Keywords: ETSP, ODZ, denitrification, nitrification, N₂O production, ¹⁵N tracer incubations

15 **Abstract.** Oxygen deficient zones (ODZs) are major sites of net natural nitrous oxide (N₂O) production and emissions. In order to understand changes in the magnitude of N₂O production in response to global change, knowledge on the individual contributions of the major microbial pathways (nitrification and denitrification) to N₂O production and their regulation is needed. In the ODZ in the coastal area off Peru, the sensitivity of N₂O production to oxygen and organic matter was investigated using ¹⁵N-tracer experiments in combination with qPCR
20 and microarray analysis of total and active functional genes targeting archaeal *amoA* and *nirS* as marker genes for nitrification and denitrification, respectively. Denitrification was responsible for the highest N₂O production with a mean of 8.7 nmol L⁻¹ d⁻¹ but up to 118 ± 27.8 nmol L⁻¹ d⁻¹ just below the oxic-anoxic interface. Highest N₂O production from ammonium oxidation (AO) of 0.16 ± 0.003 nmol L⁻¹ d⁻¹ occurred in the upper oxycline at O₂ concentrations of 10 - 30 μmol L⁻¹ which coincided with highest archaeal *amoA* transcripts/genes. Oxygen
25 responses of N₂O production varied with substrate, but production and yields were generally highest below 10 μmol L⁻¹ O₂. Particulate organic matter additions increased N₂O production by denitrification up to 5-fold suggesting increased N₂O production during times of high particulate organic matter export. High N₂O yields of 2.1% from AO were measured, but the overall contribution by AO to N₂O production was still an order of magnitude lower than that of denitrification. Hence, these findings show that denitrification is the most important
30 N₂O production process in low oxygen conditions fueled by organic carbon supply, which implies a positive feedback of the total oceanic N₂O sources in response to increasing oceanic deoxygenation.

Introduction

Nitrous oxide (N₂O) is a potent greenhouse gas (IPCC 2013) and precursor for nitric oxide (NO) radicals, which can catalyze the destruction of ozone in the stratosphere (Crutzen 1970, Johnston 1971), and is now the single most important ozone-depleting emission (Ravishankara et al. 2009). The ocean is a significant N₂O source, accounting for up to one third of all- natural emissions (IPCC 2013) and this source may increase substantially as a result of eutrophication, warming, and ocean acidification (see e.g. Capone and Hutchins 2013, Breider et al. 2019). Major sites of oceanic N₂O emissions are regions with steep oxygen (O₂) gradients (oxycline), which are usually associated with coastal upwelling regions with high primary production at the surface. There, high microbial respiratory activity during organic matter decomposition leads to the formation of anoxic waters also called oxygen deficient zones (ODZs), in which O₂ may decline to functionally anoxic conditions (O₂ < 10 nmol kg⁻¹, Tiano et al. 2014). The most intense ODZs are found in the eastern tropical North Pacific (ETNP), the eastern tropical South Pacific (ETSP) and the northwestern Indian Ocean (Arabian Sea). The anoxic waters are surrounded by large volumes of hypoxic waters (below 20 μmol L⁻¹ O₂) which are strong net N₂O sources (Codispoti 2010; Babbin et al. 2015). Latest estimates of global, marine N₂O fluxes (Buitenhuis et al. 2018, Ji et al. 2018) agree well with the 3.8 Tg N y⁻¹ (1.8 – 9.4 Tg N y⁻¹) reported by the IPCC (2013), but have large variability in the resolution on the regional scale, particularly along coasts where N₂O cycling is more dynamic. The expansion of ODZs is predicted in global change scenarios and has already been documented in recent decades (Stramma et al. 2008, Schmidtko et al. 2017). This might lead to further intensification of marine N₂O emissions, which will constitute a positive feedback on global warming (Battaglia and Joos, 2018). However, decreasing N₂O emissions have also been predicted based on reduced nitrification rates due to reduced primary and export production (Martinez-Rey et al. 2015, Landolfi et al. 2017) and ocean acidification (Beman et al. 2011, Breider et al. 2019). The parametrization of N₂O production and consumption in global ocean models is crucial for realistic future predictions, and therefore better understanding of their controlling mechanisms is needed.

