Abstract. Hypolimnetic anoxia in eutrophic lakes can delay lake recovery to lower trophic states via the release of sediment phosphorus (P) to surface waters on short time scales in shallow lakes. However, the long-term effects of hypolimnetic redox conditions and trophic state on sedimentary P-fraction retention in deep lakes are not clear yet. Hypolimnetic withdrawal of P-rich water is predicted to diminish sedimentary P and seasonal P recycling from the lake hypolimnion. Nevertheless, there is a lack of evidence from well-dated sediment cores, in particular, from deep lakes, about the long-term impact of hypolimnetic withdrawal on sedimentary P retention. In this study, long-term sedimentary P-fraction data since the early 1900s from Lake Burgäschi provides information on the benthic P retention under the influence of increasing lake primary productivity (sedimentary green-pigments proxy), variable hypolimnion oxygenation regimes (Fe/Mn ratio proxy), and hypolimnetic withdrawal since 1977. Results show that, before hypolimnetic withdrawal (during the early 1900s to 1977), redox-sensitive Fe/Mn-P fraction comprised ~50% of total P in the sediment profile. Meanwhile, long-term retention of total P and labile P-fractions in sediments was predominantly affected by past hypolimnetic redox conditions, and P retention increased in sedimentary Fe- and Mn enriched layers when the sediment overlaying water was seasonally oxic. However, from 1977-2017, eutrophication-induced persistent anoxic conditions in the hypolimnion and due to hypolimnetic water withdrawal increasing the P export out of the lake, net burial rates of total and labile P fractions decreased considerably in surface sediments. By contrast, refractory Ca-P fraction retention was primarily related to lake primary production. Due to the lake restoration since 1977, Ca-P fraction became the primary P fraction in sediments (representing ~39% of total P), indicating a lower P bioavailability of surface sediments. Our study implies that in seasonally-stratified eutrophic deep lakes (like Lake Burgäschi), hypolimnetic withdrawal can effectively reduce P retention in sediments and potentials of sediment-P release (internal P loads). However, more than 40 years of hypolimnetic syphoning have not improved the lake trophic state or decreased lake productivity. Also, this restoration has not enhanced water-column mixing and oxygenation in hypolimnetic waters. The findings of this study are relevant regarding management of deep eutrophic lakes with mixing regimes typical for temperate zones.

Keywords: Phosphorus fractions, eutrophication, hypolimnetic anoxia, hypolimnetic withdrawal, deep lakes

40 **1 Introduction**

41 Phosphorus (P) eutrophication in freshwater lakes is a global problem and has been a matter of concern to the
42 public for several decades. In lakes where the external P loading has been reduced, internal P loading (sediment-
43 P release to surface waters) is widely recognized as the key factor affecting lake trophic status and delaying lake
44 recovery from eutrophication (Burley et al., 2001; Trolle et al., 2010). Considerable work has been done on
45 sediment-P speciation to evaluate sediment-P release potentials and implications for lake restoration management
46 (Gonsiorczyk et al., 1998; Ribeiro et al., 2008).

47 The paradigm that oxygen levels control the sediment-P release via reductive dissolution of Fe-P fraction in surface
48 sediments has been accepted as the classical model for a long time (Einsele, 1936, 1938; Moosmann et al., 2006).
49 Under anoxic conditions, P bound to redox-sensitive Fe and Al/Fe (oxyhydr)oxides can be potentially released
50 from surface sediments into lake water (Burley et al., 2001), which was supported by numerous short-term (days
51 or seasonal) laboratory or in-situ studies (Chen et al., 2018). Based on this paradigm, it was assumed that an oxic
52 sediment–water interface might limit the release of Fe-P from sediments and, therefore, improve P retention in
53 lake sediments. However, the restoration measures with artificial hypolimnetic oxygenation/aeration applied in
54 eutrophic lakes proved to have only short-lasting effects but no direct effects on internal P loading and redox-
55 dependent sediment-P retention on longer terms (Gächter, 1987; Gächter and Wehrli, 1998; Moosmann et al., 2006;
56 Hupfer and Lewandowski, 2008). Gächter and Müller (2003) and Moosmann et al. (2006) further argued that, on
57 multi-decadal or longer time scales, P retention in lake sediments might eventually primarily depend on the P-
58 binding capacity of anoxic sediments and sediment composition (e.g. Fe, Mn, Al, and Ca contents). Nevertheless,
59 until now, there is a lack of evidence from well-dated sediment cores, and there is still a need to know which
60 processes may have a dominant influence on sediment P-fraction retention on longer time scales (e.g., decades or
61 more). This information is crucial for predicting and, ultimately, managing sediment-P release, especially in deep
62 lakes, because hypolimnetic anoxia in deep lakes can lead to large loads of sediment-P release. In contrast to the
63 well-established studies about sediment-P speciation in shallow polymictic lakes (e.g. Kaiserli et al., 2001;
64 Søndergaard et al., 2001; Cavalcante et al., 2008), there are only a few studies available from seasonally-stratified
65 deep lakes. Furthermore, eutrophication has been demonstrated to affect sediment-P release via controlling
66 hypolimnetic anoxia and lake mixing regime in seasonally stratified deep lakes (Tu et al., 2019). It is not yet fully
67 understood whether and how lake trophic levels and hypolimnetic anoxia can influence the long-term behavior of
68 sedimentary P-fraction retention in deep lakes.

69 The restoration technique of hypolimnetic withdrawal has been frequently applied in seasonally stratified lakes in
70 Europe (Kucklantz and Hamm, 1988; Nürnberg, 2007), whereby P-enriched water from the hypolimnion is
71 discharged directly into the lake outflow. This restoration technique has been shown to efficiently reduce P
72 concentrations in lake waters (Nürnberg, 2007). Hypolimnetic withdrawal was also expected to reduce P retention
73 in sediments and seasonal P recycling from the lake hypolimnion to the upper waters, for example, in Lake Mauen,
74 a shallow, eutrophic lake (maximum depth 6.8 m; Gächter, 1976). However, there is lack of empirical evidence
75 from sedimentary P-fraction data, which provides valuable information on possible sediment-P release

76 characteristics and potentials of internal P loadings. Furthermore, for deep lakes, the long-term influence of this
77 restoration on sedimentary P release potentials is unclear.

