10

11 **Abstract**

12 Sediments in oxygen-depleted marine environments can be an important sink or
13 source of bio-essential trace metals in the ocean. However, the key mechanisms
14 controlling the release from or burial of trace metals in sediments are not exactly
15 understood. Here, we investigate the benthic biogeochemical cycling of Fe and Cd in
16 the oxygen minimum zone off Peru. We combine bottom water and pore water
17 concentrations, as well as benthic fluxes determined from pore water profiles and in-
18 situ from benthic chamber incubations, along a depth transect at 12° S. In agreement
19 with previous studies, both concentration-depth profiles and in-situ benthic fluxes
20 indicate a release of Fe from sediments to the bottom water. Diffusive Fe fluxes and
21 Fe fluxes from benthic chamber incubations ($-0.3 - -17.5 \text{ mmol m}^{-2} \text{ y}^{-1}$) are broadly
22 consistent at most stations, indicating that diffusion is the main transport mechanism
23 of dissolved Fe across the sediment-water interface. The occurrence of mats of sulfur
24 oxidizing bacteria on the seafloor represents an important control on the spatial
25 distribution of Fe fluxes by regulating hydrogen sulfide (H_2S) concentrations and,
26 potentially, Fe sulfide precipitation within the surface sediment. Rapid removal of
27 dissolved Fe after its release to anoxic bottom waters hints to oxidative removal by
28 nitrite and interactions with particles in the near-bottom water column. Benthic flux
29 estimates of Cd suggest a flux into the sediment within the oxygen minimum zone.
30 Fluxes from benthic chamber incubations (up to $22.6 \text{ } \mu\text{mol m}^{-2} \text{ y}^{-1}$) exceed diffusive
31 fluxes ($< 1 \text{ } \mu\text{mol m}^{-2} \text{ y}^{-1}$) by a factor > 25 , indicating that downward diffusion of Cd
32 across the sediment-water interface is of subordinate importance for Cd removal from
33 benthic chambers. As Cd removal in benthic chambers co-varies with H_2S
34 concentrations in the pore water of surface sediments, we argue that Cd removal is
35 mediated by precipitation of CdS within the chamber water or directly at the sediment-
36 water interface. A mass balance approach, taking into account the contributions of
37 diffusive and chamber fluxes as well as Cd delivery with organic material, suggests
38 that CdS precipitation in the near-bottom water could make an important contribution
39 to the overall Cd mass accumulation in the sediment solid phase. According to our
40 results, the solubility of trace metal sulfide minerals ($\text{Cd} \ll \text{Fe}$) is a key-factor
41 controlling trace metal removal and consequently the magnitude as well as the
42 temporal and spatial heterogeneity of sedimentary fluxes. We argue that depending on
43 their sulfide solubility, sedimentary source or sink fluxes of trace metals will change
44 differentially as a result of declining oxygen concentrations and an associated

45 expansion of sulfidic surface sediments. Such a trend could cause a change in the
46 trace metal stoichiometry of upwelling water masses with potential consequences for
47 marine ecosystems in the surface ocean.

49

50 **1. Introduction**

51

52 **1.1 Scientific rationale**

53 The world's oceans are losing oxygen (e.g. Keeling et al. 2010; Stramma et al.
54 2010; Helm et al. 2011). In total around 2 % of oxygen has been lost over the past five
55 decades (Schmidtko et al., 2017) and an expansion of oxygen minimum zones (OMZs)
56 in the tropical oceans has been documented over the same timespan (Stramma et al.,
57 2008). The biogeochemical cycling of several nutrient-type trace metals (TMs) is likely
58 to be particularly susceptible to changing oxygen concentrations as they occur in
59 different oxidation states (e.g. Fe, Mn, Co) and/or are precipitated as sulfide mineral in
60 anoxic-sulfidic environments (e.g. Fe, Zn, Cd; listed in the order of decreasing sulfide
61 solubility). However, with the exception of Fe (Dale et al., 2015a; Lohan and Bruland,
62 2008; Rapp et al., 2018; Schlosser et al., 2018; Scholz et al., 2014a), little information
63 is available on how other TM fluxes will respond to ocean deoxygenation. As certain
64 TMs are essential for the growth of marine organisms (e.g. Fe, Mn, Co, Ni, Zn, Cd),
65 TM availability can (co-)limit primary productivity and therefore affect oceanic carbon
66 sequestration through the biological pump (Saito et al., 2008; Moore et al., 2013; Morel
67 et al., 2014). As a consequence, a better understanding of how TMs respond to low
68 oxygen conditions is essential for predicting how marine ecosystems and the carbon
69 cycle will evolve in the future ocean, with modelling scenarios predicting a continuation
70 of ocean deoxygenation (Bopp et al., 2002; Oschlies et al., 2008; Keeling et al., 2010)

71 Marine sediments are an important source or sink of TMs to the ocean under
72 low oxygen conditions (Böning et al., 2004; Brumsack, 2006; Scor Working Group,
73 2007; Severmann et al., 2010; Noble et al., 2012; Biller and Bruland, 2013; Conway
74 and John, 2015b; Klar et al., 2018). In the OMZ off the coast of Peru, substantial fluxes
75 of reduced Fe and other TMs across the sediment-bottom water interface have been

76 documented (Noffke et al., 2012; Scholz et al., 2016) or inferred (Hawco et al., 2016).
77 While a number of studies have addressed biogeochemical processes that lead to
78 benthic Fe release, the key biogeochemical processes and conditions that control the
79 sedimentary release or burial of other TMs in open marine systems are still poorly
80 constrained. Moreover, a detailed picture of removal or stabilization processes and
81 rates that take place in the highly dynamic water layer overlying the seafloor is lacking.

82 In this article, we compare the benthic biogeochemical cycling of Fe and Cd. It
83 has been established that the Peruvian OMZ represents a source of dissolved Fe to
84 the ocean (Noffke et al., 2012; Fitzsimmons et al., 2016; John et al., 2018). In contrast,
85 earlier studies have demonstrated that OMZs represent a sink for Cd (Janssen et al.,
86 2014; Böning et al., 2004). Because of their contrasting tendency to form sulfide
87 minerals and different supply pathways to the sediment, Fe and Cd can serve as
88 prototypes to provide information about how sedimentary fluxes of different TMs may
89 respond to declining oxygen concentrations. Under more reducing conditions the
90 mobility of TMs can either be enhanced or diminished, e.g., through precipitation of
91 sulfide minerals that are buried in the sediments (e.g. Westerlund et al., 1986; Rigaud
92 et al., 2013; Olson et al., 2017). Increased burial or release of TMs at the seafloor can
93 have an impact on the amplitude of primary productivity, especially at the eastern
94 ocean boundaries where the near-bottom water column is connected to the surface
95 ocean via upwelling. Moreover, since the inventories of TMs in the ocean are generally
96 dependent on the respective input and output fluxes, changes in the balance between
97 trace metal recycling and burial can have an impact on oceanic TM reservoirs on longer
98 timescales. By comparing the benthic biogeochemical cycling of Fe and Cd across
99 spatial and temporal redox gradients, we aim to provide general constraints on how
100 the stoichiometry of bio-essential TMs in seawater may be affected by ocean
101 deoxygenation.

102

103 **1.2. Marine biogeochemistry of iron**

104 Iron is the most abundant TM in phytoplankton and part of a range of
105 metalloenzymes that are involved in important biological functions, such as
106 photosynthesis or nitrogen fixation (Twining and Baines, 2013). Despite Fe being
107 highly abundant in the continental crust, its low availability limits primary productivity in
108 up to 30 % of the surface ocean area (Moore et al., 2013). This limitation arises from

109 the low solubility of its thermodynamically stable form in oxic waters, Fe(III).
110 Concentrations can reach up to ~ 1 nM when Fe(III) is kept in solution through
111 complexation with organic ligands (Rue and Bruland, 1997; Liu and Millero, 2002; Boyd
112 and Ellwood, 2010; Raiswell and Canfield, 2012). The thermodynamically stable form
113 of Fe under anoxic conditions, Fe(II), is more soluble and therefore anoxic waters are
114 typically characterized by higher dissolved Fe concentrations (up to tens of nM)
115 (Conway and John, 2014; Vedamati et al., 2014; Fitzsimmons et al., 2016; Schlosser
116 et al., 2018).

