Burgäschi.

### 185 **3.4 Phosphorus fractionation scheme and bulk elements analyses**

186 The P-fractionation extraction protocol (Fig. S3) principally follows the four-step extraction protocol in Tu et al.,  
187 (2019). In addition, we added the last extraction step from Lukkari et al. (2007) to determine refractory organic P  
188 (F5). This P fraction (F5) is practically biologically unavailable and subject to permanent P burial. The first four  
189 fractions are NaCl-TP (F1: loosely bound P), NaBD-TP (F2: redox-sensitive Fe- and Mn-bound P), NaOH-TP (F3:  
190 Al- and Fe-bound P), and HCl-TP (F4: Ca-bound P) (Tu et al., 2019), whereby NaCl-TP, NaBD-TP and NaOH-  
191 TP fractions together as considered relatively labile P fractions because they may release P back to the water  
192 column under anoxic or high pH environments (Rydin, 2000). The HCl-TP and refractory organic P (Ref.-P<sub>o</sub>)  
193 fractions are classified as relatively stable or refractory P fractions. Total P in sediments was obtained from the  
194 sum of the five P fractions. The P in extract samples was measured by inductively coupled plasma mass  
195 spectroscopy (7700× ICP-MS) (Agilent Technologies, Germany) after the dilution with nitric acid (HNO<sub>3</sub>) to reach  
196 a final concentration of 1% v/v HNO<sub>3</sub>.

197 Concentrations of total carbon (TC), total nitrogen (TN), and total sulfur (S) in sediment samples were determined  
198 using an Elementar vario EL Cube elemental analyzer. Total inorganic carbon (TIC) content was calculated by  
199 multiplying loss on ignition at 950 °C (LOI<sub>950</sub>, following the method proposed by Heiri et al. (2001)) by 0.273, i.e.  
200 the ratio of the molecular weight of C and CO<sub>2</sub>. Total organic carbon (TOC) content was calculated using the  
201 equation TOC = TC - TIC. Sediment dry bulk density and water content were determined using wet mass (g), dry  
202 mass (g) and wet volume (cm<sup>3</sup>) following the method in Håkanson and Jansson (2002).

203

### 204 **3.5 Data analyses**

205 Multivariate statistical analyses were performed with R version 3.4.2 (R Development Core Team, 2017). Prior to  
206 data analyses, RABD<sub>590-765</sub> index values (resolution 70 μm) were aggregated to a spatial resolution of 0.5 mm (the  
207 spatial resolution of XRF data). Stratigraphically constrained incremental sum of squares clustering (CONISS;  
208 Grimm, 1987) was then performed on semi-quantitative proxies (i.e. RADB<sub>590-765</sub> index and XRF-element data)  
209 with R-package “rioja” (Juggins, 2017). The number of significant clusters was determined with a broken-stick  
210 test (Bennett, 1996). A principal components analysis (PCA) was performed on the centered and standardized data  
211 of semi-quantitative proxies, using the “Vegan” package (Oksanen et al., 2013). XRF-element and RABD<sub>590-765</sub>  
212 index values were averaged within the depth range of each sample taken from core Burg17-C for P fractions. In  
213 order to identify the primary factors influencing the variations in sedimentary P fractions, a redundancy analysis  
214 (RDA) was performed on the centered and standardized dataset of P fractions (response variables) and other  
215 sediment geochemical parameters (explanatory variables) with the “vegan” package. In the RDA computation, the  
216 correlation matrix option was selected and the scaling was conducted on a correlation biplot.

## 217 **4 Results**

### 218 **4.1 <sup>137</sup>Cs and <sup>210</sup>Pb chronology**

219 The two distinctive peaks of <sup>137</sup>Cs in sediment profiles are detected at 31 cm and 15 cm depths (Fig. 2b),  
220 corresponding to the 1963 and 1986 major fallout events, respectively (Appleby, 2002). Furthermore, <sup>241</sup>Am  
221 activity peaks at the same depths (Fig. 2b) confirm that the 1963 and 1986 <sup>137</sup>Cs peaks were due to atmospheric

222 fallouts (Michel et al., 2001). The first traces of  $^{137}\text{Cs}$  occur at 37 cm depth, indicating the first widely detectable  
223 fallout from atmospheric nuclear testing in 1953/1954 (Pennington et al., 1973).