78 The objectives of this study were to (1) explore the main factors controlling long-term changes of P-fraction
79 retention in sediments of deep lakes, (2) investigate how sediment P-fraction retention responds to changes in lake
80 eutrophication and hypolimnetic anoxia of the past prior to anthropogenic eutrophication, (3) examine the long-
81 term effects of lake hypolimnetic withdrawal restoration on sedimentary P-fraction retention in seasonally-
82 stratified deep lakes, and (4) evaluate with sediment-P data the predictions from Gächter (1976) that hypolimnetic
83 withdrawal should result in reduced total P contents in sediments and sediment-P release to lake water. To achieve
84 these objectives, we investigated short sediment cores from Lake Burgäschi, a deep and eutrophic lake on the
85 Swiss Plateau. Sedimentary green-pigments (chlorophylls and diagenetic products) inferred from hyperspectral
86 imaging (HSI) scanning and XRF-inferred Fe/Mn ratios primarily reflect lake trophic state evolution (aquatic
87 primary productivity) and hypolimnetic oxygenation, respectively. A sequential P-extraction with five P fractions
88 was performed to uncover P fractionation in sediment profiles. We combined all data to identify the dominant
89 factors responsible for temporal changes in P-fraction retention.

90 Lake Burgäschi is an excellent study site because there were substantial changes in lake trophic levels and possibly
91 lake-mixing regimes since the last century (Guthruf et al., 1999; Van Raden, 2012), and exceptionally long
92 historical and limnological survey data are available for most of the last 50 years. Hypolimnetic withdrawal
93 restoration is in operation since 1977.

94

95 **2 Study site**

96 Lake Burgäschi (47°10'8.5"N, 7°40'5.9"E) is a small lake located on the Swiss Plateau (Fig. 1a). It has a very
97 restricted catchment (3.2 km²). The catchment area geologically belongs to the Molasse Basin, and mostly consists
98 of carbonate-rich sandstones and mudstones (Schmid et al., 2004). The kettle hole lake was formed after the retreat
99 of the Rhone glacier (ca. 19 k yr. BP; Rey et al., 2017). Currently the maximum water depth is ~31 m, which is
100 quite deep in contrast to the small surface area of 0.21 km² (Guthruf et al., 1999). The mean retention time of the
101 lake water is ~1.4 year (Nürnberg, 1987). The lake has several small inflows in the southwest (Rey et al., 2017)
102 and one outflow in the north (Fig. 1c).

103 Since the 19th century, the lake's water level was lowered several times to create farmland, with the most recent
104 lowering (up to 2 m) during 1943-1945 (Guthruf et al., 1999). Agricultural area currently covers ~55% of the lake
105 catchment, followed by ~29% area of forests. The lake region experiences a warm humid continental climate (Dfb;
106 Köppen-Geiger classification). The mean annual air temperature is 9 °C and the warmest month is July (mean
107 temperature 19 °C).

108 Lake Burgäschi has been highly productive (eutrophic to highly eutrophic state) since the 1970s with high algal-
109 biomass production and anoxic conditions in the hypolimnion (Guthruf et al., 1999, 2013). The eutrophication in
110 Lake Burgäschi has been linked to increased agricultural P inputs via drainage into the lake in the second half of
111 the 20th century (Guthruf et al., 1999). To mitigate the eutrophication, hypolimnetic withdrawal restoration has
112 been applied in Lake Burgäschi since 1977, and the lake water has been monitored twice a year for more than 30

113 years for various parameters, such as pH, oxygen content, phosphorus concentrations, phytoplankton biomass, etc.
114 Despite a sharp decline in hypolimnetic phosphorus concentrations due to the restoration, a high production of
115 algal biomass continues today (GSA, 2007). Additionally, hypolimnetic oxic/anoxic conditions and the lake
116 trophic state have been stabilized but not fundamentally improved (GBL, 1995; Guthruf et al., 2013).

117

118 **3 Materials and methods**

119 **3.1 Core collection and sampling**

120 In September 2017, two 75-cm-long sediment cores (Burg17-B and Burg17-C) were retrieved from the deepest
121 point of Lake Burgäschi (water depth ~31 m) (47°10'8.6"N, 07°40'5.3"E; coring site in Fig. 1c) using a UWITEC
122 gravity corer. After the collection, the cores were stored in a dark cold room (~4 °C). After opening and splitting
123 lengthwise, core-half A of Burg17-B was continuously subsampled at 2-cm resolution from 0 to 60 cm for ²¹⁰Pb
124 and ¹³⁷Cs dating. The oxidized surface of core-half B (Burg17-B) was visually described (Schnurrenberger et al.,
125 2003) before non-destructive XRF core and HSI scanning. After the opening, one-half of core Burg17-C was
126 transferred immediately into a glove box with an anoxic atmosphere where it was continuously subsampled at 2-
127 cm resolution from 0 to 72 cm. The fresh sediments from each sample slice were homogenized and used for
128 sequential P extraction. After sampling for P extraction, the remaining sediment of the 2-cm slice was freeze-dried
129 and homogenized for bulk element analyses.