N₂O can be produced by both nitrification and denitrification. Nitrification is a two-step process, comprising the oxidation of ammonia (NH₃) to nitrite (NO₂⁻) (ammonia oxidation, AO) and nitrite to nitrate (NO₃⁻) (nitrite oxidation). The relative contributions to AO by autotrophic ammonia-oxidizing archaea (AOA) and ammonia-oxidizing bacteria (AOB) have been inferred, based on the abundance of the archaeal and bacterial *amoA* genes, which encode subunit A of the key enzyme ammonia monooxygenase (e.g. (Francis et al. 2005, Mincer et al. 2007, Santoro et al. 2010, Wuchter et al. 2006)). These studies consistently revealed the dominance of archaeal over bacterial ammonia oxidizers, particularly in marine settings (Francis et al. 2005, Wuchter et al. 2006, Newell et al. 2011). In oxic conditions, AO by AOB and AOA forms N₂O as a by-product (Anderson 1964; Vajjala et al. 2013; Stein 2019) and AOA contribute significantly to N₂O production in the ocean (Santoro et al. 2011; Löscher et al. 2012). While hydroxylamine (NH₂OH) was long thought to be the only obligate intermediate in AO, NO has recently been identified as an obligate intermediate for AOB (Caranto and Lancaster 2017) and presumably AOA (Carini et al. 2018). Both intermediates are present in and around ODZs and correlated with nitrification activity (Lutterbeck et al. 2018, Korth et al. 2019). Specific details about the precursor of NO to form N₂O in AOA remains controversial. Stiegelmeier et al. (2014) concluded that NO is derived from NO₂⁻ reduction to form N₂O, while Carini et al. (2018) hypothesized that NO is derived from NH₂OH oxidation, which can then form N₂O. A hybrid N₂O production mechanism in AOA has been suggested, where NO from NO₂⁻ reacts with NH₂OH from NH₄⁺, which is thought to be abiotic, i.e., non-enzymatic (Koslovski et al. 2016). Abiotic N₂O production from intermediates like NH₂OH, NO or NO₂⁻ can occur under acidic conditions (Frame et al. 2017), or in the presence

of reduced metals like Fe or Mn and catalyzing surfaces (Zhu-Barker et al. 2015), but the evidence of abiotic N₂O
75 production in ODZs is still lacking.

When O₂ concentrations fall below 20 μmol L⁻¹, nitrifiers produce N₂O from NO₂⁻, a process referred to
as nitrifier - denitrification (Frame & Casciotti 2010), which has been observed in cultures of AOB (Frame &
Casciotti 2010) and AOA (Santoro et al. 2011). During nitrifier-denitrification, two NO₂⁻ molecules form one N₂O,
80 which thus differentiates this process from hybrid N₂O production. Overall, the yield of N₂O per NO₂⁻ increases
with decreasing O₂ concentrations, which favors higher N₂O production by nitrification in hypoxic waters (Cohen
& Gordon 1978; Yoshida 1988; Goreau et al. 1980; Löscher et al. 2012, Ji et al. 2015a, 2018a).