224 The  $^{210}\text{Pb}$  activity in core Burg17-B shows a relatively monotonic decrease down to a sediment depth of 17 cm.  
225 Further down, larger variations are found (Fig. 2a). The  $^{210}\text{Pb}$  and  $^{226}\text{Ra}$  activities do not reach equilibrium;  
226 unsupported  $^{210}\text{Pb}$  activity in the oldest sample (59 cm) is still above the limit of detection ( $14.0 \pm 6.8 \text{ Bq} \cdot \text{kg}^{-1}$ ). The  
227 observed cumulative inventory of unsupported  $^{210}\text{Pb}$  is  $2941 \text{ Bq} \cdot \text{m}^{-2}$ . We corrected this value (missing inventory  
228 correction; Tylmann et al., 2016) by applying an exponential equation using the lowermost values of cumulative  
229 dry mass and unsupported  $^{210}\text{Pb}$  activity between 8 and 60 cm depths. As a result, a correction value of  $125.2$   
230  $\text{Bq} \cdot \text{m}^{-2}$  (missing inventory) is added to the final total unsupported  $^{210}\text{Pb}$  inventory ( $3066 \text{ Bq} \cdot \text{m}^{-2}$ ).

231 The CRS-2 model (constrained through 1963) shows a better agreement with the independent  $^{137}\text{Cs}$  markers at  
232 1953/54 and 1986/87 than the CRS-1 model (Fig. 2c). Therefore, CRS-2 model results were chosen for determining  
233 the age-depth profile and sediment mass accumulation rates (MAR) of core Burg17-B. The mean age at 59 cm  
234 sediment depth dates back to  $\sim 1930$ . The extrapolated mean age at 61 cm depth is  $\sim 1926$  calculated using the mean  
235 sediment accumulation rate between 54-60 cm ( $2 \text{ yr} \cdot \text{cm}^{-1}$ ).

#### 236 **4.2 Sediment lithology, green-pigments (RABD<sub>590-765</sub> index) and XRF-element records**

237 Four sediment facies (I to IV, Fig. 3 and 4a) are identified based on visual classification and the CONISS-analysis  
238 results of XRF-element intensities.

239

240 In Zone I (75.4-61cm, pre  $\sim 1926$ ), the sediments consist of visible thin brown-to-reddish laminae (Mn- and Fe  
241 rich). Green-pigment concentrations inferred from RABD<sub>590-765</sub> index values show a homogenous distribution with  
242 the lowest values within the sediment profile (Fig. 4d). Fe/Mn ratios vary within very low values (mostly below  
243 10). The Mn, Fe, P and Fe/Ti values show high levels with large variability. Extremely low Ca amounts are noted  
244 in this zone.

245

246 In Zone II (61-34cm,  $\sim 1926$ -1960), the sediments are dark gyttja, partly laminated with light Ca-rich layers. Green-  
247 pigment concentrations slightly increase yet still show little variability. A sharp increase of green-pigments  
248 concentrations occurs at 60 cm, and the first two local peaks near 55 cm ( $\sim 1938$ ) and 48 cm (1945) are notable.  
249 Fe/Mn ratios remain at slightly higher values than in Zone I. The Mn, Fe, P contents and Fe/Ti values all decline  
250 to low levels and remain relatively stable. Ca counts increase gradually over the whole Zone II.

251

252 In Zone III (34-21.5 cm,  $\sim 1960$ -1977), the sediments are mostly characterized by brown-to-reddish laminations  
253 (Mn-Fe rich), with thicker and more distinct laminae contacts than in Zone I. Green-pigment concentrations exhibit  
254 much higher values with positive trends, intensified variability, and several maxima (seasonal algal blooms).  
255 Fe/Mn ratios first drop in the lower part (34-27 cm) and then continue to increase upward to the top-part of Zone  
256 III. Fe, Mn, P, and Fe/Ti values show generally opposing trends to Fe/Mn ratios. Ca contents are elevated during  
257 this period relative to Zones I and II.