130 **3.2 Chronology**

131 The chronology of the core Burg17-B is based on ²¹⁰Pb and ¹³⁷Cs activity profiles. The freeze-dried and
132 homogeneous samples were stored dry and dark until analysis. The ²¹⁰Pb, ¹³⁷Cs and ²²⁶Ra radiometric activities
133 were measured by gamma spectrometry at the University of Bern Department of Chemistry and Biochemistry.
134 1.3-5.1 g of the freeze-dried samples were encapsulated into polystyrene petri dishes (68 mm O.D., 11 mm height;
135 Semadeni, Ostermundigen, Switzerland) together with a polystyrene disk to fill in the headspace above the sample
136 material, and the petri dishes were vacuum-sealed into a gas-tight aluminum foil for equilibration. ²¹⁰Pb (46.5 keV),
137 ²⁴¹Am (59.5 keV), ²²⁶Ra progenies ²¹⁴Pb and ²¹⁴Bi (295.2, 351.9 and 609.3 keV), as well as ¹³⁷Cs (661.7 keV) were
138 measured using a Broad Energy Germanium (BEGe) detector (Canberra GmbH, Rüsselsheim, Germany). This
139 system is composed of a high-purity germanium crystal of 50 cm² area and 30 mm thickness with a 0.6 mm thick
140 carbon epoxy window, which shows high absolute full-energy peak efficiencies for close on-top geometries of >20%
141 and ~5% for ²¹⁰Pb and ¹³⁷Cs, respectively. Low integrated background count rates of 0.20 s⁻¹ (energy range of 30-
142 1800 keV) were achieved by application of low-background materials, installation in third underground floor (~10
143 m of water-equivalent overburden), passive shielding (outside to inside: 10 cm low-background lead, 3 mm ancient
144 lead with negligible ²¹⁰Pb content, 2 mm cadmium), flushing of the shield interior with nitrogen gas and an active
145 anti-cosmic shield (plastic scintillator panels of totally 1 m² area mounted directly above the passive shielding).
146 Supported ²¹⁰Pb in each sample was assumed to be in equilibrium with the in-situ ²²⁶Ra (equilibration time 4
147 weeks). Unsupported ²¹⁰Pb activity was calculated by subtracting ²²⁶Ra activity from total ²¹⁰Pb activity level-by-
148 level. The correction for the total unsupported ²¹⁰Pb missing inventory followed Tylmann et al. (2016).

149

150 The ^{210}Pb chronology of core Burg17-B was determined using the Constant Rate of Supply (CRS) model (Appleby,
151 2002), which accounts for variation in sediment accumulation rates. We tested two CRS models: CRS-1 model
152 was unconstrained (i.e. without reference points from the ^{137}Cs activity). The CRS-2 model was constrained with
153 the chronologic marker of peak fallout from nuclear weapons testing in 1963 (^{137}Cs and ^{241}Am). Both models were
154 then tested and validated with independent time-markers at the onset of nuclear weapons testing in 1953/54 and
155 the Chernobyl accident in 1986/87 (onset of ^{137}Cs and peak of ^{137}Cs and ^{241}Am , respectively).

156

157 The two sediment cores (Burg 17-B and Burg 17-C) are visually very similar but show a length-offset due to coring
158 compaction of approximately 2-6 cm (Fig. S1 in Supplementary data). The age-depth stratigraphy of Burg17-C
159 core was inferred from the dated core Burg17-B by visual stratigraphic correlation from high-resolution core
160 pictures.

161

162 **3.3 Non-destructive geochemical methods**

163 Non-destructive X-ray fluorescence (XRF) core scanning was done using an Avaatech XRF Core Scanner (Richter
164 et al., 2006) for semi-quantitative element composition measurements at 0.5 mm resolution to capture relative
165 elemental concentrations of the laminae. The core surface was smoothed and covered with a 4- μm -thick Ultralene
166 foil prior to the analysis. Elements were measured using a Rhodium anode and a 25 μm Be window. The lighter
167 elements (e.g. Al, Si, P etc.) were measured for 15 seconds count time at 10 kV with 1500 A, no filter; while the
168 heavier elements (e.g. Mn, Fe, Br etc.) were exposed for 40 seconds at 30 kV with 2000 A, Pd-thin filter. Element
169 intensities (semi-quantitative concentrations) of the selected elements (Mg, Si, Al, K, Ti, Rb, P, Fe, Mn, Ca) are
170 expressed as count rates (counts per second, cps).

171 Following the methodology in Butz et al. (2015), hyperspectral imaging (HSI) scanning was performed using a
172 Specim Ltd. Single Core Scanner equipped with a visual to near infrared range (VNIR, 400–1000 nm)
173 hyperspectral linescan camera (Specim PFD-CL-65-V10E). Parameters were set for a spatial resolution of ~ 70
174 $\mu\text{m}/\text{pixel}$ and a spectral sampling of 1.57 nm (binning of 2). Spectral endmembers were determined using the
175 “Spectral Hourglass Wizard” of the ENVI 5.5 software package (Exelisvis ENVI, Boulder, Colorado). The relative
176 absorption band depth (RABD) index calculation was performed following the method in Schneider et al. (2018).
177 However, based on the spectral end members (Fig. S2), we used the absorption feature between the wavelengths
178 R590 and R765 (590-765 nm), i.e. $\text{RABD}_{590-765}$. Butz et al. (2017) and Schneider et al. (2018) revealed that this
179 index is well calibrated to absolute green-pigments (chlorophyll *a* + pheophytin *a*) concentrations in sediments.
180 The sediments in Lake Burgäschi are mostly laminated and organic-rich (Van Raden, 2012), which indicates that
181 the sediments are anoxic, bioturbation is absent, and sedimentary pigments are well-preserved (Reuss et al., 2005).
182 Therefore, in our study, the relative concentrations of green-pigments inferred from $\text{RABD}_{590-765}$ index values
183 provide a semi-quantitative reconstruction of lake primary productivity (total algal abundance) at sub-annual
184 resolution, and are suggested to reflect the trophic state evolution of Lake Burgäschi.

185 **3.4 Phosphorus fractionation scheme and bulk elements analyses**

186 The P-fractionation extraction protocol (Fig. S3) principally follows the four-step extraction protocol in Tu et al.,
187 (2019). In addition, we added the last extraction step from Lukkari et al. (2007) to determine refractory organic P

188 (F5). This P fraction (F5) is practically biologically unavailable and subject to permanent P burial. The first four
189 fractions are NaCl-TP (F1: loosely bound P), NaBD-TP (F2: redox-sensitive Fe- and Mn-bound P), NaOH-TP (F3:
190 Al- and Fe-bound P), and HCl-TP (F4: Ca-bound P) (Tu et al., 2019), whereby NaCl-TP, NaBD-TP and NaOH-
191 TP fractions together are considered as relatively labile P fractions because they may release P back to the water
192 column under anoxic or high pH environments (Rydin, 2000). The HCl-TP and refractory organic P (Ref.-P_o)
193 fractions are classified as relatively stable or refractory P fractions. Total P in sediments was obtained from the
194 sum of the five P fractions. The P in extract samples was measured by inductively coupled plasma mass
195 spectroscopy (7700× ICP-MS) (Agilent Technologies, Germany) after the dilution with nitric acid (HNO₃) to reach
196 a final concentration of 1% v/v HNO₃.