117 Sediments within OMZs are considered an important source of dissolved Fe and
118 some of the highest sedimentary Fe fluxes have been observed in these regions
119 (Severmann et al., 2010; Noffke et al., 2012). Under anoxic conditions, Fe(II) can be
120 liberated from the sediments into pore waters from Fe-(oxyhydr)oxides through
121 reductive dissolution by microbes or abiotic reduction with H₂S (Canfield, 1989). In the
122 absence of oxygen, dissolved Fe(II) escapes the rapid re-oxidation and subsequent
123 (oxyhydr)oxide precipitation and can, therefore, diffuse from pore waters into bottom
124 waters. However, in anoxic OMZs, where denitrification takes place, Fe(II) can also be
125 re-oxidized with nitrate as a terminal electron acceptor, either mediated by nitrate-
126 reducing microbes or abiotically through reaction with nitrite (Straub et al., 1996;
127 Carlson et al., 2013; Scholz et al., 2016; Heller et al., 2017). The solubility of Fe in
128 sulfidic (i.e. NO₃⁻ and NO₂⁻ depleted) water is relatively high (Rickard et al., 2006) and
129 during sulfidic events dissolved Fe can accumulate in the water column (up to
130 hundreds of nM) because of decreased Fe oxidation (Scholz et al., 2016) and
131 stabilization as aqueous Fe sulfide complexes and clusters (Schlosser et al., 2018).
132 However, Fe fluxes across the benthic boundary have also been hypothesized to
133 decrease under strongly sulfidic conditions in the surface sediments, when pore waters
134 become oversaturated with respect to Fe monosulfide (Scholz et al., 2014), which is
135 the precursor for pyrite (FeS₂) (Raiswell and Canfield, 2012).

136

137 **1.3. Marine biogeochemistry of cadmium**

138 Cd is abundant in phytoplankton despite concentrations that are one order of
139 magnitude lower than Fe (Moore et al., 2013; Twining and Baines, 2013). A function
140 for Cd as a catalytic metal atom in the carbonic anhydrase protein has been found in
141 diatoms (Lane and Morel, 2000) and it can also substitute Zn and enhance

142 phytoplankton growth under Zn limitation in different phytoplankton species (Price and
143 Morel, 1990; Lee and Morel, 1995; Sunda and Huntsman, 2000; Xu et al., 2008). In
144 marine sediments Cd can be released from the solid phase to the pore waters through
145 the remineralization of organic matter (Klinkhammer et al., 1982; Collier and Edmond,
146 1984; Gendron et al., 1986; Gerringa, 1990; Audry et al., 2006; Scholz and Neumann,
147 2007). After its release to the pore water, Cd can diffuse across the sediment-water
148 interface. Under anoxic and sulfidic conditions, Cd is thought to be precipitated as CdS
149 (Greenockite) and retained in the sediment (Westerlund et al., 1986; Gobeil et al.,
150 1987; Rosenthal et al., 1995; Audry et al., 2006). Due to its low sulfide solubility, CdS
151 can precipitate at much lower H₂S concentrations than FeS (mackinawite) (Morse and
152 Luther, 1999).

153 Most previous studies have focused on the benthic cycling of Cd in near- and
154 in-shore environments such as estuaries and lagoons (e.g. Westerlund et al., 1986;
155 Colbert et al., 2001; Audry et al., 2006b; Metzger et al., 2007; Point et al., 2007; Scholz
156 and Neumann, 2007). By contrast, little is known about Cd cycling in open-marine
157 sedimentary environments, where the redox- and sediment-dynamics are different.
158 Previous studies on sedimentary Cd cycling generally concluded that the flux of organic
159 material and the presence of H₂S are the most important factors controlling the balance
160 between Cd recycling versus precipitation and burial (e.g. Westerlund et al., 1986;
161 Colbert et al., 2001; Audry et al., 2006; Metzger et al., 2007; Scholz and Neumann,
162 2007). Low oxygen regions in the ocean are considered an important sink for Cd
163 (Janssen et al., 2014; Conway and John, 2015a; Xie et al., 2019) and sediments below
164 OMZs are highly enriched in Cd (Ragueneau et al., 2000; Böning et al., 2004; Borchers
165 et al., 2005; Muñoz et al., 2012; Little et al., 2015). However, the respective
166 contributions of different Cd removal mechanisms to Cd accumulation in the sediment
167 have not been quantified.

168

169 **1.4. Study area**

170 Seasonal upwelling of nutrient-rich waters off the Peruvian coast in austral
171 winter leads to high rates of primary productivity in the photic zone (~ 300 mmol C m⁻³
172 d⁻¹) (Pennington et al., 2006). The combination of oxygen consumption through the
173 respiration of this organic matter and low oxygen concentrations in water masses that
174 supply upwelling regions, leads to the formation of one of the world's most intense

175 OMZs, with complete oxygen consumption in the OMZ core between ~ 100 m – 300 m
176 water depth (Karstensen et al., 2008; Thamdrup et al., 2012). Upon oxygen depletion,
177 NO_3^- can serve as an electron acceptor for respiration. Therefore, denitrification,
178 dissimilatory reduction of NO_3^- to ammonium (DNRA) and anaerobic ammonium
179 oxidation (anammox) with NO_2^- are important biogeochemical processes within the
180 anoxic and nitrogenous water column (Lam et al., 2009; Lam and Kuypers, 2011;
181 Dalsgaard et al., 2012). The OMZ overlying the Peruvian shelf is a temporally and
182 spatially dynamic system where biogeochemical conditions can range from fully oxic
183 to anoxic and sulfidic. Occasional shelf oxygenation events occur mostly during El Niño
184 events and are linked to the propagation of coastal trapped waves (Gutiérrez et al.,
185 2008). During such events, oxygenated water can be found on the upper slope to 200
186 m – 300 m water depth (Levin et al., 2002). By contrast, sulfidic events can occur
187 during periods of stagnation, when oxygen, NO_3^- and NO_2^- become depleted in the
188 water column due to sluggish ventilation. Once NO_3^- and NO_2^- are depleted,
189 chemolithoautotrophic H_2S oxidation is impeded. Hydrogen sulfide produced by
190 bacterial sulfate reduction in sediments can then be released to the water column
191 (Schunck et al., 2013) at rates reaching several $\text{mmol m}^{-2} \text{d}^{-1}$ (Sommer et al., 2016).

192 Our sampling campaign (cruises M136 and M137) took place in April and May
193 2017, during the decline of a coastal El Niño event. A coastal El Niño is a local
194 phenomenon that refers to reduced upwelling and increased sea surface temperatures
195 off the coasts of Peru and Ecuador, with typically heavy rainfall on land. During this
196 event in austral summer, coastal waters off Peru showed a strong positive sea surface
197 temperature anomaly of up to 2 to 4 °C (Echevin et al., 2018; Garreaud, 2018). The
198 warming is proposed to be a result of strong local alongshore wind anomalies and
199 equatorial Kelvin waves propagating towards the Peruvian coast (Echevin et al., 2018;
200 Peng et al., 2019).

201

202

203 **2. Methods**

204

205 **2.1 Sampling and sample handling**

206 In this study, data from three different types of samples were combined: (1) pore
207 waters for the determination of benthic diffusive fluxes and to study TM cycling in
208 sediments; (2) Benthic chamber incubations, to determine in-situ fluxes across the
209 sediment-water interface; (3) Bottom water concentration-depth profiles to determine
210 the fate of TMs in the particle-rich and dynamic near-bottom water column.

211 The sampling took place during RV Meteor cruises M136 and M137 in austral
212 autumn between April and May 2017. We also compared our data to benthic diffusive
213 Fe(II) fluxes from RV Meteor cruise M92 that took place in austral summer during
214 January 2013. Our sampling stations covered the entire Peruvian shelf and slope
215 across a transect at 12°S (Fig. 1) with water depths from 75 – to 950 m, thus including
216 stations above, inside and below the permanent OMZ. Our sampling of pore waters
217 and sample collection from benthic chamber incubations generally followed the
218 methodology described in Noffke et al. (2012).

219 Short sediment cores of 30 – 40 cm length were retrieved with a multiple corer
220 (MUC). Upon recovery, the cores were directly transferred into the ship's cool room
221 (4°C). The supernatant bottom water was instantly sampled and filtered through 0.2
222 µm cellulose acetate filters (Sartorius) and acidified to pH < 1 with subboiled distilled
223 HNO₃. The sediment cores were subsequently sampled in vertical sections in a glove
224 bag under Ar atmosphere to prevent any contact with oxygen. The sediment samples
225 were centrifuged to separate the pore waters from the sediment solid phase. Pore
226 waters were then filtered in another Ar-filled glove bag through 0.2 µm cellulose acetate
227 filters (Sartorius). An 8 ml aliquot was acidified to pH < 1 with subboiled distilled HNO₃
228 and stored in acid cleaned low-density polyethylene (LDPE) bottles for TM analysis.
229 Another aliquot was taken for analysis of H₂S concentrations. Additional sediment
230 subsamples were collected in pre-weighed cups for water content and porosity
231 determination as well as for Cd and organic C concentrations measurements in the
232 solid phase.

