**Contrasting conifer species productivity in relation to soil carbon, nitrogen
and phosphorus stoichiometry of British Columbia perhumid rainforests**

22 **Abstract**

23 Temperate rainforest soils of the Pacific Northwest are often carbon (C) rich and encompass a wide
24 range in fertility reflecting varying nitrogen (N) and phosphorus (P) availability. Soil resource stoichiometry
25 (C:N:P) may provide an effective measure of site nutrient status and help refine species-dependent patterns
26 in forest productivity across edaphic gradients. We determined mineral soil and forest floor nutrient
27 concentrations across very wet (perhumid) rainforest sites of southwestern Vancouver Island (Canada), and
28 employed soil element ratios as covariates in a long-term planting density trial to test their utility in defining
29 basal area growth response of four conifer species. There were strong positive correlations in mineral soil
30 C, N and organic P (P_o) concentrations, and close alignment in C:N and C: P_o both among and between
31 substrates. Stand basal area after five decades was best reflected by mineral soil and forest floor C:N but in
32 either case included a significant species-soil interaction. The conifers with ectomycorrhizal fungi had
33 diverging growth responses displaying either competitive (*Picea sitchensis*) or stress-tolerant (*Tsuga*
34 *heterophylla*, *Pseudotsuga menziesii*) attributes, in contrast to a more generalist response by an arbuscular
35 mycorrhizal tree (*Thuja plicata*). Despite the consistent patterns in organic matter quality we found no
36 evidence for increased foliar P concentrations with declining element ratios (C: P_o or C: P_{total}) as we did for N.
37 The often high C: P_o ratios (as much as 3000) of these soils may reflect a stronger immobilization sink for P
38 than N, which, along with ongoing sorption of PO_4^- , could limit the utility of C: P_o or N: P_o to adequately
39 reflect P supply. The dynamics and availability of soil P to trees, particularly as P_o , deserves greater
40 attention as many perhumid rainforests were co-limited by N and P, or, in some stands, possibly P alone.

41 **Keywords:** resource stoichiometry; temperate rainforest; soil organic matter; organic phosphorus; soil C:N
42 ratio; ectomycorrhizal conifers

43

44 **1 Introduction**

45 One of the largest global expanses of temperate rainforest (approximately 25 million ha) is located
46 along the Pacific coast of northwestern North America (DellaSala et al., 2011), an area renowned for
47 towering, conifer-dominated forests of extraordinary productivity and longevity (Waring and Franklin, 1979;
48 Smithwick et al., 2002; Keith et al., 2009). Carpenter et al. (2014) highlighted the high diversity of soil types
49 across this region and some key attributes related to soil carbon (C), nitrogen (N), and phosphorus (P) status
50 of these forests. Most notably, temperate rainforests often have substantial accumulations of organic
51 matter at the soil surface (forest floors) and in mineral horizons that rank among the highest in global soil C
52 stocks (Sun et al., 2004; Homann et al., 2005; McNicol et al., 2019). Secondly, the N concentrations of
53 certain soils can be extremely high which, along with ample moisture, underpins the tremendous
54 productivity of many forest stands (Perakis et al., 2006; Littke et al., 2011; Kranabetter et al., 2015). In
55 contrast, areas with low relief and imperfect drainage can have deep organic soils and scrubby, less
56 productive forests with very limited N availability (Sajedi et al., 2012; Kranabetter et al., 2013; Bisbing and
57 D'Amore, 2018). Thirdly, intensive weathering under high rainfall combined with acidic leachate derived
58 from coniferous vegetation has accelerated soil podzolization (Singleton and Lavkulich, 1987; Sanborn et al.,
59 2011), resulting in limited supplies of P in some areas that likely co-limit forest growth (Preston and
60 Trofymow, 2000; Blevins et al., 2006; Mainwaring et al., 2014; Kranabetter et al., 2019). Temperate
61 rainforests with these combined attributes in soil organic matter, N and P may lack analogues in forest
62 ecosystems elsewhere (Carpenter et al., 2014), and consequently a more detailed understanding of soil
63 nutrient limitations and dynamics would better support land management decisions regarding wood
64 production, C budgets, and conservation priorities.