197 Concentrations of total carbon (TC), total nitrogen (TN), and total sulfur (S) in sediment samples were determined
198 using an Elementar vario EL Cube elemental analyzer. Total inorganic carbon (TIC) content was calculated by
199 multiplying loss on ignition at 950 °C (LOI₉₅₀, following the method proposed by Heiri et al. (2001)) by 0.273, i.e.
200 the ratio of the molecular weight of C and CO₂. Total organic carbon (TOC) content was calculated using the
201 equation TOC =TC-TIC. Sediment dry bulk density and water content were determined using wet mass (g), dry
202 mass (g) and wet volume (cm³) following the method in Håkanson and Jansson (2002).

203

204 **3.5 Data analyses**

205 Multivariate statistical analyses were performed with R version 3.4.2 (R Development Core Team, 2017). Prior to
206 data analyses, RABD₅₉₀₋₇₆₅ index values (resolution 70 μm) were aggregated to a spatial resolution of 0.5 mm (the
207 spatial resolution of XRF data). Stratigraphically constrained incremental sum of squares clustering (CONISS;
208 Grimm, 1987) was then performed on semi-quantitative proxies (i.e. RADB₅₉₀₋₇₆₅ index and XRF-element data)
209 with R-package “rioja” (Juggins, 2017). The number of significant clusters was determined with a broken-stick
210 test (Bennett, 1996). A principal components analysis (PCA) was performed on the centered and standardized data
211 of semi-quantitative proxies, using the “Vegan” package (Oksanen et al., 2013). XRF-element and RABD₅₉₀₋₇₆₅
212 index values were averaged within the depth range of each sample taken from core Burg17-C for P fractions. In
213 order to identify the primary factors influencing the variations in sedimentary P fractions, a redundancy analysis
214 (RDA) was performed on the centered and standardized dataset of P fractions (response variables) and other
215 sediment geochemical parameters (explanatory variables) with the “vegan” package. In the RDA computation, the
216 correlation matrix option was selected and the scaling was conducted on a correlation biplot.

217 **4 Results**

218 **4.1 ¹³⁷Cs and ²¹⁰Pb chronology**

219 The two distinctive peaks of ¹³⁷Cs in sediment profiles are detected at 31 cm and 15 cm depths (Fig. 2b),
220 corresponding to the 1963 and 1986 major fallout events, respectively (Appleby, 2002). Furthermore, ²⁴¹Am
221 activity peaks at the same depths (Fig. 2b) confirm that the 1963 and 1986 ¹³⁷Cs peaks were due to atmospheric
222 fallouts (Michel et al., 2001). The first traces of ¹³⁷Cs occur at 37 cm depth, indicating the first widely detectable
223 fallout from atmospheric nuclear testing in 1953/1954 (Pennington et al., 1973).

224 The ^{210}Pb activity in core Burg17-B shows a relatively monotonic decrease down to a sediment depth of 17 cm.
225 Further down, larger variations are found (Fig. 2a). The ^{210}Pb and ^{226}Ra activities do not reach equilibrium;
226 unsupported ^{210}Pb activity in the oldest sample (59 cm) is still above the limit of detection ($14.0 \pm 6.8 \text{ Bq} \cdot \text{kg}^{-1}$). The
227 observed cumulative inventory of unsupported ^{210}Pb is $2941 \text{ Bq} \cdot \text{m}^{-2}$. We corrected this value (missing inventory
228 correction; Tylmann et al., 2016) by applying an exponential equation using the lowermost values of cumulative
229 dry mass and unsupported ^{210}Pb activity between 8 and 60 cm depths. As a result, a correction value of 125.2
230 $\text{Bq} \cdot \text{m}^{-2}$ (missing inventory) is added to the final total unsupported ^{210}Pb inventory ($3066 \text{ Bq} \cdot \text{m}^{-2}$).

231 The CRS-2 model (constrained through 1963) shows a better agreement with the independent ^{137}Cs markers at
232 1953/54 and 1986/87 than the CRS-1 model (Fig. 2c). Therefore, CRS-2 model results were chosen for determining
233 the age-depth profile and sediment mass accumulation rates (MAR) of core Burg17-B. The mean age at 59 cm
234 sediment depth dates back to ~ 1930 . The extrapolated mean age at 61 cm depth is ~ 1926 calculated using the mean
235 sediment accumulation rate between 54-60 cm ($2 \text{ yr} \cdot \text{cm}^{-1}$).

236 **4.2 Sediment lithology, green-pigments (RABD₅₉₀₋₇₆₅ index) and XRF-element records**

237 Four sediment facies (I to IV, Fig. 3 and 4a) are identified based on visual classification and the CONISS-analysis
238 results of XRF-element intensities.

239
240 In Zone I (75.4-61cm, pre ~ 1926), the sediments consist of visible thin brown-to-reddish laminae (Mn- and Fe
241 rich). Green-pigment concentrations inferred from RABD₅₉₀₋₇₆₅ index values show a homogenous distribution with
242 the lowest values within the sediment profile (Fig. 4d). Fe/Mn ratios vary within very low values (mostly below
243 10). The Mn, Fe, P and Fe/Ti values show high levels with large variability. Extremely low Ca amounts are noted
244 in this zone.

245
246 In Zone II (61-34cm, ~ 1926 -1960), the sediments are dark gyttja, partly laminated with light Ca-rich layers. Green-
247 pigment concentrations slightly increase yet still show little variability. A sharp increase of green-pigments
248 concentrations occurs at 60 cm, and the first two local peaks near 55 cm (~ 1938) and 48 cm (1945) are notable.
249 Fe/Mn ratios remain at slightly higher values than in Zone I. The Mn, Fe, P contents and Fe/Ti values all decline
250 to low levels and remain relatively stable. Ca counts increase gradually over the whole Zone II.