258

259 In Zone IV (21.5-0 cm,  $\sim 1977$ -2017), the sediments exhibit a clear laminated structure with much more

260 pronounced light calcite layers. The laminations are characterized by a regular succession of light calcite layers  
261 (Ca-rich) and dark organic-rich layers (Fig. S4). Green-pigment concentrations display the highest levels with  
262 large fluctuations, and reach distinct local maxima at 18 cm (1981), 15 cm (1985), 13 cm (1987), 12 cm (1988),  
263 and 8 cm (1997) depths (Fig. 4d). Fe/Mn ratios are at similarly high values as in Zone II, yet with more variability.  
264 The Fe, Mn, and P element counts and Fe/Ti all show constantly very low values. The Ca amounts are the highest  
265 in the profile and show considerable variability.

266  
267 Two principle components, PC1 and PC2 were shown to be significant using a broken stick model. They explain  
268 ~35 % and ~30 % of the total variance in the dataset, respectively (PCA-biplot; Fig. S5). The PC1 has strong  
269 positive loadings for the terrigenous elements (K, Ti, Rb etc.; Fig. 3 and S6) and thus represents mainly erosional  
270 processes related to allochthonous inputs. The PC2 has strong positive loadings for redox-sensitive elements (Fe,  
271 Mn), P and Fe/Ti, but negative loadings for Ca, Fe/Mn ratios and green-pigments index values. Therefore, PC2  
272 reflects changes in redox conditions of hypolimnetic water and lake primary productivity. The results of additional  
273 PCA analyses zone by zone (Fig. S7b) show that Mn, Fe and P were mostly independent of terrigenous elements  
274 (in Zones I to III), however in Zone IV, Mn, Fe and P become correlated with the terrigenous elements. The vertical  
275 profile of XRF-P matches very well with the changes of total P concentrations in sediments (Fig. S8). It reveals  
276 that XRF-P data can reliably represent qualitative variations of total P concentrations in sediment profiles of Lake  
277 Burgäschi.

278

#### 279 **4.3 Bulk elements and P fractions in sediment profiles**

280 Sediment TIC, TOC, TOC/TN ratio, S and P fractions also show distinctive features along the four stratigraphic  
281 zones (Fig. 5). From the upper part of Zone I (65.2-61 cm; ~1926) to Zone IV, TIC shows a similar pattern to the  
282 XRF-Ca contents (Fig. 3 and 5) suggesting that TIC is mostly present in the form of CaCO<sub>3</sub>. Over the whole profile,  
283 TOC/TN ratios are within the range of 9-11. TOC and TOC/TN ratios exhibit mostly similar patterns from Zone I  
284 to Zone III. By contrast, total sulfur (S) contents display a different pattern, showing very low values in Zone I  
285 and II (mean ~0.5%), and a substantial increase in Zone III and IV.

286  
287 The concentrations of relatively labile P fractions (i.e. NaCl-TP, NaBD-TP and NaOH-TP) and total P have a  
288 similar trend over the whole profile (Fig. 5 and 6a). They all display rather large values during the upper part of  
289 Zone I and generally reduced values in Zone II. In Zone III, the values increase to peaks at ~25 cm depth but  
290 sharply decrease to the lowest values in the upper boundary of Zone III and throughout Zone IV. HCl-TP and Ref.-  
291 P<sub>o</sub> fractions vary differently compared with the other fractions. Low contents of HCl-TP fraction are observed in  
292 Zone I and II. HCl-TP fraction has a rather similar pattern as labile P fractions in Zone III, but then it remains at  
293 high levels in Zone IV. Ref.-P<sub>o</sub> fraction contents show relatively stable values from Zone I to Zone II, followed by  
294 a gradual rise in Zone III and in the upper part of Zone IV. The net burial rates (NBR) of P-fraction since 1934  
295 (Fig. S9) show similar trends to the P-fraction concentrations (Fig. 5) (because sedimentation rates MAR are rather  
296 constant in core Burg17-C; Fig S9), except for the Ca-P and Ref.-P<sub>o</sub> fractions with decreasing NBR throughout  
297 the Zone IV.