65 Resource stoichiometry (C:N:P) of soils may be one avenue in which the combined constraints of N
66 and P on ecosystem productivity can be effectively evaluated (Zechmeister-Boltenstern et al., 2015; Spohn,
67 2016). An essential premise of ecological stoichiometry is that rates of N and P immobilization or

68 mineralization in soils are closely linked to microbial biomass stoichiometry (Manzoni et al., 2010;
69 Mooshammer et al., 2014; Zechmeister-Boltenstern et al., 2015). Element ratios (C:N and C:P) reach a
70 threshold where microbes shift from being C-limited to N- or P-limited and consequently the mineralization
71 and release of nutrients for plant uptake during decomposition should increase with declining C:N or C:P of
72 soil organic matter (e.g., Saggiar et al., 1998; Prescott et al., 2000a; Heuck and Spohn, 2016). In addition,
73 N:P ratios of organic matter can indicate the relative extent of N and P limitations on decomposition and
74 primary productivity, as N:P tends to increase in older or well-weathered soils where P constraints might
75 supersede those of N (Wardle et al., 2004, Güsewell and Gessner, 2009). In comparison to nutrient stocks
76 (e.g., kg N ha⁻¹), which require measures of soil bulk density, coarse fragment content and organic horizon
77 thickness, resource stoichiometry presents a potentially simpler interpretation of nutrient dynamics across
78 diverse landscapes (Bui and Henderson, 2013; Littke et al., 2014; Van Sundert et al., 2019). Further details
79 on the nature of soil organic matter across temperate rainforests would contribute to this comprehensive
80 depiction of global nutrient dynamics (Tipping et al., 2016; Achat et al., 2016).

81 Baseline relationships in soil resource stoichiometry and ecosystem productivity should also
82 consider the interaction with tree species. Temperate rainforests of the Pacific Northwest are exceptional
83 because of the prevalence of evergreen conifer species, many of which host ectomycorrhizal fungi (ECM)
84 (*Tsuga*, *Abies*, *Picea*, *Pseudotsuga* and *Pinus* spp.) or, alternatively, arbuscular (ARB) mycorrhiza (*Thuja* and
85 *Sequoia* spp.). Waring and Franklin (1979) postulated that most deciduous hardwood species were
86 extirpated from the Pacific Northwest by the early Pleistocene as the climate favoured evergreen trees and
87 their ability to photosynthesize during fall and winter months instead of through the driest parts of the
88 growing season. As a result, interspecific competition and adaptive traits related to soil fertility have arisen
89 primarily between the coniferous species of this landscape (Lacourse, 2009; Coates et al., 2013), and
90 exclude, with minor exceptions (*Acer*, *Prunus*), the deciduous ARB species that can dominate soils of high
91 fertility (low C:N) elsewhere (Phillips et al., 2013; Soudzilovskaia et al., 2015; Lin et al., 2017). It should also

92 be recognized that tree species, in turn, can influence soil C and nutrient cycling through differences in litter
93 (foliar and root) quality and mycorrhizal habit, which could eventually manifest as distinct species-soil
94 stoichiometry relationships (Prescott, 2002; Augusto et al., 2002; Cools et al., 2014). Quantifying both the
95 species response to soil fertility and possible feedback of tree species on soil resources is challenging in
96 uncontrolled settings and consequently well replicated, long-term field trials may be the best avenue for
97 better understanding these interactions (Binkley, 1995; Augusto et al., 2002).

98 The quintessential rainforests along the outer west coast of British Columbia are classified as
99 ‘perhumid’, with relatively high summer rainfall, cool summers, and transient snowpacks (DellaSala et al.,
100 2011). In the early 1960’s, the British Columbia Forest Service established a multi-species planting density
101 trial across several perhumid rainforest sites of southwest Vancouver Island (Omule, 1988). The study sites
102 encompassed a considerable range in forest productivity that provided a valuable opportunity to examine
103 ECM and ARB conifer species growth and nutrition in relation to soil C, N and P stoichiometry. We follow
104 the convention of Tipping et al. (2016) in this analysis by utilizing organic P (P_o) in stoichiometry
105 comparisons (rather than total P) to focus more directly on properties of soil organic matter. The element
106 enrichment of organic matter was compared by correlations among C:N, C: P_o and N: P_o (Manzoni et al.,
107 2010; Tipping et al., 2016) for each substrate because of the typically stark differences in the C density of
108 forest floors compared to mineral soils (e.g., 50 % vs. 5 % C, respectively). In addition, we relied upon foliar
109 N and P concentrations for the more conventional interpretation of stand nutrition (e.g., Carter, 1992)
110 rather than foliar C-nutrient ratios. The objectives of our study were to 1) document the range and
111 covariation in C, N and P_o concentrations and element ratios across a variety of sites and between mineral
112 soil and forest floor substrates; 2) test the utility of soil C:N, C: P_o and N: P_o ratios as explanatory variables in
113 relation to forest productivity response; and 3) quantify any divergence in conifer growth response to soil
114 fertility gradients among ECM (*Tsuga*, *Picea*, *Pseudotsuga*) and ARB (*Thuja*) tree species.