The anaerobic oxidation of ammonia by nitrite (anammox) to form N₂ is strictly anaerobic and important
in the removal of fixed N from the system, but it is not known to contribute to N₂O production (Kartal et al. 2007,
van der Star et al. 2008, Hu et al. 2019). In suboxic and O₂ free environments, oxidized nitrogen is respired by
85 bacterial denitrification, which is the stepwise reduction of nitrate to elemental N₂ via nitrite, NO and N₂O. N₂O
as an intermediate can be consumed or produced, but at the core of the ODZ N₂O consumption through
denitrification is enhanced, leading to an under saturation in this zone (Bange 2008, Kock et al. 2016). Reducing
enzymes are highly regulated by O₂ concentrations and of the enzymes in the denitrification sequence, N₂O
reductase is the most sensitive to O₂ (Zumft 1997), which can lead to the accumulation of N₂O along the upper
90 and lower ODZ boundaries (Kock et al. 2016). N₂O accumulation during denitrification is mostly linked to O₂
inhibiting the N₂O reductase, but other factors such as sulfide accumulation (Dalsgaard et al. 2014), pH (Blum et
al. 2018), high NO₃⁻ or NO₂⁻ concentrations (Ji et al. 2018), or copper limitation (Granger and Ward 2003) may
also be relevant. Recent studies contrast the view of nitrification vs. denitrification as the main N₂O source in
ODZs (Nicholls et al. 2007, Babbín et al. 2015, Ji et al. 2015a, Yang et al. 2017). They show the importance of
95 denitrification in N₂O production in the ETNP from model outputs (Babbín et al. 2015) and in the ETSP from
tracer incubation experiments (Dalsgaard et al. 2012, Ji et al. 2015a), based on natural abundance isotopes in N₂O
(Casciotti et al. 2018) or from water mass analysis of apparent N₂O production (ΔN₂O) and O₂ utilization (AOU)
(Carrasco et al. 2017).^{45,46}N₂O production from the addition of ¹⁵N-labeled NH₄⁺, NO₂⁻ and/or NO₃⁻ revealed
nitrification as a source of N₂O within the oxic-anoxic interface, but overall denitrification dominated N₂O
100 production with higher rates at the interface and in anoxic waters (Ji et al. 2015a, 2018a). Denitrification is driven
by organic matter exported from the photic zone and fuels blooms of denitrifiers leading to high N₂ production
(Dalsgaard et al. 2012, Jayakumar et al. 2009, Babbín et al. 2014). Denitrification to N₂ is enhanced by organic
matter additions and the degree of stimulation varies with quality and quantity of organic matter (Babbín et al.
2014). Because N₂O is an intermediate in denitrification, we hypothesize that its production should also be
105 stimulated by organic matter, possibly leading to episodic and variable N₂O fluxes.

N₂O concentration profiles around ODZs appear to be at steady state (Babbín et al. 2015), but are much
more variable in regions of intense coastal upwelling where high N₂O emissions can occur (Arévalo-Martínez et
al. 2015). The contributions of and controls on the two N₂O production pathways under different conditions of O₂
and organic matter supply, are not well understood and may contribute to this variability. Hence, the goal of this
110 study is to understand the factors regulating N₂O production around ODZs in order to better constrain how future
changes in O₂ concentration and carbon export will impact production, distribution and emissions of oceanic N₂O.
Our goal was to determine the impact of O₂ and particulate organic matter on N₂O production rates using ¹⁵N tracer
experiments in combination with qPCR and functional gene microarray analysis of the marker genes, *nirS* for
denitrification and *amoA* for AO by archaea, to assess how the abundance and structure of the community impacts

115 N₂O production rates from the different pathways. ¹⁵N-labelled NH₄⁺ and NO₂⁻ was used to trace the production
of single- (⁴⁵N₂O) and double- labelled (⁴⁶N₂O) N₂O to investigate the importance of hybrid N₂O production during
AO along an O₂ gradient.

2 Materials and Methods

120 2.1 Sampling sites, sample collection and incubation experiments

Seawater was collected from 9 stations in the upwelling area off the coast of Peru in June 2017 onboard
R/V Meteor (Figure 1). Water samples were collected from 10 L Niskin bottles on a rosette with a conductivity-
temperature-depth profiler (CTD, seabird electronics 9plus system). In-situ O₂ concentrations (detection limit 2
μmol L⁻¹ O₂), temperature, pressure and salinity were recorded during each CTD cast. NO₂⁻ and NO₃⁻
125 concentrations were measured on board by standard spectrophotometric methods (Hydes et al. 2010) using a
QuAatro autoanalyzer (SEAL Analytical GmbH, Germany). NH₄⁺ concentrations were determined
fluorometrically using ortho- phthaldialdehyde according to Holmes et al. (1999). At all experimental depths
nucleic acid samples were collected by filtering up to 5 L of seawater onto 0.2 μm pore size Sterivex-GP capsule
filters (Millipore, Inc., Bedford, MA, USA). Immediately after collection filters were flash frozen in liquid nitrogen
130 and kept at -80°C until extraction.