298

299 Regarding the P composition in sediment profiles (Fig. 6, absolute and relative amounts), from Zone I to Zone III  
300 (65.2-21.5 cm) NaBD-TP fraction is the most important P-form representing ~50% of total P followed by NaOH-  
301 TP fraction. However, in Zone IV (depth above ~ 21.5 cm), HCl-TP becomes the main P fraction (~39% of total  
302 P) over NaBD-TP (~30% of total P).

303

304 The relationships between response variables and explanatory variables are visible on the redundancy analysis  
305 (RDA) biplot (Fig. 7), which, in most cases, correspond well to the results of Spearman rank correlation test (Fig.  
306 S10). The relatively labile P fractions (NaCl-TP, NaBD-TP and NaOH-TP) and total P in sediments are strongly  
307 positively correlated with redox-sensitive elements (Fe and Mn) and autochthonous Fe (Fe/Ti). However, these P  
308 fractions are negatively related to hypolimnetic oxygenation proxy (Fe/Mn ratios) and, to some extent, to lake  
309 productivity indicators (green-pigments, XRF-Ca and TIC). HCl-TP and Ref.-P<sub>o</sub> fractions are positively correlated.  
310 However, only HCl-TP fraction has close positive relationships with lake productivity indicators.

## 311 **5 Discussion**

### 312 **5.1 Trophic state evolution of Lake Burgäschi**

313 Four main phases of different lake trophic levels (based on RABD<sub>590-765</sub> index values) were distinguished since the  
314 early 1900s, as summarized in Fig. 8 and Fig. S11. During the period prior to ~1926 in Zone I, the lowest green-  
315 pigments index values reflect low lake primary productivity. In the early 1900s, agricultural impacts around the  
316 catchment area of Lake Burgäschi were not prominent (Guthruf et al., 1999). It can be expected that the lake had  
317 low nutrient loads from the catchment drainage during this period. Lake Burgäschi is classified as naturally  
318 oligotrophic based on morphometric parameters (LAWA, 1998) and as naturally mesotrophic according to  
319 Binderheim-Bankay (1998). Therefore, at the times of Zone I, Lake Burgäschi was likely in low trophic levels  
320 with a possible oligotrophic-mesotrophic condition.

321

322 The transition to Zone II (~1926-1960) was marked by generally increased sedimentary green-pigment  
323 concentrations and CaCO<sub>3</sub> contents (Fig. 3, 4d and 5), respectively, indicating enhanced lake primary productivity.  
324 The slightly decreased TOC/TN ratio also suggests a rise in autochthonous organic matter proportion (Meyers and  
325 Ishiwatari, 1993). The first two algal blooms (peaks of green-pigments index; Fig. 4d) imply a very likely  
326 mesotrophic to eutrophic state of the lake. Indeed, the study of Büren (1949) revealed that in 1943-1945, the trophic  
327 state of Lake Burgäschi had already shifted between mesotrophic and eutrophic. Interestingly, the water-table  
328 lowering during 1943-1945 (Guthruff et al., 1999) with related enhanced drainage of intensive agricultural fields  
329 and meadows (Büren, 1949) did not seem to have had an immediate impact on lake primary productivity (Fig. 3).

330

331 In Zone III (~1960-1977), continuously increasing green-pigment concentrations and several algal bloom events  
332 reveal strong positive trends in lake eutrophic levels. The significant eutrophication in Lake Burgäschi might have  
333 caused intensified CaCO<sub>3</sub> precipitation (TIC) and sulfur (S) contents in sediments (Fig. 4a and 5), which is in  
334 agreement with the findings from many other eutrophic lakes (Holmer and Storkholm, 2001; Bonk et al., 2016;  
335 Schneider et al., 2018).

336

337 During Zone IV (1977-2017), we interpret that Lake Burgäschi was in highly eutrophic conditions, based on  
338 constantly high green-pigments index values and multiple prominent algal blooms (Fig. 3). Low and decreasing  
339 TOC/TN ratio values ( $< 10$ ) in this zone suggest a dominant source of organic matter in sediments from aquatic  
340 primary production, which has been interpreted as a signal of eutrophic waters (Enters et al., 2006). Our  
341 interpretation is further supported by high chlorophyll-*a* concentrations in surface waters ( $>8 \text{ ug L}^{-1}$ ; GSA, 2007)  
342 and the dominance of blue-green algae in the phytoplankton biomass during 1977 to 1992, which characterized  
343 Lake Burgäschi as highly eutrophic (GBL, 1995; Guthruf et al., 2013).