115 **2 Methods**

116 **2.1 Site and study descriptions**

117 The planting density trial (EP571) was established along low elevations (< 300 m) at seven locations
118 in the Coastal Western Hemlock very wet maritime subzone (CWHvm; Green and Klinka, 1994) of western
119 Vancouver Island (between Port Renfrew and Bamfield, B.C.), where mean annual precipitation averages
120 almost 3400 mm (Table 1). These areas supported old-growth forests before logging took place between
121 1958 and 1960, and cutblocks were subsequently slashburned in 1961. The study areas encompassed a
122 wide range in soil nutrient and moisture regimes (Green and Klinka, 1994): steep, well-drained upland sites
123 with poor to average nutrients; imperfectly-drained, nutrient-poor sites on modest slopes; steep, nutrient-
124 rich sites on base-rich colluvial material; and low-lying, nutrient-rich sites with seepage (Supplemental Table
125 1). Soils were derived from glacial morainal, fluvial or colluvial deposits, with sandy loam to loam textures,
126 moderate stone content and well defined Bf or Bfh horizons (Humo-Ferric or Ferro-Humic Podzols,
127 respectively; Soil Classification Working Group, 1998).

128 The four conifer species utilized in the study are native to the Pacific Northwest: western hemlock
129 (*Tsuga heterophylla* [Raf.] Sarg.), Sitka spruce (*Picea sitchensis* [Bong.] Carr.), coastal Douglas-fir
130 (*Pseudotsuga menziesii* var. *menziesii* [Mirb.] Franco), and western redcedar (*Thuja plicata* Donn ex D. Don
131 in Lamb.). Single seedlots for each species were collected from the CWHvm on Vancouver Island and
132 planted as 2+0 bareroot stock in April of 1962 (Omule, 1988). The three planting density treatments were
133 2.7 × 2.7 m (1329 stems ha⁻¹), 3.7 × 3.7 m (748 stems ha⁻¹), and 4.6 × 4.6 m (479 stems ha⁻¹). Each plot
134 consisted of 81 trees planted in rows of 9, with the inner 7 × 7 rows (49 trees) tagged for remeasurement.
135 Plot size ranged proportionally with planting density (0.037, 0.066, and 0.102 ha, respectively). All four
136 conifer species were planted at every site, but the density treatment was not fully replicated across the
137 study installations; San Juan and Branch 136 had only the 2.7 m spacing (n = 4), while WC1000 lacked the
138 4.6 m spacing (n = 8; Table 1).

139 **2.2 Soil and tree measures**

140 Individual tree heights and diameters at 1.3 m were measured most recently in 2014 (52 years in
141 age). In May of 2018 we sampled the upper soil profile (i.e., the predominant rooting zone) for chemical
142 properties mirroring the methodology of Kranabetter et al. (2019). Forest floors were cut and removed
143 over a 10 cm diameter area to the mineral soil interface, and the forest floor depth noted at each microsite.
144 Mineral soils were sampled to a 20 cm depth with a stony soil auger. Subsamples from 12 random
145 microsites were composited into 3 forest floor and 3 mineral soil samples per plot (an occasional plot had
146 very thin forest floors [< 1 cm] so in those cases we took only one or two bulked samples). Soils were air-
147 dried, ground and sieved to 2 mm for chemical analysis. Foliar samples were collected at the end of the
148 growing season (mid-November 2018) by searching each plot for fresh branches that had broken off during
149 recent storms. We strove to obtain needles from current year foliage off at least 12 separate branches and
150 combined these into 3 samples per plot. Foliar samples were oven-dried at 60° C for 24 hours and then
151 ground for nutrient analysis.

152 Total C and N concentrations of soil and foliage were measured using combustion elemental
153 analysis with a Fisons/Carlo-Erba NA-1500 NCS analyzer (Thermo Fisher Scientific, Waltham, MA) (Carter
154 and Gregorich, 2008). Mineral soil and forest floors were finely ground to < 0.15 mm (100 mesh sieve)
155 before combustion analysis. Total P ($P_t = \text{inorganic } P_i + \text{organic } P_o$) of mineral soils and forest floors was
156 determined by an ignition method using sulfuric acid and an UV/visible spectrophotometer (O'Halloran and
157 Cade-Menum, 2008). Foliar P was determined by ICP-Atomic Emission Spectroscopy (Teledyne Leeman
158 Labs, Hudson, NH) following microwave digestion.

159 **2.3 Statistics**

160 Element ratios (C:N, C: P_o and N: P_o as molar ratios) were determined on each soil subsample and
161 then averaged by plot for statistical analysis. The covariation among average concentrations of C, N, P_o and
162 their element ratios was determined by pair-wise Pearson correlation coefficients (SAS Institute Inc., 2014).
163 Element ratios as a proportional rather than absolute metric are potentially prone to spurious correlations

164 (Jackson and Somers, 1991) so our purpose was to aid in data visualization and confirm direction of the
165 relationships (Tipping et al., 2016), rather than implying causation. Conifer productivity was assessed by
166 stand basal area ($\text{m}^2 \text{ha}^{-1}$ of live trees in 2014). Scaling factors in the conversion to hectares (to account for
167 differences in plot size) were 27.1 for 2.7 m spacing, 15.3 for 3.7 m spacing, and 9.8 for 4.6 m spacing.