251
252 In Zone III (34-21.5 cm, ~ 1960 -1977), the sediments are mostly characterized by brown-to-reddish laminations
253 (Mn-Fe rich), with thicker and more distinct laminae contacts than in Zone I. Green-pigment concentrations exhibit
254 much higher values with positive trends, intensified variability, and several maxima (seasonal algal blooms).
255 Fe/Mn ratios first drop in the lower part (34-27 cm) and then continue to increase upward to the top-part of Zone
256 III. Fe, Mn, P, and Fe/Ti values show generally opposing trends to Fe/Mn ratios. Ca contents are elevated during
257 this period relative to Zones I and II.

258
259 In Zone IV (21.5-0 cm, ~ 1977 -2017), the sediments exhibit a clear laminated structure with much more
260 pronounced light calcite layers. The laminations are characterized by a regular succession of light calcite layers
261 (Ca-rich) and dark organic-rich layers (Fig. S4). Green-pigment concentrations display the highest levels with
262 large fluctuations, and reach distinct local maxima at 18 cm (1981), 15 cm (1985), 13 cm (1987), 12 cm (1988),

263 and 8 cm (1997) depths (Fig. 4d). Fe/Mn ratios are at similarly high values as in Zone II, yet with more variability.
264 The Fe, Mn, and P element counts and Fe/Ti all show constantly very low values. The Ca amounts are the highest
265 in the profile and show considerable variability.

266

267 Two principle components, PC1 and PC2 were shown to be significant using a broken stick model. They explain
268 ~35 % and ~30 % of the total variance in the dataset, respectively (PCA-biplot; Fig. S5). The PC1 has strong
269 positive loadings for the terrigenous elements (K, Ti, Rb etc.; Fig. 3 and S6) and thus represents mainly erosional
270 processes related to allochthonous inputs. The PC2 has strong positive loadings for redox-sensitive elements (Fe,
271 Mn), P and Fe/Ti, but negative loadings for Ca, Fe/Mn ratios and green-pigments index values. Therefore, PC2
272 reflects changes in redox conditions of hypolimnetic water and lake primary productivity. The results of additional
273 PCA analyses zone by zone (Fig. S7b) show that Mn, Fe and P were mostly independent of terrigenous elements
274 (in Zones I to III), however in Zone IV, Mn, Fe and P become correlated with the terrigenous elements. The vertical
275 profile of XRF-P matches very well with the changes of total P concentrations in sediments (Fig. S8). It reveals
276 that XRF-P data can reliably represent qualitative variations of total P concentrations in sediment profiles of Lake
277 Burgäschi.

278

279 **4.3 Bulk elements and P fractions in sediment profiles**

280 Sediment TIC, TOC, TOC/TN ratio, S and P fractions also show distinctive features along the four stratigraphic
281 zones (Fig. 5). From the upper part of Zone I (65.2-61 cm; ~1926) to Zone IV, TIC shows a similar pattern to the
282 XRF-Ca contents (Fig. 3 and 5) suggesting that TIC is mostly present in the form of CaCO₃. Over the whole profile,
283 TOC/TN ratios are within the range of 9-11. TOC and TOC/TN ratios exhibit mostly similar patterns from Zone I
284 to Zone III. By contrast, total sulfur (S) contents display a different pattern, showing very low values in Zone I
285 and II (mean ~0.5%), and a substantial increase in Zone III and IV.

286

287 The concentrations of labile P fractions (i.e. NaCl-TP, NaBD-TP and NaOH-TP) and total P have a similar trend
288 over the whole profile (Fig. 5 and 6a). They all display rather large values within the upper part of Zone I and
289 generally decreased values in Zone II. In Zone III, the values increase to peaks at ~25 cm depth but sharply decrease
290 to the lowest values in the upper boundary of Zone III and throughout Zone IV. HCl-TP and Ref.-P_o fractions vary
291 differently compared with the other fractions. Low contents of HCl-TP fraction are observed in Zone I and II. HCl-
292 TP fraction has a rather similar pattern as labile P fractions in Zone III, but then it remains at high levels in Zone
293 IV. Ref.-P_o fraction contents show relatively stable values from Zone I to Zone II, followed by a gradual rise in
294 Zone III and in the upper part of Zone IV. The net burial rates (NBR) of P-fraction since 1934 (Fig. S9) show
295 similar trends to the P-fraction concentrations (Fig. 5) (because sedimentation rates MAR are rather constant in
296 core Burg17-C; Fig S9), except for the Ca-P and Ref.-P_o fractions with decreasing NBR throughout the Zone IV.

297

298 Regarding the P composition in sediment profiles (Fig. 6, absolute and relative amounts), from Zone I to Zone III
299 (65.2-21.5 cm) NaBD-TP fraction is the most important P-form representing ~50% of total P followed by NaOH-
300 TP fraction. However, in Zone IV (depth above ~ 21.5 cm), HCl-TP becomes the main P fraction (~39% of total
301 P) over NaBD-TP (~30% of total P).

302

303 The relationships between response variables and explanatory variables are visible on the redundancy analysis
304 (RDA) biplot (Fig. 7), which, in most cases, correspond well to the results of Spearman rank correlation test (Fig.
305 S10). The relatively labile P fractions (NaCl-TP, NaBD-TP and NaOH-TP) and total P in sediments are strongly
306 positively correlated with redox-sensitive elements (Fe and Mn) and autochthonous Fe (Fe/Ti). However, these P
307 fractions are negatively related to hypolimnetic oxygenation proxy (Fe/Mn ratios) and, to some extent, to lake
308 productivity indicators (green-pigments, XRF-Ca and TIC). HCl-TP and Ref.-P_o fractions are positively correlated.
309 However, only HCl-TP fraction has close positive relationships with lake productivity indicators.