233 Benthic landers, constructed from titanium frames, containing two circular
234 benthic chambers for in-situ incubations, were deployed on the seafloor (see Sommer
235 et al. (2009) for details). After placement of the lander on the seafloor, the benthic
236 chambers (internal diameter of 28.8 cm) were partially driven into the sediment,
237 covering a sediment area of 651.4 cm². A volume between 12 – 18 l, overlying the first
238 20 – 30 cm of the seafloor, was enclosed in the chamber, depending on the insertion

239 depth of the chamber into the sediment. Prior to the incubation, the seawater contained
240 in the chamber was repeatedly replaced with ambient seawater to replace solutes and
241 flush out particles that might have been mobilized during the insertion of the chamber
242 into the sediment. Over the incubation time of around 32 hours, 8 consecutive samples
243 of 12 ml were filtered in-situ through 0.2 μm cellulose acetate filters (Sartorius) via
244 peristaltic pumps and collected in quartz glass tubes. All sampling tubes were acid
245 cleaned prior to use to guarantee a TM clean sampling. After recovery of the lander,
246 the quartz glass tubes were transferred to the laboratory and samples were stored in
247 acid cleaned LDPE bottles and acidified to $\text{pH} < 2$ with subboiled distilled HNO_3 . Other
248 samples were collected simultaneously for analysis of nitrogen species. The incubated
249 sediments within the benthic chamber were sampled after recovery of the lander and
250 pore waters were extracted to analyze H_2S concentrations for comparison with pore
251 water profiles from parallel MUCs.

252 To determine TM concentrations across the near-bottom water column, water
253 samples were collected at 0.5, 1.0, 2.0, 3.0 and 4.0 m above the seafloor using
254 sampling apparatus attached to the landers. Filter holders with 0.2 μm polyether
255 sulfone filters (Supor) were attached at the various depths and connected to sampling
256 tubes that went through peristaltic pumps into gas sampling bags (Tedlar). Sampling
257 at 3.0 m and 4.0 m above the seafloor was realized by attaching the filter holders and
258 tubing to an arm that was automatically unfolded upon placement of the lander at the
259 seafloor. The peristaltic pumps transferred the seawater from the sampling depths into
260 the sampling bags over the same time period as the lander incubations of around 32
261 hours. This resulted in an average sample volume of 1.5 l per depth. All filters, tubing
262 and sampling bags were acid cleaned prior to deployment to guarantee a TM clean
263 sampling. Directly after sample retrieval, a 60 ml aliquot was stored in acid cleaned
264 LDPE bottles and acidified to $\text{pH} < 2$ for TM analysis. Another aliquot was taken for
265 analysis of silicic acid ($\text{Si}(\text{OH})_4$).

266

267 **2.2 Analytical methods**

268 Concentrations of $\text{Fe}(\text{II})$ in pore waters were measured on board directly after
269 sample retrieval by photometry using the ferrozine method (Stookey, 1970). Other
270 geochemical parameters in our different samples were also determined photometrical
271 (U-2001 Hitachi spectrometer) using standard techniques (Grasshoff et al., 1999).

272 Hydrogen sulfide concentrations were determined using the methylene blue method
273 and Si(OH)_4 concentrations were determined using a heptamolybdate solution as
274 reagent. Concentrations of nitrogen species were determined by an auto-analyzer
275 (QuAatro, SEAL Analytical) using sulfanilamide as reagent (Hydes et al., 2010).

276 For TM analysis of bottom water samples we followed the procedure described
277 by Rapp et al. (2017), whereby the TMs were pre-concentrated by a fully automated
278 device (SeaFAST). After raising the sample pH to 6.4 with an ammonium acetate buffer
279 (1.5 M), 15 ml of sample was loaded onto a chelating resin column, where the seawater
280 matrix was rinsed off, before the TMs were collected into 1ml elution acid (1 M
281 subboiled HNO_3). Due to the smaller size of pore water samples and samples from
282 benthic lander incubations, a half-automated device (Preblab) with a smaller sample
283 loop and thus dead volume was used. On this device, sample loading and collection
284 as well as the addition of buffer was done manually. For samples from benthic lander
285 incubations and pore waters, an amount of 3 ml and 1 ml, respectively, was needed
286 for pre-concentration. The samples were diluted with de-ionised water (MilliQ,
287 Millipore) to increase the sample volume to 5 ml for samples from benthic chamber
288 incubations and to 3 ml for pore waters. The pre-concentrated samples were measured
289 by ICP-MS (HR-ICP-MS; Thermo Fisher Element XR) and TM concentrations were
290 quantified by isotope dilution. The detection limits were 28.8 pM for Fe and 0.8 pM for
291 Cd (Rapp et al., 2017). Accuracies for replicate measurements of reference seawater
292 certified for TMs are listed in Table 1.

293 For the calculation of sedimentary Cd enrichments (Cd_{xs}), Cd and Al contents
294 in sediments were determined following total digestions of freeze dried and ground
295 sediment samples. The sediment was digested in 40 % HF (suprapure), 65 % HNO_3
296 (suprapure) and 60 % HClO_4 (suprapure). Concentrations were measured by ICP-OES
297 (VARIAN 720-ES). The reference standard MESS was used to check the digestion
298 procedure. The accuracy was ± 0.3 % for Cd and ± 1.3 % for Al (MESS-3 Cd: $0.24 \pm$
299 $0.01 \mu\text{g g}^{-1}$, recommended value $0.24 \pm 0.01 \mu\text{g g}^{-1}$, MESS-3 Al: $8.59 \pm 0.11 \mu\text{g g}^{-1}$,
300 recommended value $8.59 \pm 0.23 \mu\text{g g}^{-1}$).

301 Organic carbon content in the sediment was determined using an Elemental
302 Analyzer (Euro EA) after removal of inorganic carbon with 0.25 mM HCl. Precision of
303 the measurement was ± 1 %.

304

305 **2.3 Diffusive flux calculations**

306 Benthic diffusive fluxes (F_D) were determined using Fick's first law of diffusion
307 using concentration gradients between the uppermost pore water sample (0 – 1 cm)
308 and the overlying bottom water (dC/dx) (Boudreau, 1997):

$$309 \quad F_D = -\Phi D_{sed}(dC/dx) \quad (1)$$

310 The effective molecular diffusion coefficients of Fe and Cd for sediments (D_{sed}) were
311 calculated from the molecular diffusion coefficient in seawater (D_{sw}) under standard
312 conditions (Li and Gregory, 1974) by adjusting it to in-situ temperature, pressure and
313 salinity applying the Stokes-Einstein Equation. We determined the diffusion
314 coefficients for sediments as follows:

$$315 \quad D_{sed} = D_{sw}/\theta^2 \quad (2)$$

316 Tortuosity (θ) was calculated from porosity (Φ) as follows (Boudreau, 1997):

$$317 \quad \theta^2 = 1 - \ln(\phi^2) \quad (3)$$

318 Positive values represent a flux from the bottom water into the sediment pore
319 water, negative values a flux from the sediment pore water into the bottom water. All
320 input values for the diffusive flux calculations are listed in Tables S1 and S2 in the
321 supplement.

322 Due to the coarse resolution of our pore water profiles and the steep gradients
323 between the uppermost pore water and bottom water sample (see close-up profiles,
324 Fig. S1 and S2 in the supplement), we chose to follow previous studies (e.g. Noffke et
325 al., 2012; Lenstra et al., 2019; Scholz et al., 2019) and calculate diffusive benthic fluxes
326 based on a two point concentration gradient. Including deeper samples into a linear
327 regression or applying more advanced curve fitting methods would reduce the
328 statistical uncertainty but fail to capture the sharp concentration gradients at the
329 sediment surface, thus, leading to erroneous flux estimates (cf. Shibamoto and
330 Harada, 2010).

331 The fluxes from benthic lander incubations were calculated by fitting a linear
332 regression to the concentration change over time. The relevant equations are listed
333 together with the coefficients of determination (R^2) in Table S4 in the supplement.
334 Concentration changes over time were converted to fluxes by taking into account the
335 water volume enclosed in the benthic chamber, estimated for each deployment from

336 the insertion depth of the benthic chamber into the sediment. The uncertainties of
337 fluxes were estimated by propagating the uncertainties of the linear regressions.
338 Following previous studies (e.g. Friedrich et al. (2002); Lenstra et al. (2019)), only
339 fluxes where the linear regression has an $R^2 > 0.3$ are reported in Tables 2 and 3.