168 The experimental treatment effects (Species and Spacing) on soil nutrient concentrations, forest
169 floor depth, stand basal area and stocking (stems ha^{-1}) were tested by fitting separate linear mixed effect
170 models in SAS (Mixed Procedure, Method=REML) (SAS Institute 2014), with Site set as a random effect. We
171 examined the relationships between stand basal area and soils by including each element ratio as a single
172 continuous variable in the model, along with the full set of interactions. The interaction terms Spacing \times
173 Soil and Species \times Spacing \times Soil were consistently nonsignificant for all soil variables tested, so the final
174 models were refitted with these terms removed. Goodness of fit for the model was evaluated by the F
175 statistic of each parameter, as well as by the lowest overall model Akaike information criterion (AIC).
176 Model outputs were also assessed graphically by plotting the observed dependent variable versus predicted
177 values to ensure a relationship close to 1:1. Foliar N, P and N:P in relation to Species, Spacing and soil
178 element ratios were examined in the same manner but the final models were refitted without Species \times
179 Spacing, Spacing \times Soil, Species \times Soil, and Species \times Spacing \times Soil interaction terms as they were
180 consistently nonsignificant for all soil variables tested.

181 **4 Results**

182 **4.1 Soil nutrient concentrations and resource stoichiometry by substrate**

183 We found a considerable range in nutrient concentrations (e.g., 0.15-0.60 % N; Table 1) and strong,
184 positive correlations among C, N, and P_o for mineral soils (Pearson $r > 0.7$) across these temperate rainforest
185 sites (Table 2, Fig. 1). Inorganic P_i concentrations of mineral soils were relatively limited, often $< 200 \text{ mg kg}^{-1}$,
186 which was substantially less than the contribution of P_o to total P for a majority of plots (53 of 64 plots
187 had $P_o > 70\%$ of P_i). In addition to limited P_i , the extent of soil podzolization was reflected by typically low

188 pH and elevated concentrations of exchangeable Al and Fe (Table 1). Forest floors averaged 5.5 cm in
189 depth (SE 0.6) overall, and displayed a narrower range in C (31 – 55 %C, average = 46 % C [SE 0.7]) but also
190 exhibited a significant positive correlation between N and P_o concentrations (Table 2). Similar to mineral
191 substrates, the concentrations of inorganic P_i (average 110 mg kg⁻¹ [SE 5.8]) were uniformly low in forest
192 floors, in contrast to P_o (average 970 mg kg⁻¹ [SE 71]), and consequently contributed only a small proportion
193 of total P (P_o ~ 90 % of P_t in forest floors).

194 C:N ratios of the mineral soils became significantly narrower (declining from 44 to 23) with
195 increasing % C (Table 2, Fig. 2a), similar to C:P_o (range approx. 300-1200) (Table 2). In contrast, C:N of forest
196 floors widened with increasing % C (Fig. 2b, Table 2) but nevertheless C:N of both substrates were well
197 aligned across sites ($r = 0.85, p < 0.001$; Fig. 3a). The same symmetry in element ratios between substrates
198 was found with C:P_o ($r = 0.78, p < 0.001$) and, to a lesser degree, N:P_o ($r = 0.58, p < 0.001$) (Fig. 3b,c). In all
199 cases the relationships in element ratios were not 1:1 as the organic horizons were less concentrated than
200 mineral soils (e.g., a forest floor C:N of 40 would be matched with a mineral soil C:N of 30, on average; Fig.
201 3a). Lastly, there was typically a high degree of correlation ($r > 0.7$) in element ratios within a substrate,
202 such as C:N vs. C:P_o, for both mineral soils and forest floors (Table 2).

203 At this juncture in plantation age (52 years) we found no evidence that conifer species or planting
204 density had an effect on mineral soil nutrient concentrations or ratios (for Species, $p = 0.99$ for C:N, $p = 0.48$
205 for C:P_o, and $p = 0.35$ for N:P_o; and for Spacing, $p = 0.61$ for C:N, $p = 0.65$ for C:P_o, and $p = 0.73$ for N:P_o).
206 There was, however, a slight difference detected in N % of forest floors with Species ($p = 0.034$). Forest
207 floor N concentration under *P. menziesii* averaged 1.52 % N (SE 0.06), which was slightly greater than the
208 other three species (combined average 1.35 % N), although forest floors also tended to be thinner under *P.*
209 *menziesii* (4.7 cm [SE 0.8], on average, compared to 5.9 cm for the other three species; $p = 0.13$). Despite
210 the modification in N concentrations under *P. menziesii*, this Species effect did not extend to element ratios

211 of forest floors (for Species, $p = 0.30$ for C:N, $p = 0.97$ for C:P_o, and $p = 0.53$ for N:P_o; and for Spacing, $p =$
212 0.25 for C:N, $p = 0.42$ for C:P_o, and $p = 0.25$ for N:P_o).