310 **5 Discussion**

311 **5.1 Trophic state evolution of Lake Burgäschi**

312 Four main phases of different lake trophic levels (based on RABD₅₉₀₋₇₆₅ index values) were distinguished since the
313 early 1900s, as summarized in Fig. 8 and Fig. S11. During the period prior to ~1926 in Zone I, the lowest green-
314 pigments index values reflect low lake primary productivity. In the early 1900s, agricultural impacts around the
315 catchment area of Lake Burgäschi were not prominent (Guthruf et al., 1999). It can be expected that the lake
316 received low nutrient loads from the catchment drainage during this period. Lake Burgäschi is classified as
317 naturally oligotrophic based on morphometric parameters (LAWA, 1998) and as naturally mesotrophic according
318 to Binderheim-Bankay (1998). Therefore, at the times of Zone I, Lake Burgäschi was likely oligo- to mesotrophic.
319

320 The transition to Zone II (~1926-1960) was marked by generally increased sedimentary green-pigment
321 concentrations and CaCO₃ contents (Fig. 3, 4d and 5), respectively, indicating enhanced lake primary productivity.
322 The slightly decreased TOC/TN ratio also suggests a rise in autochthonous organic matter proportion (Meyers and
323 Ishiwatari, 1993). The first two algal blooms (peaks of green-pigments index; Fig. 4d) imply a very likely
324 mesotrophic to eutrophic state of the lake. Indeed, the study of Büren (1949) revealed that in 1943-1945, the trophic
325 state of Lake Burgäschi had already shifted between mesotrophic and eutrophic. Interestingly, the water-table
326 lowering during 1943-1945 (Guthruff et al., 1999) with related enhanced drainage of intensive agricultural fields
327 and meadows (Büren, 1949) did not seem to have had an immediate impact on lake primary productivity (Fig. 3).
328

329 In Zone III (~1960-1977), continuously increasing green-pigment concentrations indicating several algal bloom
330 events and intensified CaCO₃ precipitation (TIC) and sulfur (S) contents in sediments (Fig. 4a and 5) are in
331 agreement with the findings from other eutrophic lakes (Holmer and Storkholm, 2001; Bonk et al., 2016; Schneider
332 et al., 2018).

333

334 During Zone IV (1977-2017), we interpret that Lake Burgäschi was in highly eutrophic conditions, based on
335 constantly high green-pigments index values and multiple prominent algal blooms (Fig. 3). Low and decreasing
336 TOC/TN ratio values (< 10) in this zone suggest a dominant source of organic matter in sediments from aquatic
337 primary production, which has been interpreted as a signal of eutrophic waters (Enters et al., 2006). Our
338 interpretation is further supported by high chlorophyll-*a* concentrations in surface waters (>8 ug L⁻¹; GSA, 2007)

339 and the dominance of blue-green algae in the phytoplankton biomass during 1977 to 1992, which characterized
340 Lake Burgäschi as highly eutrophic (GBL, 1995; Guthruf et al., 2013).

341 **5.2 Reconstruction of hypolimnetic oxygenation regimes of Lake Burgäschi**

342 A large number of studies have used the proxy of Fe/Mn ratios in sediments to reconstruct past water oxygenation
343 and mixing regimes of the lake, such as Mackereth (1966), Frugone-Álvarez et al. (2017), and Żarczyński et al.
344 (2019) etc. However, this proxy and its interpretation are limited to cases in which the annual cycle of Fe and Mn
345 deposition in lakes is mostly driven by redox changes in the hypolimnion and related diagenetic processes in
346 surface sediments instead of driven by terrestrial inputs (Boyle, 2001; Naeher et al., 2013). In Lake Burgäschi, in
347 Zone I to III, Mn and Fe varied mostly independently of erosion indicators as shown in Fig. S7b. Furthermore,
348 Van Raden (2012) has revealed that the presence of Mn-rich laminae in sediments of Lake Burgäschi can indicate
349 frequent short-term wind-induced mixing events in the lake. Therefore, we suggest that the deposition of Fe and
350 Mn during these three zones was mainly controlled by in-lake processes. The proxy of XRF-inferred Fe/Mn ratios
351 together with Mn precipitation in sediments reliably tracks past changes of hypolimnetic oxygenation of Lake
352 Burgäschi.

353 In Zone I (pre ~1926), the sediments feature well-preserved Mn-Fe rich laminations and very low Fe/Mn ratios
354 (Fig. 3 and 4a), suggesting that the lake hypolimnion was seasonally well-oxygenated. The similar occurrence of
355 visible Mn- and Fe rich laminae in sediments were also reported by Rey et al. (2017) in Lake Burgäschi and from
356 other lakes, for example, Lake of the Clouds in the US (Anthony, 1977), Lake Cadagno in the Swiss Alps (Wirth
357 et al., 2013), and Lake Żabińskie in Poland (Żarczyński et al., 2018). They revealed that the red-orange Mn-rich
358 layers mostly consist of authigenic rhodochrosite (MnCO_3) that was formed when Mn-rich anoxic bottom waters
359 are mixed with oxygenated surface waters for short intervals. The preservation of this Mn-rich layer is only
360 possible when its sedimentation process exceeds the release process under anoxic hypolimnetic conditions
361 (Stevens et al., 2000). Therefore, during this period, short-term mixing events and associated oxygenation may
362 have occurred during overall stratified or anoxic conditions in the hypolimnion.

363
364 In Zone II (~1926-1960), the higher Fe/Mn ratios and very low Mn- and autochthonous Fe (Fe/Ti) amounts are
365 interpreted as the results of stable anoxic hypolimnetic waters. The formation and preservation of Fe- and Mn-
366 oxides in sediments is largely prevented under long-term stratification/reducing conditions (Stevens et al., 2000).
367 The lake most likely developed anoxic hypolimnetic conditions with yearly incomplete or missing circulation in
368 the hypolimnion.

369
370 In Zone III (1960-1977), overall decreased Fe/Mn ratios combined with reappearing Mn- and Fe-rich laminations
371 reflect better short-term oxic conditions in hypolimnetic waters than in Zone II. However, during ~1970 to 1977,
372 Fe/Mn ratios gradually increased (Fig. 3), which points to less oxic conditions in the hypolimnion. It seems to be
373 related to synchronously progressive lake eutrophication (see Sect. 5.1). Higher primary productivity and
374 strengthened anoxia in the hypolimnion are commonly observed in stratified lakes (Giguet-Covex et al., 2010;
375 Mikomägi et al., 2016). Higher lake primary productivity increases high-rate aerobic degradation of organic matter
376 and, consequently, oxygen-depletion in the hypolimnion and sediments (Gächter and Müller, 2003; Nürnberg,
377 2007).