340

341

342 **3. Results**

343

344 **3.1 Biogeochemical conditions in the water column**

345 Due to the particular atmospheric and oceanographic conditions, the decline of
346 a coastal El Niño during our sampling campaign (cruises M136 and M137), the water
347 column overlying the Peruvian shelf was oxygenated. Oxygen concentrations were $>$
348 $20 \mu\text{M}$ in the water column down to around 100 m water depth. However, bottom water
349 oxygen concentrations directly above the seafloor, measured using optodes attached
350 to lander, were below the detection limit ($> 1 \mu\text{M}$) at the shallowest station (Station 1).
351 The OMZ, with O_2 concentrations $< 5 \mu\text{M}$, extended from around 120 to 400 m water
352 depth. The water column within the OMZ was nitrogenous (i.e. NO_3^- reducing) as
353 indicated by the presence of NO_2^- ($\geq 4 \mu\text{M}$), an intermediate product of denitrification
354 (Zumft, 1997). Oxygen gradually increased to $> 50 \mu\text{M}$ below 400 m towards 950 m
355 water depth (Fig. 2). As we will compare some of our data to those of an earlier cruise
356 (M92), the corresponding oxygen distribution across the Peruvian continental margin
357 is shown for comparison (Fig. 2).

358

359 **3.2 Bottom water, pore water and benthic flux data**

360

361 **3.2.1 Iron**

362 Iron concentrations in near-bottom waters decreased from near-shore to off-
363 shore stations, from $> 100 \text{ nM}$ at the shallowest shelf station at 75 m water depth
364 (Station 1) to 6 nM at 750 m water depth (Station 9) (Fig. 3). At a number of stations
365 within the OMZ (Stations 3 and 4), vertical concentration gradients were observed.

366 Here Fe concentrations decreased by 15 – 20 nM from 0.5 to 4 m above the seafloor.
367 Multiple sampling at the shallowest shelf station (Station 1) revealed that Fe
368 concentrations were temporally variable and ranged from ~ 100 nM at the end of April
369 to < 60 nM at the end of May 2017.

370 Concentrations of Fe(II) in pore waters were highest (up to a few μM) in the
371 upper 5 – 10 cm of the sediment cores. Deeper in the sediment cores, concentrations
372 decreased to > 0.2 μM (Fig. 4). At all stations, sharp concentration gradients between
373 the uppermost pore water and bottom water sample were observed, with higher
374 concentrations in pore waters at the sediment surface (μM) than in the overlying bottom
375 water (nM). This observation implies a diffusive flux from pore waters into bottom
376 waters. The steepest concentration gradients across the sediment-water interface
377 were observed within the OMZ. The highest Fe(II) concentrations at the sediment
378 surface (> 6 μM) were observed at Station 4 (145 m water depth). At this station, the
379 benthic diffusive flux into the bottom waters was also highest at $-17.5 \text{ mmol m}^{-2} \text{ y}^{-1}$.
380 The lowest diffusive fluxes of 0.0 (due to concentrations below the detection limit) and
381 $-0.3 \text{ mmol m}^{-2} \text{ y}^{-1}$ were observed on the upper slope below the OMZ at Stations 9 and
382 10 respectively (Table 2). An accumulation of H_2S in pore waters coincided with a
383 depletion of Fe(II) concentrations (Fig. 4). At Station 1, we observed the highest H_2S
384 concentrations throughout the core and in particular at the sediment surface, with
385 maximum concentrations reaching > 4 mM. At Stations below the OMZ (Stations 9 and
386 10), no H_2S was detected within pore waters (Fig. 4).

387 Iron concentrations inside the benthic chambers reached maximum
388 values > 300 nM. At Stations 4 and 6, located inside the OMZ, concentrations in the
389 chambers increased in a linear way during the incubation. At stations above and below
390 the OMZ, we did not observe a similar trend over time. For comparison with diffusive
391 fluxes, we estimated benthic Fe fluxes from linear regressions of Fe concentrations
392 versus time (Table 2). We also calculated the theoretical concentration gradients over
393 time in the benthic chambers based on our diffusive flux estimates (Fig. 5). The
394 incubation data were largely consistent in direction and slope with the diffusive fluxes.
395 In particular, the projected and observed concentration gradients were in good
396 agreement at stations inside the OMZ (Station 4 and 6), where the highest diffusive
397 fluxes of -17.5 and $-8.0 \text{ mmol m}^{-2} \text{ y}^{-1}$ were observed. At these stations also the highest
398 R^2 for the linear regressions of the concentration change over the incubation time were

399 calculated (Station 4: $R^2 = 0.7$, Station 6: $R^2 = 0.5$) (Table S4). At stations below the
400 OMZ, diffusive fluxes of $< 1 \text{ mmol m}^{-2} \text{ y}^{-1}$ were too low to be detected over the
401 incubation time of 32 hours.

402

403 **3.2.2 Cadmium**

404 In near-bottom waters Cd concentrations increased with distance from the
405 coast, from 0.4 nM at the shallowest station at 75 m water depth (Station 1) to 1.1 nM
406 below the OMZ at 750 m water depth (Station 9). Cadmium concentrations were
407 constant at each station between 0.5 and 4 m above the seafloor (Fig. 3).

408 Cadmium concentrations in pore waters ranged between 0.1 – 2 nM (Fig. 6).
409 Within the OMZ, bottom water concentrations were higher than concentrations in pore
410 water at the sediment surface (0 - 1 cm), indicating a downward diffusive flux into the
411 sediments. The benthic diffusive fluxes inside the OMZ were on the order of 0.6 – 0.8
412 $\mu\text{mol m}^{-2} \text{ y}^{-1}$ (Table 3). In contrast, at Stations 1 and 9 an upward-directed
413 concentration gradient was observed, indicating a diffusive flux from the sediments into
414 bottom waters. The upward diffusive flux was $-1.9 \mu\text{mol m}^{-2} \text{ y}^{-1}$ above the permanent
415 OMZ and $-0.2 \mu\text{mol m}^{-2} \text{ y}^{-1}$ below the OMZ (Table 3). Pore water Cd concentrations at
416 greater sediment depths were mostly higher than bottom water concentrations. In
417 some cases (Stations 3 and 4), elevated pore water Cd concentrations (up to 2 nM)
418 coincided with elevated H_2S concentrations (few hundred μM).

419 In the benthic chambers three different Cd trends were observed (Fig. 7). Above
420 the permanent OMZ (Station 1), Cd concentrations in the chambers were low (< 0.2
421 nM) throughout the incubation period, indicating no Cd flux. At sites within the OMZ
422 (Stations 4, 5 and 6), concentrations decreased from $\sim 0.6 - 0.3$ nM over the course
423 of the incubation. Below the OMZ (Stations 9 and 10), Cd concentrations in the
424 chamber were high (~ 1 nM) and remained constant or increased slightly during the
425 incubation. At sites within the OMZ, Cd removal within the chamber was near-linear
426 (Stations 4, 5 and 6: $R^2 = \geq 0.9$) (Table S4), which translates to a removal flux of 13 –
427 23 $\mu\text{mol m}^{-2} \text{ y}^{-1}$. The Cd removal fluxes in benthic chambers were more than one order
428 of magnitude higher than diffusive benthic fluxes ($0.6 - 0.8 \mu\text{mol m}^{-2} \text{ y}^{-1}$) (Table 3).

429

430

431 **4. Discussion**

432

433 **4.1 Benthic iron cycling**

434 **4.1.1 Comparison of diffusive and in-situ benthic chamber iron fluxes**

435 Concentrations of Fe in bottom waters from benthic chamber incubations are
436 mostly higher than in ambient bottom waters because of Fe release from the sediment
437 and an accumulation in the enclosed water volume inside the benthic chamber. In the
438 absence of oxygen and, thus, bottom-dwelling macrofauna at stations within the OMZ,
439 bioturbation and bioirrigation are unlikely to exert an important control on sedimentary
440 Fe release. Consistent with this notion, the slope calculated from benthic diffusive
441 fluxes is largely consistent with the concentration gradients observed within the benthic
442 chambers (Fig. 5). Moreover, our fluxes from benthic chamber incubations and
443 diffusive fluxes are generally of the same order of magnitude (Table 2). Therefore,
444 diffusive transport of dissolved Fe from the sediment into the bottom water seems to
445 be the main control on the concentration evolution observed within the benthic
446 chamber.