213 **4.2 Stand productivity in relation to soil resource stoichiometry**

214 Stand density (stems ha⁻¹) in 2014 was well aligned with initial planting spacing, and there were
215 significant differences among conifer species in stocking (Supplemental. Fig. 1). *Thuja plicata* had the least
216 mortality (average 80 % survival), followed by *P. sitchensis* (76 %), *T. heterophylla* (71 %) and then *P.*
217 *menziesii* (65 %). With the original study design we could only detect a significant effect of Spacing on stand
218 basal area (2.7 m Spacing = 70 m² ha⁻¹, 3.7 m = 61 m² ha⁻¹, and 4.6 m = 53 m² ha⁻¹, on average) (Table 3).
219 Including a soil element ratio of either substrate as a covariate in the analysis provided further details on
220 Species response, particularly with C:N (Table 3). Stand basal area was well aligned with mineral soil and
221 forest floor C:N for all four species, with a significant species interaction due to the sharper gains in *P.*
222 *sitchensis* basal area with decreasing C:N (Fig. 4a, b and Supplemental Fig. 2). Soil C:P_o and N:P_o were also
223 mostly significant covariates in the analysis of basal area, but neither ratio invoked the same degree of
224 Species response (i.e., lower F values) nor significant Species × Soil interactions, and both models had
225 poorer AIC scores than C:N (Table 3). For comparison we also tested C:P_t and N:P_t of each substrate against
226 basal area but found virtually identical model outputs as C:P_o and N:P_o (data not shown).

227 **4.3 Foliar nutrition in relation to soil resource stoichiometry**

228 Foliage collections were not entirely successful as a few plots, particularly under *P. sitchensis*, had
229 insufficient branches to obtain three composite subsamples (n = 167 from a target of 192 subsamples, and
230 with two *P. sitchensis* plots removed from the analysis). Carbon concentrations of the foliage were very
231 uniform, averaging 52.9 (SE 0.17) for *T. plicata*, 52.3 for *P. menziesii* (0.17), 52.3 for *T. heterophylla* (0.18)
232 and 51.9 (0.19) for *P. sitchensis*. We were able to demonstrate an overall gain in foliar N with declining soil
233 C:N ratio, both for mineral and forest floor substrates, as well as a significant difference in foliar N among
234 Species due to the enhanced nutrition of *P. sitchensis* (Table 4; Fig. 5a; note that Species × Soil interaction p

235 = 0.538 for mineral soil and $p = 0.305$ for forest floor). In contrast, there was no relationship between foliar
236 P and C:P_o ratio for either substrate (Table 4, Fig. 5b; Species × Soil interaction $p = 0.533$ for mineral soil, $p =$
237 0.561 for forest floor). The better predictor of foliar P was instead the concentration of P_i in soils, with
238 again significant differences among Species largely due to *P. sitchensis* (Table 4; Supplemental Fig. 3;
239 Species × Soil interaction $p = 0.468$ for mineral soil, $p = 0.425$ for forest floor). We also tested soil P_t and P_o
240 concentrations in relation to foliar P but neither of these attributes were significant (for P_t, $p = 0.41$ for
241 forest floors and $p = 0.12$ for mineral soil; for P_o, $p = 0.94$ for mineral soil; $p = 0.61$ for forest floors). Foliar
242 N:P ratios across the plots averaged 19.5 (SE 0.8) for *T. plicata*, 18.2 (SE 0.8) for *P. menziesii*, 20.6 (SE 0.8)
243 for *T. heterophylla*, and 17.4 (SE 1.1) for *P. sitchensis*. We were unable to find a significant relationship
244 between foliar N:P and soil N:P_o for either substrate (Table 4).

245 **5 Discussion**

246 **5.1 Organic matter quality and conifer species productivity**

247 Our results provide further details on baseline nutrition and resource stoichiometry for soils of
248 perhumid rainforests along the southwest coast of British Columbia, and complement studies of temperate
249 rainforests in the southern hemisphere (Parfitt et al., 2005; Turner et al., 2012). Soil C and N concentrations
250 were at times very high (up to 12 % C and 0.6 % N for mineral soil), as has been reported previously across
251 this region (Carpenter et al., 2014; Kranabetter, 2019; McNichol et al., 2019), while P_i was for the most part
252 notably limited (< 200 mg kg⁻¹) in comparison to less-weathered soils on the drier east side of Vancouver
253 Island (Kranabetter et al., 2019). The intense rainfall, acidic leachate (from coniferous vegetation), and, at
254 some sites, possible NO₃⁻ losses (Perakis et al., 2013) have combined to reduce soil pH and enhance the
255 sorption of P_i with reactive (Fe and Al oxides) soil components (a sink-driven P limitation; Vitousek et al.,
256 2010). Some differences in parent materials (e.g., colluvial slope, fluvial terrace, morainal till) may also
257 have contributed to the inherent range in P content of these soils (Kranabetter and Banner, 2000). The high
258 degree of positive correlations in C, N and P_o concentrations for mineral soils (and between N and P_o for