378

379 Finally, in Zone IV (1977- 2017) Fe/Mn ratios proxy is no longer valid to indicate hypolimnetic oxygenation
380 regime, as suggested by predominantly terrestrial sources of sediment Fe and Mn (Fig. S7b). Nevertheless, the
381 well-preserved laminated sediments during this period are a clear sign of absent benthic bioturbation and thus
382 represent an indicator of generally strong anoxic conditions in hypolimnetic waters, occurring simultaneously with
383 a highly eutrophic period. According to the limnological monitoring data of Lake Burgäschi between 1978 and
384 2007 (GSA, 2007), the lake water was anoxic at depths below 20 m during the summer-autumn stratification; even
385 during winter overturn of most years, the lake water was not completely mixed.

386

387 **5.3 Phosphorus composition and factors controlling long-term P-fraction retention in sediments**

388 Prior to 1977 (i.e. Zones I-III), NaBD-TP (redox-sensitive Fe- and Mn bound P) and NaOH-TP (partly non-
389 reducible Fe oxides-P) fractions were the primary P forms in sediments of Lake Burgäschi (Fig. 6 and 8). This
390 seems to compare well with the study of Moosmann et al. (2006), who suggested that sediment Fe contents control
391 P retention in sediments of the Swiss Plateau lakes. However, after ~1977, we observed a change to predominantly
392 Ca-P (apatite-P), occurring concurrently with the operation of hypolimnetic withdrawal restoration. This clear
393 pattern in sedimentary P-fraction change can be largely attributed to this restoration measure. The hypolimnetic
394 withdrawal treatment in Lake Burgäschi removes not only hypolimnetic P but also dissolved metal (Al, Fe and
395 Mn) ions and, thus leads to calcite as the main sorbent for P in upper waters and to an enhanced proportion of Ca-
396 P fraction in sediments.

397

398 In spite of the effects of lake restoration on sedimentary P retention in Zone IV, overall, the retention of total P
399 and labile P fractions in the sediment profile was mainly controlled by autochthonous Fe (Fe/Ti), Mn, and
400 hypolimnetic oxygenation proxy-Fe/Mn ratios, as shown by the results of RDA analysis (Fig. 7). Our results
401 support the previous suggestion that long-term permanent sediment-P retention is largely limited by the sediment's
402 binding capacity in anoxic conditions (Moosmann et al., 2006; Hupfer and Lewandowski, 2008), which,
403 specifically in our case, is determined by redox-sensitive elements (autochthonous Fe and Mn) preserved in
404 sediments. These findings are discussed in the context of each cluster zone as follows: During Zone I and Zone
405 III, when the hypolimnion had better seasonally oxic conditions (see Fig. 8 and Fig. S11), the increased retention
406 of Mn and Fe, and labile P fractions occurred simultaneously (Fig. 3 and 5). This phenomenon might be caused
407 by efficient P-trapping in Mn- and Fe enriched layers. It has been suggested that the formation of laminated Mn-
408 and Fe enriched layers could serve as a protective cap to reduce P release from surface sediment layers to the
409 anoxic hypolimnion (Żarczyński et al., 2018) which, thus, can help improve P retention within these sedimentary
410 layers. In Zone II, small amounts of labile P fractions might result from decreased P-bearing solid phases (Mn and
411 Fe minerals) in sediments under anoxic conditions in the hypolimnion (see higher Fe/Mn ratios in Sect. 5.2; Fig.
412 S11). However, in Zone IV, we observed the lowest retention and NBR of total P and labile P fractions in recent
413 sediments (Fig. 5; Fig. S9). We interpret this as a combined result of eutrophication-induced hypolimnetic anoxia
414 and hypolimnetic withdrawal since 1977 whereby P-rich hypolimnetic water is discharged out of the lake. On the
415 one hand, under stable anoxic conditions in the hypolimnion caused by strong eutrophication, reduced Mn and Fe
416 preservation (Fig. 3) suggests a low capacity of permanent P-trapping within the anoxic sediments. On the other

417 hand, hypolimnetic withdrawal restoration in Lake Burgäschi has substantially reduced hypolimnetic P
418 concentrations by a factor of 5-6 since 1978 (Fig. S11; GSA, 2007) and MARs (Fig. 2c and Fig. S9). This indicates
419 a concomitant decrease in sediment-P release to the hypolimnion and P sedimentation to the water-sediment
420 interface (gross sedimentation of P) as well. Consequently, decreased total P concentrations and total P-NBR in
421 sediments were observed (Fig. 6a and S9). The reduction of total P contents in upper sediments caused by
422 hypolimnetic withdrawal was also reported from Lake Kortowskie of Poland (Dunalska et al., 2007). Moreover,
423 our findings confirm that this restoration is an effective method to reduce sediment-P release potentials, as
424 indicated by considerably decreased NBR of labile P fractions in upper sediments (Fig. S9).

425

426 In the whole sediment profile, HCl-P and Ref.-P_o fractions had mainly autochthonous origins and were mainly
427 controlled by in-lake processes rather than by clastic inputs (e.g. apart from molasses sandstone), as indicated by
428 absent positive correlations between the two fractions and detrital elements such as Ti, K and Al (Fig. 7). HCl-P
429 (i.e. Ca-P) fraction retention, to a large extent, resulted from authigenic CaCO₃-P precipitation, and increased with
430 higher eutrophic levels in Zone III and IV (Fig. 5; Sect. 5.1). We interpret this as an incidence of biologically
431 driven co-precipitation of Ca and P in highly productive lakes. The phenomenon of Ca-P co-precipitation has been
432 observed and studied in many calcareous lakes (Dittrich and Koschel 2002; Whitehouse, 2010), and is assumed to
433 be responsible for the scavenging of dissolved P from surface waters of eutrophic lakes (Hamilton et al., 2009). In
434 addition, large amounts of Ca-P in surface sediments (top 21 cm) can act as a potential negative feedback to
435 eutrophication in Lake Burgäschi, because Ca-P fraction is relatively stable in sediments and has low potentials of
436 P-release from surface sediments back to lake waters. Interestingly, HCl-P fraction retention and NBR in sediments
437 of Zone IV were generally lower than in Zone III (Fig. 5 and Fig. S9), although the lake in Zone IV had relatively
438 higher eutrophic levels (see Sect. 5.1; Fig. S11). The pH in the hypolimnion of Lake Burgäschi varied between 7.0
439 and 7.5 according to the monitoring data in 1993, 2003, and 2013 (Guthruf et al., 2013). Therefore, the acid
440 dissolution of Ca-P in the hypolimnion and at the water-sediment interface is small and unlikely significant during
441 Zone IV. The generally decreased retention and NBR of Ca-P fraction were seemingly related to hypolimnetic
442 withdrawal, which has caused lower water-P concentrations and MAR of sediments as discussed above. As a result,
443 there are reductions of CaCO₃-P co-precipitation in the epilimnion and consequently of Ca-P net sedimentation in
444 surface sediments. Overall, Ref.-P_o fraction retention and NBR in the sedimentary profile show less variability
445 compared with other P fractions (Fig. 5 and Fig. S9). Nevertheless, the lower NBR of Ref.-P_o fraction in the upper
446 sediments (~ top 10 cm) could be derived from the ongoing early degradation of fresh organic matters.