## 344 **5.2 Reconstruction of hypolimnetic oxygenation regimes of Lake Burgäschi**

345 A large number of studies have used the proxy of Fe/Mn ratios in sediments to reconstruct past water oxygenation  
346 and mixing regimes of the lake, such as Mackereth (1966), Frugone-Álvarez et al. (2017), and Żarczyński et al.  
347 (2019) etc. However, this proxy and its interpretation are limited to cases in which the annual cycle of Fe and Mn  
348 deposition in lakes is mostly driven by redox changes in the hypolimnion and related diagenetic processes in  
349 surface sediments instead of driven by terrestrial inputs (Boyle, 2001; Naeher et al., 2013). In Lake Burgäschi,  
350 during Zone I to III, Mn and Fe were mostly independent of erosion indicators as shown in Fig. S7b. Furthermore,  
351 Van Raden (2012) has revealed that the presence of Mn-rich laminae in sediments of Lake Burgäschi can indicate  
352 frequent short-term wind-induced mixing events in the lake. Therefore, we suggest that the deposition of Fe and  
353 Mn during these three zones was mainly controlled by in-lake processes. Fe/Mn ratios together with Mn  
354 precipitation reliably track past changes of hypolimnetic oxygenation of Lake Burgäschi.

355 In Zone I (pre ~1926), the sediments feature well-preserved Mn-Fe rich laminations and very low Fe/Mn ratios  
356 (Fig. 3 and 4a), suggesting that the lake hypolimnion was seasonally well-oxygenated. The similar occurrence of  
357 visible Mn- and Fe rich laminae in sediments were also reported by Rey et al. (2017) in Lake Burgäschi and from  
358 other lakes, for example, Lake of the Clouds in the US (Anthony, 1977), Lake Cadagno in the Swiss Alps (Wirth  
359 et al., 2013), and Lake Żabińskie in Poland (Żarczyński et al., 2018). They revealed that the red-orange Mn-rich  
360 layers mostly consist of authigenic rhodochrosite ( $\text{MnCO}_3$ ) that was formed when Mn-rich anoxic bottom waters  
361 are mixed with oxygenated surface waters for short intervals. The preservation of this Mn-rich layer is only  
362 possible when its sedimentation process exceeds the release process under anoxic hypolimnetic conditions  
363 (Stevens et al., 2000). Therefore, during this period, short-term mixing events and associated oxygenation may  
364 have occurred during overall stratified or anoxic conditions in the hypolimnion.

365  
366 In Zone II (~1926-1960), the higher Fe/Mn ratios and very low Mn- and autochthonous Fe (Fe/Ti) amounts are  
367 interpreted as the results of stable anoxic hypolimnetic waters. The formation and preservation of Fe- and Mn-  
368 oxides in sediments is largely prevented under long-term stratification/reducing conditions (Stevens et al., 2000).  
369 The lake most likely developed anoxic hypolimnetic conditions with yearly incomplete or missing circulation in  
370 the hypolimnion.

371  
372 In Zone III (1960-1977), overall decreased Fe/Mn ratios combined with reappearing Mn- and Fe-rich laminations  
373 reflect better short-term oxic conditions in hypolimnetic waters than in Zone II. However, during ~1970 to 1977,  
374 Fe/Mn ratios gradually increased (Fig. 3), which points to less oxic conditions in the hypolimnion. It seems to be  
375 related to synchronously progressive lake eutrophication (see Sect. 5.1). Higher primary productivity and

376 strengthened anoxia in the hypolimnion are commonly observed in stratified lakes (Giguet-Covex et al., 2010;  
377 Mikomägi et al., 2016). Higher lake primary productivity increases high-rate aerobic degradation of organic matter  
378 and, consequently, oxygen-depletion in the hypolimnion and sediments (Gächter and Müller, 2003; Nürnberg,  
379 2007).