Three different experiments were carried out at coastal stations, continental slope and offshore stations.
Experiments 1 and 2 aimed to investigate the influence of O₂ concentration along a natural and artificial O₂ gradient
and experiment 3 targeted the impact of large particles (>50 μm) on N₂O production. Serum bottles were filled
from the Niskin bottles with Tygon tubing after overflowing three times to minimize O₂ contamination. Bottles
135 were sealed bubble free with grey butyl rubber septa (National Scientific) and crimped with aluminum seals
immediately after filling. A 3 mL helium (He) headspace was created and samples from anoxic water depths were
He purged for 15min. Natural abundance 1000 ppm N₂O carrier gas (50 μL in He) was injected to trap the produced
labeled N₂O and to ensure a sufficient mass for isotope analysis. ¹⁵N-NO₂⁻, ¹⁵N-NO₃⁻, and ¹⁵N-NH₄⁺ tracer
(¹⁵N/(¹⁴N+¹⁵N) = 99 atom-%) were injected into five bottles each from the same depth to a final concentration of
140 0.5 μmol L⁻¹, except for the NO₃⁻ incubations where 2 μmol L⁻¹ final concentration were anticipated to obtain 10
% label of the NO₃⁻ pool. The fraction labeled of the substrate pools was 0.76 – 0.99 for NH₄⁺, 0.11 – 0.99 for
NO₂⁻, 0.055 – 0.11 for NO₃⁻. In the ¹⁵N-NO₃⁻ treatment, ¹⁴N-NO₂⁻ was added to trap the label in the product pool
for nitrate reduction rates and in the ¹⁵N-NH₄⁺ treatment, ¹⁴N-NO₂⁻ was added to a final concentration of 0.5 μmol
L⁻¹ to trap the label in the product pool for AO rates.

145 For the O₂ manipulation experiments, headspace volume was adjusted depending on the amount of site
water added and all samples were He purged. Site water from the incubation depth was shaken and exposed to air
to reach full O₂ saturation. Then 0.2, 0.5, 2 and 5mL O₂ saturated seawater was added into serum bottles and to
reach final measured O₂ concentration of 0 ± 0.18 μM, 0.4 ± 0.24 μM, 1.6 ± 0.12 μM, 5.2 ± 0.96 μM and 11.7
± 1.09 μM in seawater. For the ¹⁵N-NO₃⁻ incubations two more O₂ treatments with 13.6 ± 1.4 μM and 21.5 ± 3.35
150 μM O₂ were carried out. The O₂ concentration was monitored with an O₂ sensor spot in one serum bottle per
treatment using an O₂ probe and meter (FireSting, PyroScience, Aachen, Germany). The sensor spots are highly
sensitive in the nanomolar range and prepared according to Larsen et al. (2016).

For the organic matter additions, concentrated particles > 50 μm from 3 different depths were collected
with a Challenger stand-alone pump system (SAPS *in situ* pumps, Liu et al. 2005), autoclaved and He purged

155 before 200 μ L of POC solution were added to each serum bottle. The final concentrations and C/N ratios varied
between 0.18 – 1.37 μ M C and 8.1 – 15.4, respectively (Table 2). The concentration and C/N ratio of PON and
POC of the stock solutions were analyzed by mass spectrometry using GV Isoprime mass spectrometer.

A set of five bottles was incubated per time course. One bottle was sacrificed at t_0 , two bottles at t_1 and
two at t_2 to determine a single rate. Total incubation time for each experiment varied from 12 hours (at the shelf
160 stations) to 24 hours (at the slope stations). Incubation was terminated by adding 0.1 mL saturated mercuric
chloride (HgCl₂). All samples were stored at room temperature in the dark and shipped back to the lab.