447 Some of the concentration gradients in benthic chambers are non-linear,
448 indicating that the Fe flux was not constant during the incubations. This is a common
449 observation in Fe flux data from benthic chamber incubations and higher Fe fluxes
450 generally have higher R^2 values for the linear regressions (Friedrich et al., 2002;
451 Turetta et al., 2005; Severmann et al., 2010; Lenstra et al., 2019). However, the non-
452 linearity can be used to identify additional processes affecting Fe concentrations and
453 fluxes within the benthic chamber, which may also affect fluxes under natural
454 conditions. One possible process that can remove dissolved Fe(II) under anoxic
455 conditions is Fe oxidation with NO_3^- as the terminal electron acceptor or oxidation with
456 NO_2^- (Straub et al., 1996; Carlson et al., 2013; Klueglein and Kappler, 2013). The
457 oxidation of reduced Fe in the absence of oxygen, either microbially mediated with
458 NO_3^- or abiotically with NO_2^- , has been hypothesized to be important in the water
459 column of the Peruvian OMZ (Scholz et al., 2016; Heller et al., 2017). During our
460 incubation at Station 4 (Fig. 8), we observed a decline in Fe concentrations during the
461 first ten hours of the incubation time. Concurrently, NO_3^- concentrations were

462 decreasing, while NO_2^- accumulated, presumably due to progressive denitrification and
463 release from the sediments. Once NO_3^- and NO_2^- were depleted, Fe concentrations
464 started to rise again, resulting in the highest in-situ Fe flux observed throughout our
465 sampling campaign (Table 2). The coincidence in timing of Fe accumulation and NO_2^-
466 decrease suggest that depletion of Fe at the beginning of the incubation was most
467 likely caused by Fe oxidation with NO_2^- . The incubation at Station 4 was the only one
468 where NO_3^- and NO_2^- were substantially removed during the incubation. However, the
469 high Fe flux cannot be interpreted as a natural flux estimate at steady state. In general,
470 we argue that bottom water NO_2^- concentrations exert a first order control on the
471 intensity of Fe efflux at the absence of oxygen and, therefore, need to be considered
472 in the evaluation of sedimentary Fe mobility in anoxic-nitrogenous OMZs.

473 During the incubations at Stations 1, 9 and 10, Fe concentrations did not
474 continuously increase but fluctuated between high and low values. This observation
475 could be explained by a combination of bioirrigation and bioturbation at stations where
476 oxygen was present (stations 9 and 10), as well as rapid Fe oxidation and precipitation
477 processes. Under oxic conditions, bottom-dwelling macrofauna is likely to increase the
478 transfer of dissolved Fe from the sediments into the bottom water (Elrod et al., 2004;
479 Lenstra et al., 2019). During episodes of oxygenation a population of macrofauna that
480 can enhance bioturbation and bioirrigation was observed on the Peruvian shelf
481 (Gutiérrez et al., 2008). However, under oxic conditions, any Fe delivered to the
482 chamber is prone to rapid oxidative removal. Moreover, ex-situ experiments have
483 demonstrated a fast and efficient removal of up to 90% of dissolved Fe in incubated
484 bottom waters due to particle resuspension (Homoky et al., 2012). Bioturbation and
485 bioirrigation could also contribute to particle resuspension at oxic stations, thus leading
486 to removal of dissolved Fe.

487 Furthermore, colloidal Fe could modify Fe concentrations within our samples
488 and explain some of the fluctuations observed during the incubations. Colloids are
489 quite reactive, they are much more soluble than larger particles and can be rapidly
490 reduced and dissolved in anoxic environments, but they can also aggregate into larger
491 particles (Raiswell and Canfield, 2012). The transfer of Fe between dissolved, colloidal
492 and particulate pools is likely to affect the balance between Fe transport and re-
493 precipitation and -deposition to some extent. However, since did not differentiate

494 between colloidal and truly dissolved fractions during our sampling, we cannot discuss
495 this aspect further based on our data.

496 Oxidation processes and interactions with particles can efficiently remove Fe
497 shortly after its transfer to bottom waters and this process is likely to be most intense
498 close to the seafloor where the highest particle concentrations prevail. We argue that
499 the same processes are reflected by declining Fe concentrations away from the
500 seafloor in some of the bottom water profiles (at Stations 3 and 4) (Fig. 3).

501

502 **4.1.2 Removal rates of dissolved iron in the near-bottom water column**

503 We observed declining Fe concentrations in the first 4 m away from the seafloor
504 at Stations 3 and 4, which hints at removal of dissolved Fe in the near bottom waters
505 after its release from the sediments. To differentiate between dilution with ambient
506 bottom water (by currents) from Fe removal from the dissolved phase, Fe
507 concentrations were normalized by Si(OH)₄ measured in the same samples (Fig. 3).
508 Due to opal dissolution within Peru margin sediments, Si(OH)₄ is released into bottom
509 waters (Ehlert et al., 2016). In contrast to Fe, we assume that Si(OH)₄ behaves
510 conservatively and precipitation reactions within the bottom waters are of subordinate
511 importance. The decreasing Fe to Si(OH)₄ ratios at Station 3 and 4 with distance from
512 the seafloor indicate that there is Fe removal within the near-bottom water column that
513 must be related to precipitation processes or scavenging.

514 We further constrained rates of dissolved Fe removal at stations with a
515 discernable Fe to Si(OH)₄ gradient within the first 4 m distance from the seafloor. To
516 this end, we first determined an eddy diffusion coefficient (K_y) using Si(OH)₄ fluxes
517 from benthic chamber incubations (F_{Si}) (see chapter 2.3 for methodology) and the
518 known concentration gradient of dissolved Si(OH)₄ within the bottom water (d_{Si}/d_x),
519 where x is the height above the seafloor. At the seafloor, the flux of Si(OH)₄ from the
520 sediment is equal to the flux in the water column.

$$521 \quad F_{Si} = -K_y(d_{Si}/d_x) \quad (4)$$

522 This equation can be solved for the eddy diffusion coefficient.

523 Dissolved Fe in the bottom water (DFe) can be described by the solving the
524 diffusion-reaction equation for DFe (ignoring advection and assuming a steady-state
525 first-order consumption of dissolved Fe):

$$526 \quad DFe = C_{BW} * \exp.(-\sqrt{k_{Feox}}/\sqrt{K_y}) \quad (5)$$

527 The equation can be fitted to the measured DFe concentrations in the bottom water by
528 adjusting the Fe concentration directly above the seafloor (C_{BW}) and the Fe oxidation
529 constant (k_{Feox}). From the fitted first-order rate constant k_{Feox} , the half-life for dissolved
530 Fe in bottom waters can be calculated.

531 The half-lives of dissolved Fe in the first 4 m away from the seafloor are 2.5 min
532 and 0.3 min at Stations 3 and 4, respectively (Table 4). Another study reported a
533 dissolved Fe half-life of 17 hours under nitrogenous conditions in the first 10 – 20 m
534 above the seafloor in the Peruvian OMZ (Scholz et al., 2016). Our calculations suggest
535 that Fe removal in near-bottom waters is much faster. The approach assumes that
536 $Si(OH)_4$ is transported vertically by eddy diffusion and eddy diffusion and oxidation
537 control the half-life of Fe in the first 4 m above the seafloor. It is possible that our
538 assumption of solute transport by eddy diffusion is not correct. Alternatively,
539 decreasing Fe and $Si(OH)_4$ concentration above the seafloor could be due to super-
540 imposed water layers with different Fe and $Si(OH)_4$ concentrations but little vertical
541 exchange. In this case our calculated half-life would be an underestimation.

542 As mentioned above (chapter 4.1.1), in the absence of oxygen, removal
543 processes of dissolved Fe could be related to oxidation of dissolved Fe with NO_2^- or to
544 interactions with suspended particles, which are likely to be most abundant directly
545 above the seafloor. Further research on dissolved-particulate interactions, including
546 the role of colloidal Fe, in bottom waters is needed to better constrain how sedimentary
547 Fe fluxes are modified in the near-bottom water column.

548

549 **4.1.3 Controls on the temporal variability of benthic iron fluxes**

550 The Peruvian OMZ is known to experience high-amplitude fluctuations in
551 upwelling intensity as well as variability in bottom water oxygen, NO_3^- , NO_2^- and H_2S
552 concentrations (Pennington et al., 2006; Gutiérrez et al., 2008; Graco et al., 2017;
553 Ohde, 2018). To get an insight into how different biogeochemical conditions control

554 benthic diffusive Fe(II) fluxes, we compared the fluxes from our recent cruise with
555 fluxes from our earlier cruise M92 (Fig. 9). Cruise M92 took place in austral autumn
556 2013 following the main upwelling season and during a period of intense primary
557 productivity. Due to reduced upwelling and stable density stratification, the water
558 column on the shallow shelf was not only depleted in oxygen but also in NO_3^- and NO_2^-
559 during cruise M92 (Sommer et al., 2016). Under such conditions,
560 chemolithoautotrophic H_2S oxidation with NO_3^- or NO_2^- was impeded so that pore water
561 H_2S could be released from the sediment into the water column. As a result, the water
562 column during M92 was sulfidic between around 50 – 150 m water depth with the
563 highest H_2S concentration of 13 μM observed at 50 m depth (Fig. 2). While the
564 biogeochemical conditions on the shallow shelf were fundamentally different to those
565 during M136 and M137, below 150 m water depth the conditions were largely
566 comparable (oxygen-depleted, NO_3^- : 20 – 30 μM , NO_2^- up to 9 μM between 150 – 300
567 m). At the stations with similar biogeochemical water column conditions, the Fe(II)
568 fluxes during both sampling campaigns were remarkably similar (Fig. 9). However,
569 similar to the temporal variability of Fe concentrations in bottom waters at Station 1
570 (Fig. 3), we observed a pronounced difference in the diffusive flux magnitude on the
571 shallow shelf where the biogeochemical conditions differed between both cruises. The
572 highest diffusive flux during M92 in 2013 of $-22.7 \text{ mmol m}^{-2} \text{ y}^{-1}$ was measured at Station
573 1. By contrast, during M136/137 in 2017 we determined a much lower flux of -2.6 mmol
574 $\text{m}^{-2} \text{ y}^{-1}$ at this station. During M136 and M137 the highest flux of $-17.5 \text{ mmol m}^{-2} \text{ y}^{-1}$ was
575 measured at Station 4 at 145 m water depth.