259 forest floors) was consistent with coniferous forests in Oregon (Perakis et al., 2013) and global datasets of
260 soil organic matter (Xu et al., 2013; Tipping et al., 2016). Somewhat surprisingly we did not find evidence
261 for decoupling of P_o from organic matter as suggested by Yang and Post (2011) for highly-weathered soils.
262 Nevertheless, we surmise from the generally low soil P_i concentrations, modest to high deficiencies in foliar
263 P (0.10-0.15 %; Carter, 1992) for a large number of stands¹ and elevated range (16-25) in foliar N:P (greater
264 than a hypothesized threshold of 14 to delineate N-only deficiencies; Reich and Oleksyn, 2004) that these
265 perhumid rainforests were often limited by N and P together (Blevins et al., 2006), or, in some stands,
266 possibly P alone. The dynamics and availability of soil P to trees, particularly P_o , is challenging to reconcile
267 given such strong and consistent patterns in soil organic matter quality.

268 The clear relationship between mineral soil and forest floor C:N with stand productivity and foliar N
269 was consistent with many other biomes (Littke et al., 2014; Albertini et al., 2015; Van Sundert et al., 2018)
270 and affirms the widely recognized relationship of increasing N availability with declining soil C:N (Booth et
271 al., 2005). In contrast, C: P_o and N: P_o were less aligned with species growth response (and likely only
272 significant as a surrogate for C:N) and not a significant predictor of foliar P, despite the expectation of
273 positive correlations in net N and P mineralization rates (Heuck and Spohn, 2016). Estimates of a critical
274 C: P_o for gross P mineralization of leaf litter range from 1400-1800 (Mooshammer et al., 2012; Heuck and
275 Spohn, 2016), but thresholds for forest floor horizons and mineral soil are likely much lower (perhaps < 500;
276 Saggar et al., 1998; Heuck and Spohn, 2016). The substrate distinction is important as very few of our study
277 sites had C: P_o ratios < 500, suggesting pervasive, low quality organic matter in regards to P. Furthermore,
278 the element ratios of saprotrophic fungi, as key decomposers, in these perhumid rainforests averaged 120
279 and 10 for C:P and C:N, respectively (Kranabetter et al., 2019), which when compared to soil organic matter
280 would indicate a greater elemental imbalance for P, especially in forest floors (Mooshammer et al., 2014).
281 The biotic (microbes, plants) competition for P is also very likely exacerbated by abiotic competition for

¹ note that *P. menziesii*, *T. heterophylla* and *T. plicata* averaged 0.20% P on less-weathered soils of eastern Vancouver Island (Kranabetter et al., 2019 and unpub. data)

282 phosphate (PO_4^-) via sorption to Fe and Al oxides, much more so than would be present for NH_4^+ or NO_3^-
283 (Olander and Vitousek, 2004). A greater sink strength via immobilization and sorption for PO_4^- would
284 require conifers to bypass mineralization of P by decomposers to some degree and instead access organic P
285 more directly for uptake. A concurrent study of extracellular enzyme activity associated with ECM roots of
286 *P. menziesii* has revealed substantial increases in P-acquiring enzymes (J. Meeds, pers. comm.) that are
287 likely acting upon the orthophosphate monoesters and diesters of organic P (Cade-Menun et al., 2000;
288 Preston and Trofymow, 2000). Despite the expected contribution of P_o to forest nutrition, however, we
289 found it more effective to gauge P availability through soil P_i concentrations (as the only significant
290 correlate with foliar P), but other methods may prove to be more sensitive as a measure of plant-available
291 P_o (DeLuca et al., 2015; Darch et al., 2016).

292 One unique aspect of soil organic matter found here was a decrease in mineral soil C:N and C: P_o
293 ratios with increasing soil C % (Fig 2a), in contrast to the inverse relationships described by Tipping et al.
294 (2016). This may reflect the significant legacy of N-fixing red alder (*Alnus rubra*) in coastal forest
295 ecosystems, which has been found to promote soil C sequestration and P mobilization while simultaneously
296 adding high quality (low C:N) litter (Binkley, 2005; Perakis and Pett-Ridge, 2019). A second key source of N-
297 rich litter could be from epiphytic cyanolichens and cyanobacteria-bryophyte associations (Antoine, 2004;
298 Lindo and Whiteley, 2011). Canopy lichens and bryophytes are noteworthy in low-frequency disturbance
299 ecosystems such as rainforests because they produce a steady input of N while growing independently of
300 the soil environment (Menge and Hedin, 2009). Red alder, in comparison, is an early-seral species that can
301 be hindered in its establishment and vigour by low P_i availability (Brown et al., 2011; Kranabetter et al.,
302 2013). Hedin et al. (2009) described a similar N paradox in tropical forests, and proposed N-fixing epiphytes
303 as one mechanism that allows soil N regimes to increase despite soil P_i deficiencies or physiological down-
304 regulation of N-fixation in high soil N environments.