380  
381 Finally, in Zone IV (1977- 2017) Fe/Mn ratios proxy is no longer valid to indicate hypolimnetic oxygenation  
382 regime, as suggested by predominantly terrestrial sources of sediment Fe and Mn (Fig. S7b). Nevertheless, the  
383 well-preserved laminated sediments during this period are a clear sign of absent benthic bioturbation and thus  
384 represent an indicator of generally strong anoxic conditions in hypolimnetic waters, occurring simultaneously with  
385 a highly eutrophic period. According to the limnological monitoring data of Lake Burgäschi between 1978 and  
386 2007 (GSA, 2007), the lake water was completely anoxic at depths below 20 m during the summer-autumn  
387 stratification; even during winter circulation of most years, the lake water was still not completely mixed.

388

### 389 **5.3 Phosphorus composition and factors controlling long-term P-fraction retention in sediments**

390 Prior to 1977 (i.e. Zones I-III), NaBD-TP (redox-sensitive Fe- and Mn bound P) and NaOH-TP (partly non-  
391 reducible Fe oxides-P) fractions were the primary P forms in sediments of Lake Burgäschi (Fig. 6 and 8). This  
392 seems to compare well with the study of Moosmann et al. (2006), who suggested that sediment Fe contents control  
393 P retention in sediments of the Swiss Plateau lakes. However, after ~1977, we observed a change to predominantly  
394 Ca-P (apatite-P), occurring concurrently with the operation of hypolimnetic withdrawal restoration. This clear  
395 pattern in sedimentary P-fraction change can be largely attributed to this restoration measure. The hypolimnetic  
396 withdrawal treatment in Lake Burgäschi removes not only hypolimnetic P but also dissolved metal (Al, Fe and  
397 Mn) ions and, thus leads to calcite as the main sorbent for P in upper waters and to an enhanced proportion of Ca-  
398 P fraction in sediments.

399

400 In spite of the effects of lake restoration on sedimentary P retention in Zone IV, overall, the retention of total P  
401 and labile P fractions in the sediment profile was mainly controlled by autochthonous Fe (Fe/Ti), Mn, and  
402 hypolimnetic oxygenation proxy-Fe/Mn ratios, as shown by the results of RDA analysis (Fig. 7). Our results  
403 support the previous suggestion that long-term permanent sediment-P retention is largely limited by the sediment's  
404 binding capacity in anoxic conditions (Moosmann et al., 2006; Hupfer and Lewandowski, 2008), which,  
405 specifically in our case, is determined by redox-sensitive elements (autochthonous Fe and Mn) preserved in  
406 sediments. These findings are discussed in the context of each cluster zone as follows: During Zone I and Zone  
407 III, when the hypolimnion had better seasonally oxic conditions (see Fig. 8 and Fig. S11), the increased retention  
408 of Mn and Fe, and labile P fractions occurred simultaneously (Fig. 3 and 5). This phenomenon might be caused  
409 by efficient P-trapping in Mn- and Fe enriched layers. It has been suggested that the formation of laminated Mn-  
410 and Fe enriched layers could serve as a protective cap to reduce P release from surface sediment layers to the  
411 anoxic hypolimnion (Żarczyński et al., 2018) which, thus, can help improve P retention within these sedimentary  
412 layers. In Zone II, small amounts of labile P fractions might result from decreased P-bearing solid phases (Mn and  
413 Fe minerals) in sediments under anoxic conditions in the hypolimnion (see higher Fe/Mn ratios in Sect. 5.2; Fig.  
414 S11). However, in Zone IV, we observed the lowest retention and NBR of total P and labile P fractions in recent

415 sediments (Fig. 5; Fig. S9). We interpret this as a combined result of eutrophication-induced hypolimnetic anoxia  
416 and hypolimnetic withdrawal since 1977 whereby P-rich hypolimnetic water is discharged out of the lake. On the  
417 one hand, under stable anoxic conditions in the hypolimnion caused by strong eutrophication, reduced Mn and Fe  
418 preservation (Fig. 3) suggests a low capacity of permanent P-trapping within the anoxic sediments. On the other  
419 hand, hypolimnetic withdrawal restoration in Lake Burgäschi has substantially reduced hypolimnetic P  
420 concentrations by a factor of 5-6 since 1978 (Fig. S11; GSA, 2007) and MARs (Fig. 2c and Fig. S9). This indicates  
421 a concomitant decrease in sediment-P release to the hypolimnion and P sedimentation to the water-sediment  
422 interface (gross sedimentation of P) as well. Consequently, decreased total P concentrations and total P-NBR in  
423 sediments were observed (Fig. 6a and S9). The reduction of total P contents in upper sediments caused by  
424 hypolimnetic withdrawal was also reported from Lake Kortowskie of Poland (Dunalska et al., 2007). Moreover,  
425 our findings confirm that this restoration is an effective method to reduce sediment-P release potentials, as  
426 indicated by considerably decreased NBR of labile P fractions in upper sediments (Fig. S9).