576 Diffusive fluxes are a function of the concentration gradient between pore water
577 and bottom water (Eq. (1)). As dissolved Fe concentrations in bottom waters are
578 generally much lower (nM) compared to those observed in pore waters (μM), the flux
579 magnitude is chiefly determined by differences in pore water Fe concentrations. During
580 M92, pore waters at the sediment surface were characterized by high dissolved Fe
581 concentrations (4.8 μM in the upper pore water sample), which resulted in a steep
582 gradient and a comparably high Fe flux. Under the slightly sulfidic conditions that
583 prevailed in the water column during M92, oxidative removal of dissolved Fe(II) with
584 NO_3^- or NO_2^- was impeded (Scholz et al., 2016) and dissolved Fe(II) could be stabilized
585 as aqueous iron sulfide (Schlosser et al., 2018). Therefore, the bottom water was
586 characterized by high dissolved Fe concentrations (up to 0.7 μM in the supernatant
587 bottom water of MUCs).

588 Despite oxic conditions in the water column during M136 and M137, we
589 observed much higher H₂S concentrations in surface sediments at Station 1 compared
590 to M92 (4100 μM during M136 and M137 versus 1800 μM during M92 within the first 8
591 cm of the core) (Fig. 4). Because of higher H₂S concentrations, Fe concentrations were
592 controlled by the solubility of Fe monosulfide minerals (FeS). It may seem
593 counterintuitive that the surface sediment was highly sulfidic, while the overlying water
594 column was oxygenated. In order to explain this observation, we need to consider the
595 role of mats of filamentous sulfur oxidizing bacteria in controlling H₂S concentrations
596 in surface sediments. (Gutiérrez et al., 2008; Noffke et al., 2012; Yücel et al., 2017).
597 During M92 these mats were generally abundant on the shelf and upper slope
598 (Sommer et al., 2016), thus limiting the extent of H₂S accumulation within surface
599 sediments. Previous studies demonstrated that mats of sulfur oxidizing bacteria can
600 disappear during periods of oxygenation (Gutiérrez et al., 2008). Consistent with this
601 previous finding, visual inspection of the seafloor using the video-guided MUC revealed
602 that the abundance of bacterial mats on the seafloor seemed greatly reduced, which
603 is most probably related to oxic bottom water conditions on the shallow shelf during
604 the coastal El Niño event. As these microaerophilic organisms tend to avoid high
605 oxygen concentrations they probably started to die off or withdraw into the sediment
606 once oxygen levels raised. We suggest that the disappearance of sulfide-oxidizing
607 bacteria under oxic conditions created a situation where H₂S accumulation in the
608 surface sediment and FeS precipitation limited the extent of Fe release into the bottom
609 water.

610

611 **4.2 Benthic cadmium cycling**

612 **4.2.1 Comparison of diffusive and in-situ benthic chamber cadmium fluxes**

613 At stations above and below the permanent OMZ (Stations 1, 9 and 10), the
614 slopes of Cd concentrations versus time during benthic chamber incubations were
615 largely consistent with theoretical Cd concentration gradients over time based on our
616 diffusive flux estimates (Fig. 7). In contrast, the fluxes determined with benthic
617 chambers at stations within the OMZ (Station 4, 5 and 6) were 25 to 40 times higher
618 than the diffusive flux (Table 3). This discrepancy demonstrates that diffusion cannot
619 be the dominant process leading to the continuous decrease of dissolved Cd during
620 benthic chamber incubations. Alternatively, Cd could be precipitated within the benthic

621 chamber and removed through downward sinking of Cd-rich particles. Cadmium
622 sulfide (greenockite) has a relatively low solubility compared to sulfide minerals of other
623 TMs ($\text{CdS} \ll \text{FeS}$). It is generally agreed that CdS precipitation can take place at trace
624 amounts of H_2S ($\text{H}_2\text{S} < 1 \mu\text{M}$, i.e., below the detection limit of the method applied in
625 this study) (Davies-Colley et al., 1985; Rosenthal et al., 1995). Previous studies using
626 in-situ benthic flux chambers have concluded that production of H_2S in the sediment
627 or the accumulation of H_2S in benthic chambers during incubations can switch the
628 direction of the Cd flux or intensify Cd removal through CdS precipitation (Westerlund
629 et al., 1986; Colbert et al., 2001). Precipitation of CdS during the incubation is,
630 therefore, a viable explanation for the discrepancy between diffusive Cd flux and Cd
631 fluxes in benthic chambers observed in our study. Furthermore, the three different
632 trends of Cd concentrations observed in benthic chamber incubations can be related
633 to H_2S concentrations in the surface sediment below the benthic chambers (Table 3).
634 At stations within the OMZ (Stations 4,5 and 6), pore water H_2S concentrations in
635 surface sediments were moderate (few μM). It is likely that there was a continuous
636 leakage of trace amounts of H_2S from the pore water into the bottom waters during the
637 incubation, thus leading to CdS precipitation and declining Cd concentrations. On the
638 shallowest shelf station (Station 1), where pore water H_2S concentrations in the surface
639 sediment were high (hundreds of μM), a potentially large amount could have been
640 released at the beginning of the incubation, thus explaining pronounced Cd depletion
641 in the chamber compared to the surrounding bottom water (0.1 nM within the chamber
642 compared to 0.4 nM outside the chamber). Below the OMZ (Stations 9 and 10), where
643 there was no H_2S present in surface sediments, there was no Cd depletion in the
644 chamber during the incubation and, consistent with previous studies in oxic settings
645 (Westerlund et al., 1986; Ciceri et al., 1992; Zago et al., 2000; Turetta et al., 2005),
646 both diffusive and benthic chamber flux data were indicative of an upward-directed flux
647 out of the sediment. Due to the absence of H_2S , dissolved Cd released from biogenic
648 particles in the surface sediment could accumulate in the pore water thus driving a
649 diffusive flux out of the sediment.

650

651 **4.2.2 Quantification of the sedimentary cadmium sink**

652 Consistent with our Cd flux data there is general consent that OMZs are a sink
653 for Cd. Several water column studies have observed Cd depletion in water masses

654 within the Peruvian and other OMZs, which was mostly attributed to Cd removal via
655 CdS precipitation in sulfidic micro-niches within particles in the water column (Janssen
656 et al., 2014; Conway and John, 2015b). Sedimentary studies showed that Cd is highly
657 enriched in OMZ sediments, which has mostly been attributed to the delivery of Cd
658 with organic material and subsequent fixation as CdS within sulfidic sediments
659 (Ragueneau et al., 2000; Böning et al., 2004; Borchers et al., 2005; Muñoz et al., 2012;
660 Little et al., 2015). Based on our data, we can quantify the delivery of Cd to the
661 sediments via three different pathways: (1) diffusion across the sediment-water
662 interface and CdS precipitation within the sediment; (2) Cd incorporation by
663 phytoplankton and delivery to the sediment with organic matter; (3) CdS precipitation
664 in the water column and particulate delivery to the sediment (Table 3).