2.2 Isotope measurement and rate determination

The total N₂O in each incubation bottle was extracted with a purge-trap system according to Ji et al.
165 (2015). Briefly, serum bottles were flushed with He for 35 min (38 ml min⁻¹), N₂O was trapped by liquid nitrogen,
H₂O removed with an ethanol trap, a Nafion® trap and a Mg(ClO₄)₂ trap and CO₂ removed with an Ascarid CO₂-
Adsorbance column and afterwards mass 44, 45, 46 and isotope ratios 45/44, 46/44 were detected with a GC-
IRMS system (Delta V Plus, Thermo). Every two to three samples, a 20 mL glass vial with a known amount of
N₂O gas was measured to calibrate for the N₂O concentration (linear correlation between N₂O peak size and
170 concentration, $r^2=0.99$). The isotopic composition of the reference N₂O was $\delta^{15}\text{N}=1.75 \pm 0.10 \text{ ‰}$ and $\delta^{18}\text{O}=1.9$
 $\pm 0.19 \text{ ‰}$ present in ¹⁵N¹⁴N¹⁶O or ¹⁴N¹⁵N¹⁶O for ⁴⁵N₂O and the less abundant ¹⁵N¹⁵N¹⁶O for ⁴⁶N₂O. To evaluate the
analyses of ¹⁵N-enriched N₂O samples, internal isotope standards for ¹⁵N₂O were prepared by mixing natural
abundance KNO₃ of known $\delta^{15}\text{N}$ values with 99% Na¹⁵NO₃ (Cambridge Isotope Laboratories) and converted to
N₂O using the denitrifier method (Sigman et al. 2001, Weigand et al. 2016). Measured and expected values were
175 compared based on a binominal distribution of ¹⁵N and ¹⁴N within the N₂O pool (Frame et al. 2017).

After N₂O analysis, samples incubated with ¹⁵NH₄⁺ and ¹⁵NO₃⁻ were analyzed for ¹⁵NO₂⁻ to determine
rates of NH₄⁺ oxidation and NO₃⁻ reduction, respectively. The individual sample size, adjusted to contain 20 nmol
of N₂O, was transferred into 20 mL glass vials and He purged for 10 min. NO₂⁻ was converted to N₂O using sodium
azide in acetic acid (McIlvin and Altabet, 2005) and the nitrogen isotope ratio was measured on a Delta V Plus
180 (Thermo).

For each serum bottle, total N₂O concentration (moles) and ⁴⁵N₂O/⁴⁴N₂O and ⁴⁶N₂O/⁴⁴N₂O ratios were
converted to moles of ⁴⁴N₂O, ⁴⁵N₂O and ⁴⁶N₂O. N₂O production rates were calculated from the slope of the increase
in mass 44, 45 and 46 over time. To quantify the pathways for N₂O production, rates were calculated based on the
equations for N₂ production for denitrification and anammox (Thamdrup and Dalsgaard, 2002). In incubations
185 with ¹⁵NH₄⁺ and unlabeled NO₂⁻, it is assumed that AO produces ⁴⁶N₂O from two labeled NH₄⁺ (equation 1) and
some ⁴⁵N₂O-labeled N₂O based on binomial distribution (equation 2). If more single labelled N₂O is produced than
what is expected (equation 2 and 3) than a hybrid formation of one nitrogen atom from NH₄⁺ and one from NO₂⁻
(equation 4) is taking place as found in archaeal ammonia oxidizers (Kozłowski et al. 2016). In incubations with
¹⁵NO₂⁻, we assume that ⁴⁶N₂O comes from nitrifier-denitrification or denitrification, which cannot be distinguished
190 (equation 1). Hence, any production of ⁴⁵N₂O not attributed to denitrification stems from hybrid N₂O formation
by archaeal nitrifiers (equation 4). In incubations with ¹⁵NO₃⁻, denitrification produces ⁴⁶N₂O and was the only
process considered and hence was calculated based on equation (1). Rates (R) are calculated as nmol N₂O L⁻¹ d⁻¹
(Trimmer et al. 2016):

$$(1) R_{external} = slope^{46}N_2O \times (f_N)^{-2}$$

$$195 (2) R_{expected} = slope^{46}N_2O \times 2 \times (1 - f_N) \times (f_N)^{-1}$$

$$(3) R_{above} = slope^{45}N_2O - p^{45}N_2O_{expected}$$

$$(4) R_{hybrid} = (f_N)^{-1} \times (slope^{45}N_2O + 2 \times slope^{46}N_2O \times (1 - f_N))$$