305 **5.2 Conifer species interactions by ARB and ECM mycorrhizal guild**

306 The more significant differences in species productivity in relation to soil C:N was among the ECM
307 species rather than solely between mycorrhizal types. *Tsuga heterophylla* and *P. menziesii* had the most
308 limited increase in basal area with declining C:N, a finding that was similar for these species in correlations
309 of site index with organic matter quality across a broader region of the US northwest (Edmonds and
310 Chappel, 2004). These two conifers would be considered relatively stress-tolerant under the C-S-R model
311 (Hodgson et al., 1999) as their growth on high C:N soils outperformed that of either *P. sitchensis* or *T.*
312 *plicata*. *Picea sitchensis*, in contrast, would clearly be a strong competitor as exemplified by the impressive
313 linear increase in biomass with declining soil C:N. Perakis and Sinkhorn (2011) found *P. menziesii*
314 productivity plateaued with increasing N mineralization rates, but this relationship with N supply may be
315 species-dependent and not necessarily apply to *P. sitchensis*. A possible functional trait related to this
316 growth response is the low capacity of ECM roots of *P. menziesii* to maximize uptake of NO_3^- , as would be in
317 plentiful supply on these richer soils (Prescott et al., 2000b; Perakis et al., 2006), but whether *P. sitchensis*
318 ECM roots would perform any differently has not been established (Boczulak et al., 2014; Hawkins and
319 Kranabetter, 2017). As an aside, we noted some naturally-regenerated *Abies amabilis* within the study
320 areas that had the same girth as *P. sitchensis*, so it is likely *Abies* would be an equally competitive member
321 of these rainforest ecosystems. *Thuja plicata* as the only ARB tree species in the trial was intermediate in
322 growth response to soil C:N, and displayed no particular advantage in foliar N or P over the ECM conifers. .
323 *Thuja plicata* is recognized to have a wide ecological amplitude, from highly productive to very nutrient
324 poor or wet sites (Antos et al., 2016), and so would fit well within a generalist or intermediate C-S strategy.
325 The coexistence of ARB and ECM conifers affirms each mycorrhizal type is competent in the acquisition of
326 nutrients from organic and inorganic sources (Hodge, 2017), and the contrasting patterns in productivity
327 emphasize a diversity of traits within mycorrhizal guilds rather than a simple dichotomy in the distribution
328 of ARB and ECM trees between N-rich and N-poor soils (Koele et al., 2012; Dickie et al., 2014).

329 **5.3 Conifer species effects on soil organic matter quality**

330 After five decades the possibility of tree species effects on soil nutritional status is also worth
331 considering. Enhanced N inputs via foliar litter are considered a positive reinforcement in sustaining soil
332 fertility (Prescott, 2002), which would be consistent with the overall trend in foliar N across this productivity
333 gradient. It was interesting to note that correlations between substrates for C:N were closer to a 1:1
334 relationship than C:P_o, indicating that P cycling through litterfall has been greatly impeded in comparison to
335 N. The small increase in forest floor N concentrations under *P. menziesii* may reflect slightly better litter
336 quality (lower lignin content) and potentially faster decomposition rates for this species (Vesterdal and
337 Raulund-Rasmussen, 1998; Thomas and Prescott, 2000). Overall, however, there were no clear differences
338 in element ratios of either forest floors or mineral soils by tree species, which leads us to conclude these
339 conifers lack substantial enough differences in leaf or root litter to have more profoundly and consistently
340 diverged from inherent soil conditions. The glaciated landscape along Vancouver Island has been in the
341 current iteration of temperate perhumid rainforests for at least 7500 years (Brown and Hebda, 2002;
342 Lacourse, 2005), during which time the various site drivers (e.g., drainage, slope, soil mineralogy,
343 vegetation) have collectively produced the very wide disparity in soil fertility found today. It would
344 undoubtedly take a very sizable influence of tree species on C, N or P cycling to overcome the inertia of site
345 type in such complex terrain (Prescott et al., 2000b). For example, an ecologically minor shift in forest floor
346 C:N from 50 to 40 (equivalent to an average increase in foliar N from 1.17 % to 1.23 %; Fig. 5a), would
347 require a gain of approximately 200 kg ha⁻¹ in N (based on a depth of 5 cm and bulk density of 0.14 g cm⁻³),
348 which would seem implausible for coniferous stands to confer in mere decades. In addition, much of the
349 focus on tree species effects has focused on surface organic horizons, but given the symmetry in element
350 ratios between mineral and forest floor substrates we would argue that a true tree species effect should
351 extend throughout the rooting zone of the soil profile.