427  
428 In the whole sediment profile, HCl-P and Ref.-P<sub>o</sub> fractions had mainly autochthonous origins and were mainly  
429 controlled by in-lake processes rather than by clastic inputs (e.g. apart from molasses sandstone), as indicated by  
430 absent positive correlations between the two fractions and detrital elements such as Ti, K and Al (Fig. 7). HCl-P  
431 (i.e. Ca-P) fraction retention, to a large extent, resulted from authigenic CaCO<sub>3</sub>-P precipitation, and increased with  
432 higher eutrophic levels in Zone III and IV (Fig. 5; Sect. 5.1). We interpret this as an incidence of biologically  
433 driven co-precipitation of Ca and P in highly productive lakes. The phenomenon of Ca-P co-precipitation has been  
434 observed and studied in many calcareous lakes (Dittrich and Koschel 2002; Whitehouse, 2010), and is assumed to  
435 be responsible for the scavenging of dissolved P from surface waters of eutrophic lakes (Hamilton et al., 2009). In  
436 addition, large amounts of Ca-P in surface sediments (top 21 cm) can act as a potential negative feedback to  
437 eutrophication in Lake Burgäschi, because Ca-P fraction is relatively stable in sediments and has low potentials of  
438 P-release from surface sediments back to lake waters. Interestingly, HCl-P fraction retention and NBR in sediments  
439 of Zone IV were generally lower than in Zone III (Fig. 5 and Fig. S9), although the lake in Zone IV had relatively  
440 higher eutrophic levels (see Sect. 5.1; Fig. S11). The pH in the hypolimnion of Lake Burgäschi varied between 7.0  
441 and 7.5 according to the monitoring data in 1993, 2003, and 2013 (Guthruf et al., 2013). Therefore, the acid  
442 dissolution of Ca-P in the hypolimnion and at the water-sediment interface is small and unlikely significant during  
443 Zone IV. The generally decreased retention and NBR of Ca-P fraction were seemingly related to hypolimnetic  
444 withdrawal, which has caused lower water-P concentrations and MAR of sediments as discussed above. As a result,  
445 there are reductions of CaCO<sub>3</sub>-P co-precipitation in the epilimnion and consequently of Ca-P net sedimentation in  
446 surface sediments. Overall, Ref.-P<sub>o</sub> fraction retention and NBR in the sedimentary profile show less variability  
447 compared with other P fractions (Fig. 5 and Fig. S9). Nevertheless, the lower NBR of Ref.-P<sub>o</sub> fraction in the upper  
448 sediments (~ top 10 cm) could be derived from the ongoing early degradation of fresh organic matters.

449  
450 The interesting observation is that the water-P reductions caused by the hypolimnetic withdrawal in Lake  
451 Burgäschi (GSA, 2007; Nürnberg, 2007) have been ineffective in reducing algal blooms and curbing  
452 eutrophication. Similar findings were also reported from some lakes in Europe and the US (Kosten et al., 2012;  
453 Kolzau et al., 2014; Fastner et al., 2016). These authors have attributed this phenomenon to insufficient external  
454 P-load reduction, higher water temperatures under global warming of the last few decades, and the light or nitrogen

455 limitation of surface-water phytoplankton. In Lake Burgäschi, phytoplankton growth in the trophic zone is still  
456 limited by P after 1978 rather than by the nitrogen (GSA, 2007) as the nitrate concentrations stay as high as 0.5-3  
457 mg N / L in the upper 5-m waters. Hence, we suggest that these factors mentioned above, except for nitrogen  
458 limitation of lake productivity, may also contribute to promoting persistently high primary productivity in Lake  
459 Burgäschi. But the main driver keeping productivity high, is the continuing high external P loads from the lake  
460 catchment. During summer stratification, the high loads of P into the lake epilimnion primarily support  
461 phytoplankton growth in the photic zone, which is not strongly influenced by the hypolimnetic-P discharge and  
462 internal P loadings. From a management perspective, it is still critically important to focus on lowering external P  
463 loads in order to decrease primary production and eutrophication in seasonally-stratified small deep lakes which  
464 are more likely to favor stable stratification during phytoplankton growth season.