$$(5) R_{total} = pN_2O_{external} + pN_2O_{hybrid}$$

where f_N is the fraction of ^{15}N in the substrate pool (NH_4^+ , NO_2^- or NO_3^-) which is assumed to be constant over the incubation time. Hence, changing f_N due to any other concurrent N-consumption or production process during the incubation is neglected. For example, accounting for a decrease in f_N of the nitrate pool by active nitrite oxidation, the process with highest rates (Sun et al. 2017), had an effect of only $\pm 0.2\%$ on the final rate estimate. Slope of $^{46}N_2O$ and slope of $^{45}N_2O$ represent the $^{46}N_2O$ and $^{45}N_2O$ production rates, which were tested for significance based on a linear regression ($n=5$, student t-test, $p<0.05$). Linear regressions that were not significantly different from zero were reported as 0. The error for each N_2O production rate was calculated as the standard error of the slope. Detection limits were $0.002 \text{ nmol L}^{-1} \text{ d}^{-1}$ for N_2O production from AO and $0.1 \text{ nmol L}^{-1} \text{ d}^{-1}$ for N_2O production from denitrification based on the average measured standard error for rates (Dalsgaard et al. 2012). The curve-fitting tool of Sigma Plot was used for the O_2 sensitivity experiments. A one-way ANOVA was performed on the N_2O production rates to determine if rates were significantly different between POM treatments.

The rates (R) of NH_4^+ oxidation to NO_2^- and NO_3^- reduction to NO_2^- were calculated based on the slope of the linear regression of $^{15}NO_2^-$ enrichment over time ($n = 5$) (equation 6).

$$(6) R = f_N^{-1} \times slope \delta^{15}NO_2^-$$

where f_N is the fraction of ^{15}N in the substrate pool (NH_4^+ or NO_3^-).

Yield (%) of N_2O production during NH_4^+ oxidation was defined as the ratio of the production rates (equation 7).

$$(7) Yield_{NH_4} = \frac{N - N_2O \left(\frac{nM}{d}\right)}{N - NO_2^- \left(\frac{nM}{d}\right)} \times 100\%$$

Yields of N_2O production during denitrification were calculated based on the fact that N_2O is not a side product during nitrate reduction to NO_2^- but rather the next intermediate during denitrification (equation 8).

$$(8) Yield_{NO_3} = \frac{N - N_2O \left(\frac{nM}{d}\right)}{N - NO_2^- \left(\frac{nM}{d}\right) + N - N_2O \left(\frac{nM}{d}\right)} \times 100\%$$

All rates, yields and errors are reported in Table S3.

220

2.3 Molecular Analysis – qPCR, Microarrays

DNA and RNA were extracted using the DNA/RNA ALLPrep Mini Kit (Qiagen) followed by immediate cDNA Synthesis from purified and DNA-cleaned RNA using a SuperScript III First Strand Synthesis System (Invitrogen). The PicoGreen dsDNA Quantification Kit (Invitrogen) was used for DNA quantification and Quant-iT OliGreen ssDNA Quantification Kit (life technologies) was used for cDNA quantification.

225

The abundances of total and active *nirS* and archaeal *amoA* communities were determined by quantitative PCR (qPCR) with assays based on SYBR Green staining according to methods described previously (Jayakumar et al. 2013, Peng et al. 2013). Primers *nirS1F* and *nirS3R* (Braker et al. 1998) were used to amplify a 260-bp conserved region within the *nirS* gene. Primers Arch-*amoAF* and Arch-*amoAR* (Francis et al. 2005) were used to quantify archaeal *amoA* abundance. A standard curve containing 6 serial dilutions of a plasmid with either an archaeal *amoA* fragment or a *nirS* fragment was used on respective assay plates. Assays were performed in a

230

StratageneMx3000P qPCR cycler (Agilent Technologies) in triplicates of 20- 25ng DNA or cDNA, along with a no primer control and a no template control. Cycle thresholds (Ct values) were determined automatically and used to calculate the number of *nirS* or archaeal *amoA* copies in each reaction, which was then normalized to copies per milliliter of seawater (assuming 100% recovery). The detection limit was around 15 copies mL⁻¹ based on the Ct values of the no template control.

Microarray experiments were carried out to describe the community composition of the total and active *nirS* and archaeal *amoA* groups using the DNA and cDNA qPCR products. Pooled qPCR triplicates were purified and cleaned using the QIAquick PCR Purification Kit (Qiagen). Microarray targets were prepared according to Ward and Bouskill (2011). Briefly, dUaa was incorporated into DNA and cDNA targets during linear amplification with random octomers and a Klenow polymerase using the BioPrime kit (Invitrogen) and then labeled with Cy3, purified and quantified. Each probe is a 90-mer oligonucleotide consisting of a 70-mer archetype sequence combined with a 20-mer reference oligo as a control region bound to the glass slide. Each archetype probe represents a group of related sequences with 87 ± 3% sequence identity of the 70-mer sequence. Microarray targets were hybridized in duplicates on a microarray slide, washed and scanned using a laser scanner 4200 (Agilent Technologies) and analyzed with GenePix Pro 6.0. The resulting fluorescence ratio (FR) of each archaeal *amoA* or *nirS* probe was divided by the FR of the maximum archaeal *amoA* or *nirS* FR on the same microarray to calculate the normalized FR (nFR). nFR represents the relative abundance of each archetype and was used for further analyses.