447

448 The interesting observation is that the water-P reductions caused by the hypolimnetic withdrawal in Lake
449 Burgäschi (GSA, 2007; Nürnberg, 2007) have been ineffective in reducing algal blooms and curbing
450 eutrophication. Similar findings were also reported from some lakes in Europe and the US (Kosten et al., 2012;
451 Kolzau et al., 2014; Fastner et al., 2016). These authors have attributed this phenomenon to insufficient external
452 P-load reduction, higher water temperatures under global warming of the last few decades, and the light or nitrogen
453 limitation of surface-water phytoplankton. In Lake Burgäschi, phytoplankton growth in the trophic zone is more
454 likely limited by P during growth season after 1978 rather than by the nitrogen (GSA, 2007) as the algae-available
455 ortho-phosphate is almost completely used up in the epilimnion when the nitrate concentrations stay as high as
456 0.5-3 mg N / L in the upper 5-m waters (GBL, 1995). Hence, we suggest that these factors mentioned above,

457 except for nitrogen limitation of lake productivity, may also contribute to promoting persistently high primary
458 productivity in Lake Burgäschi. But the main driver keeping productivity high, is the continuing high external P
459 loads from the lake catchment. During summer stratification, the high lake external P load into the epilimnion
460 primarily supports phytoplankton growth in the photic zone, which is not strongly influenced by the hypolimnetic-
461 P discharge and internal P loadings. From a management perspective, it is still critically important to focus on
462 lowering external P loads in order to decrease primary production and eutrophication in seasonally-stratified small
463 deep lakes which are more likely to favor stable stratification during phytoplankton growth season.

464

465 **6 Conclusion**

466 This study shows that in Lake Burgäschi, more than half of sediment P is buried in relatively labile P fractions
467 (Fe/Mn/Al-P), yet with low potentials for P-release from these labile P fractions in deeper layers (below ~21 cm).
468 Our results highlight the importance of hypolimnetic oxygenation/mixing regime in controlling long-term P
469 retention and net burial rates of labile P fractions in sediments of this small deep lake. Irrespective of increasing
470 lake primary productivity during early 1900s to 1977, the two periods of high sedimentary retention of total P and
471 labile P-fraction occurred in Fe- and Mn enriched laminae, which appears to be linked to seasonal mixing of the
472 hypolimnion in the past. Importantly, the positive effects of hypolimnetic withdrawal in Lake Burgäschi were
473 observed primarily in sediment P-fraction data but not in lake trophic state. The 40-year operation of hypolimnetic
474 withdrawal has impoverished sedimentary P, in particular largely decreased net burial rates of labile P fractions
475 (potential internal P loads), and increased the relative proportion of stable Ca-P fraction in top sediment layers (0-
476 21 cm). Nevertheless, the lake is currently still highly eutrophic. We attribute the delay of lake recovery primarily
477 to still high nutrient inputs from the nearby or surrounding agricultural area into the lake trophic zone during
478 stratification seasons. This study calls for consistently more effective measures to minimize external P loadings
479 from the catchment, such as optimizing fertilizer application practices and technical measures in the drainages.

482

483 **Data availability**

484 The data is available at PANGAEA at <https://doi.org/10.1594/PANGAEA.908896>.

485

486

487 **Author contributions**

488 L.T. helped with sample collection, analyzed the sediment, conducted data analysis, wrote the manuscript, and
489 acquired most of the funding for the project.

490 P. Z. helped with sediment core subsampling, conducted the hyperspectral imaging (HSI) scanning, helped with
491 XRF-scanning, substantially contributed to the data interpretation.

492 S.S. measured gamma-spectroscopy radiometric activities, generated the data for chronology and helped with
493 data interpretation.

494 R.L. conducted the XRF-scanning and helped with data interpretation.

495 M.G. designed the study, helped discussing the results, editing the manuscript and supervised the project.

496 All authors commented on the manuscript.

497

498 **Competing interests**

499 The authors declare that they have no conflict of interest.

500

501 **Acknowledgements**

502 We thank Stamatina Makri and Dr. Andre F. Lotter for their help during the fieldwork. We thank Irene Brunner,
503 Patrick Neuhaus, Dr. Daniela Fischer and Andrea Sanchini for their expertise and the lab assistance. Further, we
504 acknowledge Dr. Klaus A. Jarosch for the valuable suggestions about phosphorus data. The thoughtful comments
505 and suggestion by the two anonymous reviewers greatly improved this paper. The project was funded by the Swiss
506 National Science Foundation under the grant number 200021-172586, a Fellowship Grant from the Chinese
507 Scholarship Counsel and the International PhD Fellowship from University of Bern.

808 Figure 8: Conceptual diagram, summarising the inputs/outputs of phosphorus (P), hypolimnetic withdrawal

809 restoration, lake trophic levels, mixing regime and phosphorus (P) fractions retention in sediments of Lake Burgäschi

810 during four stages/zones. Note that the illustrated sizes of P fractions (Fe/Mn/Al-P and Ca-P) among different stages

811 overall indicate the relative amounts of P fractions in sediments.