465

## 466 **6 Conclusion**

467 This study shows that in Lake Burgäschi, more than half of sediment P is buried in relatively labile P fractions  
468 (Fe/Mn/Al-P), yet with low potentials for P-release from these labile P fractions in deeper layers (below ~21 cm).  
469 Our results highlight the importance of hypolimnetic oxygenation/mixing regime in controlling long-term P  
470 retention and net burial rates of labile P fractions in sediments of this small deep lake. Irrespective of increasing  
471 lake primary productivity during early 1900s to 1977, the two periods of high sedimentary retention of total P and  
472 labile P-fraction occurred in Fe- and Mn enriched laminae, which appears to be linked to seasonal mixing of the  
473 hypolimnion in the past. Importantly, the positive effects of hypolimnetic withdrawal in Lake Burgäschi were  
474 observed primarily in sediment P-fraction data but not in lake trophic state. The 40-year operation of hypolimnetic  
475 withdrawal has impoverished sedimentary P, in particular largely decreased net burial rates of labile P fractions  
476 (potential internal P loads), and increased the relative proportion of stable Ca-P fraction in top sediment layers (0-  
477 21 cm). Nevertheless, the lake is currently still highly eutrophic. We attribute the delay of lake recovery primarily  
478 to still high nutrient inputs from the nearby or surrounding agricultural area into the lake trophic zone during  
479 stratification seasons. This study calls for consistently more effective measures to minimize external P loadings  
480 from the catchment, such as optimizing fertilizer application practices and technical measures in the drainages.

481

482

483

## 484 **Data availability**

485 The data will be made available at PANGAEA at <https://doi.pangaea.de/10.1594/PANGAEA.908896>.

486

487

## 488 **Author contributions**

489 L.T. helped with sample collection, analyzed the sediment, conducted data analysis, wrote the manuscript, and  
490 acquired most of the funding for the project.

491 P. Z. helped with sediment core subsampling, conducted the hyperspectral imaging (HSI) scanning, helped with  
492 XRF-scanning, substantially contributed to the data interpretation.

493 S.S. measured gamma-spectroscopy radiometric activities, generated the data for chronology and helped with  
494 data interpretation.

495 R.L. conducted the XRF-scanning and helped with data interpretation.  
496 M.G. designed the study, helped discussing the results, editing the manuscript and supervised the project.  
497 All authors commented on the manuscript.

498

#### 499 **Competing interests**

500 The authors declare that they have no conflict of interest.

501

#### 502 **Acknowledgements**

503 We thank Stamatina Makri and Dr. Andre F. Lotter for their help during the fieldwork. We thank Irene Brunner,  
504 Patrick Neuhaus, Dr. Daniela Fischer and Andrea Sanchini for their expertise and the lab assistance. Further, we  
505 acknowledge Dr. Klaus A. Jarosch for the valuable suggestions about phosphorus data. The thoughtful comments  
506 and suggestion by the two anonymous reviewers greatly improved this paper. The project was funded by the Swiss  
507 National Science Foundation under the grant number 200021-172586, a Fellowship Grant from the Chinese  
508 Scholarship Counsel and the International PhD Fellowship from University of Bern.

788 **Figure 6: Vertical profile of (a) P fractions concentrations and (b) their proportions of total P in sediments. The y-axis**  
 789 **(left) refers to the sediment depth of Core Burg17-B. Note that the sample between 3.6-4.5 cm depth was removed from**  
 790 **dataset because the values were extremely higher than any sample data (data not shown), which is abnormal according**  
 791 **to XRF-P counts at the corresponding depth (Fig. S8b). We attributed this to the result of contamination during the**  
 792 **sample measurements.**