Two different arrays were used, BCO16 which contains 99 archaeal *amoA* archetype probes representing ~8000 archaeal *amoA* sequences (Biller et al. 2012) and BCO15 which contains 167 *nirS* archetype probes representing ~2000 sequences (collected from NCBI in 2009). A total of 74 assays were performed with 21 *nirS* cDNA targets, 21 *nirS* DNA targets, 16 *amoA* cDNA targets and 16 *amoA* DNA samples. The original microarray data from BCO15 and BCO16 are available via GEO (Gene Expression Omnibus; <http://www.ncbi.nlm.nih.gov/geo/>) at NCBI (National Center for Biotechnology Information) under GEO Accession No XXXX.

2.4. Data analysis

Spearman Rank correlation was performed from all N₂O production rates, AO and nitrate reduction rates, environmental variables, *nirS* and archaeal *amoA* gene and transcript abundance as well as the 20 most abundant archetypes of total and active *nirS* and *amoA* using R. Only significant values (p<0.05) are shown. Archetype abundance (nFR) data were square-root transformed and beta-diversity was calculated with the Bray-Curtis coefficient. Alpha diversity of active and total *nirS* and *amoA* communities was estimated by calculating the Shannon diversity index using PRIMER6. Bray-Curtis dissimilarities were used to perform a Mantel test to determine significant differences between active and total communities of *nirS* and *amoA* using R (Version 3.0.2, package “vegan” (Oksanen et al., 2019). Canonical Correspondence Analysis (CCA) (Legendre & Legendre 2012) was used to visualize differences in community composition dependent upon environmental conditions using the software PAST (Hammer et al. 2001). Before CCA analysis, a forward selection (Borcard et al. 1992) of the parameters that described the environmental and biological variables likely to explain the most significant part of the changes in the archetypes was performed.

The make.lefse command in MOTHUR was used to create a linear discriminant analysis (LDA) effect size (LEfSe) (Segata et al. 2011) input file from the MOTHUR shared file. This was followed by a LEfSe (<http://huttenhower.sph.harvard.edu/lefse/>) to test for discriminatory archetypes between O₂ levels. With a

normalized relative abundance matrix, LEfSe uses the Kruskal-Wallis rank sum test to detect features with significantly different abundances between assigned archetypes in the different O₂ levels and performs an LDA to estimate the effect size of each feature. A significant alpha of 0.05 and an effect size threshold of 2 were used for all marker genes discussed in this study.

3. Results

3.1 Hydrographic conditions

The upwelling system off Peru is a hot spot for N₂O emissions (Arévalo-Martínez et al. 2015) with most intense upwelling in austral winter but maximum chlorophyll during December to March (Chavez and Messié, 2009; Messié and Chavez, 2015). The sampling campaign took place during austral fall in the absence of intense upwelling or maximum chlorophyll. The focus of this study was the region close to the coast, which has highly variable N₂O concentration profiles (Kock et al. 2016) and N₂O emissions (Arévalo-Martínez et al. 2015). The Peru Coastal Water (PCW, temperature <19.5°C, salinity 34.9 - 35.1) and the equatorial subsurface waters (ESSW, temperature 8-12°C, salinity 34.7 - 34.9) (Pietri et al. 2013) were the dominant water masses off the Peruvian coast sampled for N₂O production rate measurements (Table 1). At the southern-most transect at 15.5° - 16°S a meso-scale anticyclonic mode water eddy (McGillicuddy et al. 2007), which was about to detach from the coast, was detected from deepening/shoaling of the main/seasonal pycnoclines (Bange et al. 2018, Figure S1). Generally, the stations were characterized by a thick anoxic layer (254 m - 427 m) reaching to the seafloor at two shelf stations (894, 883). NO₂⁻ concentration accumulated only up to 2 μmol L⁻¹ in the secondary nitrite maximum (SNM) at the northern transect (stations 882, 883), but up to 7.19 μmol L⁻¹ along the southern transect (Figure 2, station 907, 912). N₂O concentration profiles showed a high variability with respect to depth and O₂ concentrations (Figure 2). The southern transect (station 907,912) showed the lowest N₂O concentrations (5 nmol L⁻¹) in the center of the anoxic zones. At the same time, station 912 in the center of the eddy showed highest N₂O concentration with 78.9 nmol L⁻¹ at [O₂] below detection limit in the upper part of the anoxic zone. Above the ODZ, the maximum N₂O peak ranged from 57.9 - 78.9 nmol L⁻¹ and was found at an O₂ concentration range from below detection (883, 894, 892, 912) up to 67 μmol L⁻¹ (907). Three stations (892, 894 and 904) showed high surface N₂O concentrations of 64 nmol L⁻¹.