352 **5.4 Regional significance of P deficiencies**

353 With mean annual precipitation near 3500 mm, these perhumid rainforests are at the extreme
354 range in rainfall for the Pacific west coast (Carpenter et al., 2014). The evidence for P constraints outlined
355 in this trial have been substantiated by fertilizer studies of very similar perhumid forests along northern
356 Vancouver Island (Blevins et al., 2006; Negrave et al., 2007), but other areas in the Pacific Northwest have
357 shown more variation in growth response to added P (Radwan et al., 1991; Mainwaring et al. 2014). Lower
358 precipitation levels or differences in soil mineralogy could mediate rates of soil podzolization and
359 reductions in P_i so the full regional extent of these presumed P deficiencies should be examined and tested
360 more thoroughly. We expected some utility in soil $N:P_o$ as a measure of forest productivity (Wardle et al.,
361 2004) but it is possible the mismatch in element thresholds for N and P_o turnover, as discussed above,
362 reduced the efficacy of this index. Ultimately soil C:N and soil P_i together might best explain variations in
363 rainforest productivity but the limitations in study size (64 plots distributed among 4 conifer species and 3
364 planting densities) prevented an adequate statistical analysis of all main factor interactions for two soil
365 covariates. Phosphorus deficiencies are also relevant in the noted nutrient exchange between marine and
366 terrestrial environments through anadromous salmon biomass (Cederholm et al., 1999). Our results
367 support the likelihood that both salmon-derived N and P contribute to alleviating nutrient limitations of *P.*
368 *sitchensis* on riparian sites of the Pacific west coast (Reimchen and Arbellay, 2019).

369 **6 Conclusions**

370 Quantifying the fundamental relationships between soil element ratios and conifer species
371 productivity was facilitated in this study by the planting of single provenances at controlled densities,
372 alongside a uniform macroclimate and narrow elevation band among plot locales. Soil organic matter
373 content of perhumid rainforests was often high and displayed strong positive correlations in soil C, N and P_o
374 concentrations. Inorganic P was generally in low supply, reflecting soil podzolization processes, and
375 contributed a relatively minor proportion of total P. Element ratios of C:N and C: P_o were well correlated in
376 forest floors and mineral soils, yet only C:N was an effective measure of forest productivity and foliar

377 nutrition. High C:P_o ratios (as much as 3000) may reflect a stronger immobilization sink for P than N, which,
378 along with ongoing sorption of PO₄⁻, could limit the capacity of organic P turnover to meet tree
379 requirements. The interplay of conifers and soils after five decades suggests species growth response to
380 inherent soil C:N was more intrinsic to ecosystem productivity than any reciprocal effects of tree species on
381 soil resources. The conifers with ectomycorrhizal fungi had widely diverging responses in basal area over
382 the N gradient, illustrating the extent of both competitive (*Picea sitchensis*) and stress-tolerant (*Tsuga*
383 *heterophylla*, *P. menziesii*) traits for these tree species. The chemical nature and availability of soil P to
384 trees, particularly as P_o, deserves further investigation as many of these perhumid rainforests were co-
385 limited by both N and P, or, in some stands, possibly P alone.

386

387 **Acknowledgements**

388 The planting density trial (EP571) was established by J.C. Hetherington of the B.C. Ministry of
389 Forests, Lands and Natural Resources in cooperation with British Columbia Forest Products Ltd. and
390 MacMillan Bloedel Ltd. Plot maintenance and stand remeasurements over the many decades were
391 managed by research personnel of the B.C. Ministry of Forests, Lands and Natural Resources including S.A.Y
392 Omule, D. Paul, L. Meyer and D. Goldie, plus a number of dedicated contractors. We thank Justin Meeds
393 (University of UBC Okanagan) and Heather Klassen (B.C. Ministry of Forests, Lands and Natural Resources)
394 for assistance in field sampling of soils and foliage. Laboratory analysis was undertaken by Kristopher
395 Beaudet and Amber Sadowy of the B.C. Ministry of Environment Analytical Laboratory. Statistical advice
396 was provided by Peter Ott (B.C. Ministry of Forests, Lands and Natural Resources). Funds for this study
397 were provided by the B.C. Ministry of Forests, Lands and Natural Resources.

398 **Data Availability**

399 All data related to the study archived with Dryad at <https://doi.org/10.5061/dryad.0gb5mkkwr>

400 **Author Contribution**

401 LD was responsible for EP571 administration, including research site maintenance, tree measurements and
402 data archiving; JK conceived study design for soil covariates; JK and AS undertook field soil sampling and
403 laboratory preparation; JK and AS contributed statistical analysis; JK wrote manuscript with substantial
404 contributions by AS and LD.

405 **Competing interests**

406 The authors declare that they have no conflict of interest.