665 The enrichment of Cd in the sediment relative to the lithogenic background
666 (expressed as excess Cd concentration; Cd_{xs}) was calculated using the following
667 equation (Brumsack, 2006):

$$668 \quad Cd_{xs} = Cd_{sample} - Al_{sample} * (Cd/Al)_{crust} \quad (6)$$

669 The Cd/Al ratio of the upper continental crust ($1.22 \cdot 10^{-6}$) was used as lithogenic
670 background reference (Taylor and McLennan, 2009). To calculate the flux of Cd to the
671 sediment, Cd_{xs} was multiplied with the mass accumulation rate (MAR) from published
672 data for each individual site (Dale et al., 2015b). To approximate the amount of Cd
673 delivered to the sediment with organic material, the average concentration ratio of Cd
674 to C in phytoplankton (Moore et al., 2013) was multiplied by published particulate
675 organic carbon rain rates (maximum estimate) or burial rates (minimum estimate) for
676 each individual site (Dale et al., 2015b). The Cd delivery via precipitation in the water
677 column was determined as the remainder of $Cd_{xs} * MAR$ after subtraction of the two
678 other sources (i.e., diffusive flux and minimum/maximum delivery by organic material).

679 Sediments at all stations on the Peruvian shelf and slope are enriched in Cd
680 relative to the lithogenic background. The accumulation rate of Cd decreases with
681 distance from the coast from $250 \mu\text{mol m}^{-2} \text{y}^{-1}$ at Station 1 to $4 \mu\text{mol m}^{-2} \text{y}^{-1}$ at Station 9
682 (Table 3). These fluxes generally exceed the amount of Cd delivered to the sediments
683 via diffusion and associated with organic material. Together these mechanisms of Cd
684 delivery can only account for ~ 20 % of the Cd enrichment at stations above and inside
685 the permanent OMZ, with the delivery with organic material being of greater

686 importance. The remaining Cd enrichment in the sediment (~ 80 %), after subtraction
687 of diffusive and minimum/maximum organic Cd sources, must be related to CdS
688 precipitation in the water column and delivery of Cd-rich particles to the sediment. This
689 removal process can be a combination of CdS precipitation in sulfidic micro-niches
690 around sinking particles (Janssen et al., 2014; Bianchi et al., 2018), CdS precipitation
691 in sulfide plumes (Xie et al., 2019) when sedimentary H₂S can spread throughout the
692 water column (Schunck et al., 2013; Ohde, 2018), and precipitation of CdS in the near-
693 bottom water (this study). Our estimated CdS precipitation in the water column within
694 the OMZ agrees with the Cd fluxes determined from benthic chamber incubations,
695 where dissolved Cd removal takes place in the 20 – 30 cm of overlying water above
696 the seafloor. These Cd removal fluxes from benthic chambers alone are sufficient to
697 account for 41 % – 68 % of the estimated particulate Cd removal from the water column
698 and 38 % – 60 % of total Cd enrichment in the sediment within the OMZ (Table 3).
699 Considering that Cd precipitation in near-bottom water is unlikely to be restricted to the
700 20 – 30 cm above the seafloor, covered by our benthic chambers, the removal flux
701 associated with this process is likely to be even higher. At Station 1, where the surface
702 sediment below the benthic chamber was highly sulfidic, the particulate Cd removal
703 calculated from the concentration difference between the bottom water (0.5 m) and the
704 first sample from the benthic chamber incubation (taken after 0.25 h) was high enough
705 to explain the total Cd enrichment in the sediment.

706 Below the OMZ, at Station 9, where the smallest Cd enrichment was observed, the
707 relative contribution of Cd delivery with organic material increases. About half of the
708 Cd enrichment can be attributed to organic material at this station.

709 Once Cd is delivered to the sediment, it can either stay fixed in the solid phase
710 or be released to the pore waters. Cadmium concentrations in pore waters of
711 subsurface sediments (> 10 cm sediment depth) were mostly higher than bottom water
712 concentrations (Fig. 6), indicating a transfer of Cd from the solid phase into pore waters
713 during early diagenesis. Cadmium sulfides are considered highly insoluble and stable
714 within sediments (Elderfield et al., 1981), even upon re-oxygenation (Rosenthal et al.,
715 1995). Therefore, Cd release through re-dissolution of CdS is ruled out as a potential
716 source of dissolved Cd. Alternatively, Cd liberation upon remineralization of organic
717 material could explain elevated Cd concentrations in the pore water. Elevated Cd
718 concentrations in sulfidic pore waters have been observed in previous studies and

719 attributed to Cd stabilization through formation of organic and inorganic complexes
720 (Gobeil et al., 1987; Sundby et al., 2004). Experimental data gave evidence for the
721 presence of dissolved Cd bisulfide and polysulfide complexes in pore waters. An
722 increase of electrochemically active Cd after UV irradiation, was explained by the
723 destruction of electrochemically inactive bisulfide and polysulfide complexes (Gobeil et
724 al., 1987). At very high H₂S concentrations ($> 10^{-3}$ M) the solubility of Cd may increase
725 due to an increase in these bisulfide and polysulfide complexes. Under such highly
726 sulfidic conditions, Cd solubility may even exceed the solubility in oxygenated waters
727 and highly sulfidic sediment can eventually lead to a diffusive source of Cd to the
728 bottom water (Davies-Colley et al., 1985). Such a scenario may explain the negative
729 (i.e., upward-directed) diffusive Cd flux at Station 1, where the pore waters of surface
730 sediments are highly sulfidic.

731

732

733 **5. Conclusions and implications for trace metal sources and sinks in the future** 734 **ocean**

735 Consistent with earlier work, our results demonstrate that that OMZ sediments
736 are a source for Fe and a sink for Cd. Moreover, based on our findings, biogeochemical
737 conditions and processes that control the benthic fluxes of these TM across the
738 Peruvian OMZ can be further constrained.

739 Within the OMZ, where bottom dwelling macrofauna is absent, diffusion is the
740 main process that transports Fe from the sediment pore water into the bottom water.
741 The accumulation of high levels of H₂S in pore waters, modulated by the abundance
742 of sulfur oxidizing bacteria, can reduce diffusive Fe release through sulfide precipitation
743 within pore waters. In anoxic bottom waters Fe can be rapidly removed, likely via
744 oxidation with NO₂⁻ and/or interaction with particles. Benthic Cd fluxes are directed
745 from the bottom water into the sediment within the OMZ. Diffusive fluxes and delivery
746 of Cd via organic material cannot account for the sedimentary Cd enrichment. Instead
747 CdS precipitation in near-bottom waters could be the most important pathway that
748 delivers Cd to the sediments.

749 According to our results, H₂S concentrations in surface sediments exert a first
750 order control on the magnitude and direction of Fe and Cd fluxes across the sediment-

751 water interface. With generally decreasing oxygen concentrations in the ocean and an
752 expansion of OMZs (Stramma et al., 2008; Schmidtko et al., 2017), sulfidic surface
753 sediments will likely also expand. With regard to the solubility of their sulfide minerals,
754 Fe and Cd represent two opposite end members. The solubility of sulfide minerals of
755 other important nutrient-type TMs, such as Ni and Zn, is intermediate between those
756 of Fe and Cd ($Fe > Ni > Zn > Cd$). An expansion of sulfidic surface sediments is thus
757 likely to affect sedimentary TM fluxes in a differing manner. This notion is illustrated in
758 Fig. 10, showing saturation indices calculated based on the range of TM
759 concentrations observed in the ocean and typical H_2S concentrations observed in
760 anoxic marine environments (nM – μ M concentrations represent sulfidic events in the
761 water column; μ M – mM concentrations are typical for pore waters). Cadmium sulfide
762 minerals become oversaturated at nM to μ M H_2S concentrations, which explains why
763 Cd removal can take place in the bottom water in OMZs. By contrast, FeS is highly
764 undersaturated under the typical biogeochemical conditions in the water column.
765 Therefore, FeS precipitation is unlikely to take place in the water column, even under
766 somewhat more reducing conditions. Other sulfide-forming TMs have an intermediate
767 sulfide solubility (e.g. Zn, Ni), which could imply that the direction and magnitude of
768 their sedimentary fluxes is susceptible to expanding ocean anoxia. The differing
769 response of TMs to an expansion of sulfidic conditions may cause a change in the TM
770 stoichiometry of upwelling water masses with potential consequences for TM-
771 dependent marine ecosystems in surface waters.

772

773

774 **Data availability**

775 The data will be made available at Pangaea upon publication of the article.

776

777

778 **Author contribution**

779 AP and FS conceived the study. AP, FS, AD, SS conducted the sampling at sea. AP
780 analyzed the trace metal concentrations. AP and FS prepared the manuscript with
781 contributions from all co-authors.

782

783

784 **Competing Interests**

785 The authors declare that they have no conflict of interest.

786

787

788 **Acknowledgements**

789 We are grateful for the support of the crew of RV Meteor during the fieldwork. For their
790 technical and analytical assistance we thank A. Beck, A. Bleyer, B. Domeyer, D.
791 Jasinski, A. Petersen, T. Steffens, R. Surberg and M. Türk. This study was supported
792 by the German Research Foundation through the Emmy Noether
793 Nachwuchsforschergruppe ICONOX (Iron Cycling in Continental Margin Sediments
794 and the Nutrient and Oxygen Balance of the Ocean) and Sonderforschungsbereich
795 754 (Climate-Biogeochemistry Interactions in the Tropical Ocean). We also would like
796 to thank Edouard Metzger and Michael Staubwasser for their constructive reviews, as
797 well as S. Wajih A. Naqvi for the editorial handling.

1169

1170 Fig. 1: Sampling stations on the Peruvian continental margin during cruises M136 &
1171 M137 along a latitudinal depth transect at 12° S. The sampling stations for pore
1172 waters are depicted by white stars, for bottom waters by yellow dots and for benthic
1173 chamber incubations by red dots.

1174 Fig. 2: Oxygen, nitrate, nitrite and hydrogen sulfide concentrations on the Peruvian
1175 slope (Station 10, 1000 m depth), crossing the oxygen minimum zone (upper panel),
1176 and the upper shelf (Station 1, 75 m depth) (lower panel) during cruises M136 &
1177 M137 and M92 along the 12° S transect.

1178 Fig. 3: Near-bottom water concentrations of dissolved Fe and Cd and dissolved Fe to
1179 silicic acid ratios 0.5 m to 4 m above the seafloor across the 12° S transect. The red
1180 diamonds show results from a second sampling at Station 1 one month later.
1181 Concentrations of silicic acid are listed in Table S3 in the supplement.

1182 Fig. 4: Pore water dissolved Fe(II) and hydrogen sulfide concentrations. Data from
1183 an earlier cruise, M92, at Station 1 (75 m water depth) are displayed for comparison.
1184 The uppermost sample represents the bottom water concentration. The analytical
1185 error is smaller than the symbol size.

1186 Fig. 5: Dissolved Fe concentrations in incubated bottom waters from benthic chamber
1187 incubations. The black dashed line represents the linear regressions of the
1188 concentration change over the incubation time. The equations for these linear
1189 regressions are listed together with the coefficients of determination (R^2) in Table S4
1190 in the supplement. The grey dashed line represents theoretical concentration
1191 gradients over the incubation time based on our benthic diffusive fluxes (Table 2).
1192 The analytical error is smaller than the symbol size.

1193 Fig. 6: Pore water dissolved Cd and hydrogen sulfide concentrations. The uppermost
1194 sample represents the bottom water concentrations. The analytical error is smaller
1195 than the symbol size.

1196 Fig. 7: Dissolved Cd concentrations in incubated bottom waters from benthic
1197 chamber incubations. The black dashed line represents the linear regressions of the
1198 concentration change over the incubation time. The equations for these linear

1199 regressions are listed together with the coefficients of determination (R^2) in Table S4
1200 in the supplement. The grey dashed line represents theoretical concentration
1201 gradients over the incubation time based on our benthic diffusive fluxes (Table 3).
1202 The analytical error is smaller than the symbol size.

1203 Fig. 8: Dissolved Fe, nitrate and nitrite concentrations in incubated bottom waters
1204 from the benthic chamber incubation at Station 4 (145 m water depth).

1205 Fig. 9: Comparison of benthic diffusive Fe(II) fluxes between cruises M136 & M137
1206 and M92 on the Peruvian shelf. Negative values represent fluxes from the sediment
1207 pore water into the bottom waters. Shaded bars on the upper panel display the
1208 geochemical conditions in the water column during the time of sampling.

1209 Fig. 10: Schematic overview of the possible mobility of different trace metal to an
1210 expansion of sulfidic conditions. Saturation indices (SI) were calculated for different
1211 H_2S concentrations and reported minimum and maximum concentrations of trace
1212 metals in the water column (data from Bruland and Lohan 2003). Equilibrium
1213 constants ($\log K$ under standard conditions) for Fe (FeS ppt: -3.92), Ni (millerite: -
1214 8.04), Zn (sphalerite: -11.62) and Cd (greenokite: -15.93) were taken from the
1215 PHREEQC WATEQ4F database (Ball and Nordstrom, 1991). The results are
1216 approximate since concentrations instead of activities were used for calculations. A
1217 positive SI is indicative of oversaturation whereas a negative SI is indicative of
1218 undersaturation.

1219 Table 1: Accuracy of replicate concentration measurements (n = 7) of certified
 1220 reference seawater for trace metals NASS-7 and CASS-6 by ICP-MS.

	NASS-7 certified value	NASS-7 measured value	CASS-6 certified value	CASS-6 measured value
Fe (µg/L)	0.351 ± 0.026	0.352 ± 0.017	1.56 ± 0.12	1.56 ± 0.03
Cd (µg/L)	0.0161 ± 0.0016	0.0162 ± 0.0024	0.0217 ± 0.0018	0.0216 ± 0.0016

1221

1222

1223 Table 2: Comparison of benthic diffusive Fe(II) fluxes out of the sediment and
 1224 geochemical bottom water conditions between M136 & M137 and M92 on the
 1225 Peruvian shelf. Fluxes during M92 correspond to similar depth (see Fig. 9).

station	M136 & M137	M136 & M137	M136 & M137	M136 & M137	M136 & M137	M136 & M137	M92	M92

1229

1230 Table 3: Comparison of sedimentary Cd excess compared to the lithogenic
 1231 background and the contribution of Cd delivery to the sediment via different
 1232 pathways: (1) diffusion across the sediment-water interface and Cd sulfide
 1233 precipitation within the sediment; (2) Cd incorporation by phytoplankton and delivery
 1234 to the sediment with organic matter; (3) Cd sulfide precipitation in the water column
 1235 and particulate delivery to the sediment.

station	water depth (m)	Cd excess sediment ¹ ($\mu\text{mol m}^{-2} \text{y}^{-1}$)	(1) Cd flux diffusive ($\mu\text{mol m}^{-2} \text{y}^{-1}$)	Cd flux benthic chamber ($\mu\text{mol m}^{-2} \text{y}^{-1}$)	H ₂ S in surface sediment below benthic chamber (μM)	(2) Cd from organic matter ² ($\mu\text{mol m}^{-2} \text{y}^{-1}$)	(3) CdS precipitation in water column ³ ($\mu\text{mol m}^{-2} \text{y}^{-1}$)
1	75	248.87	-1.85	– (3109.5) ⁴	641.02	8.34 – 49.04	199.83 – 240.53
3	130	153.41	0.83	–	–	4.87 – 17.40	135.19 – 147.72
4	145	35.07	0.54	13.4 ± 1.05	1.30	1.55 – 6.48	28.07 – 32.99
5	195	44.76	0.63	22.6 ± 3.24	9.52	5.71 – 7.71	36.36 – 38.36
6	245	35.15	0.55	21.2 ± 3.31	0.40	3.60 – 6.54	28.06 – 31.00
9	750	4.44	-0.30	0.00 ± 0.02	0.00	1.48 – 3.21	1.23 – 2.96
10	950	–	–	–	0.00	–	–

1236
 1237 ¹ Calculated after Brumsack (2006) and multiplied by the mass accumulation rate for
 1238 each site (Dale et al., 2015b).

1239 ² Determined by multiplication of Cd/C ratio in average phytoplankton (Moore et al.,
 1240 2013) with particulate organic carbon rain rates (maximum values) and organic
 1241 carbon accumulation rates (minimum values) for each individual site (data from Dale
 1242 et al., 2015b).

1243 ³ Remainder of Cd excess in sediment after subtraction of diffusive and minimum and
 1244 maximum organic Cd sources.

1245 ⁴ Flux calculated from the concentration difference between the bottom water (0.5 m)
 1246 and the first sample from the benthic chamber incubation (taken after 0.25 h).

1247

1248

1249 Table 4: Modelled half-lives ($t_{1/2}$) of dissolved Fe within the first 4 m distance from the
 1250 seafloor at Stations 3 and 4 and data used for determination of $t_{1/2}$ using Eq. (4) and
 1251 Eq. (5).

station	water depth (m)	Si(OH) ₄ flux benthic chamber (F_{Si}) ($\mu\text{mol cm}^{-2} \text{d}^{-1}$)	Si(OH) ₄ concentration gradient (d_{Si}) ($\mu\text{mol cm}^{-3} \text{cm}^{-1}$)	eddy diffusion coefficient (K_y) ($\text{m}^2 \text{s}^{-1}$)	modelled Fe at sediment surface (C_{BW}) (nM)	Fe oxidation constant (k_{Feox}) (d^{-1})	half-life in near- bottom water column ($t_{1/2}$) (min)
3	130	0.73	$-4.05 \cdot 10^{-6}$	$1.55 \cdot 10^6$	70	400	2.5
4	145	0.33	$-1.44 \cdot 10^{-6}$	$1.96 \cdot 10^6$	81	3500	0.3