3.2 Depth Distribution of N₂O production rates and total and active nirS and amoA abundance

N₂O production varied with depth and substrate (Figure 3, Table S3). In the oxycline, highest AO (34 ± 0.1 nmol L⁻¹ d⁻¹ and 35 ± 9.2 nmol L⁻¹ d⁻¹) coincided with highest N₂O production from AO (0.141 ± 0.003 nmol L⁻¹ d⁻¹ and 0.159 ± 0.003 nmol L⁻¹ d⁻¹) at both stations of the northern transect, stations 883 and 882, respectively (Figure 3(I)a, b). NH₄⁺ oxidation and its N₂O production decreased to zero in the ODZ. The rates of the reductive source pathways for N₂O increased with depth. N₂O production from NO₂⁻ and NO₃⁻ displayed similar patterns with highest production at or below the oxic -anoxic interface (Figure 3(II)). N₂O production from NO₂⁻ showed highest rates of 3.06 ± 1.17 nmol L⁻¹ d⁻¹ (912) and 2.37 ± 0.54 nmol L⁻¹ d⁻¹ (906) further south (Figure 3(II) m, q) compared to lower rates at northern stations, where the maximum rate was 0.71 ± 0.38 nmol L⁻¹ d⁻¹ (Figure 3(II) c, 883). A similar trend was found for N₂O production from NO₃⁻: lower maximum rates at northern stations with 2.7 ± 0.4 nmol L⁻¹ d⁻¹ (882) and 5.7 ± 2.8 nmol L⁻¹ d⁻¹ (883, Figure 3(II) b) and highest rates in southern transects

with $7.2 \pm 1.64 \text{ nmol L}^{-1} \text{ d}^{-1}$ ((Figure 3(II) l, 904) in transect 3 and up to $118.0 \pm 27.8 \text{ nmol L}^{-1} \text{ d}^{-1}$ (Figure 3(II) p, 912) in transect 4. Generally, N_2O production rates from NO_2^- and NO_3^- were 10 to 100-fold higher than from AO.

qPCR analysis detected lowest gene and transcript numbers of archaeal *amoA* and *nirS* in the surface mixed layer (Figure 3(I) k, l, 3(II)r, s). Highest archaeal *amoA* gene and transcript abundance was in the oxycline (1 – 40 $\mu\text{mol L}^{-1} \text{ O}_2$) with $24,500 \pm 340 \text{ copies mL}^{-1}$ and $626 \pm 29 \text{ copies mL}^{-1}$ at station 883 (Figure 3(I)c, d). *amoA* gene and transcript number decreased in the ODZ to 1000 – 6500 gene copies mL^{-1} and 20 - 250 transcript copies mL^{-1} . The profiles of *nirS* gene and transcript abundance were similar to each other (Figure 3(II) d, e) with highest abundance in the ODZ up to $1 \times 10^6 \text{ copies mL}^{-1}$ and $2.9 \times 10^5 \text{ copies mL}^{-1}$, respectively. Denitrifier *nirS* genes and transcripts peaked in the anoxic layer and were significantly correlated with N_2O production from NO_2^- but not from NO_3^- . Archaeal *amoA* gene and transcript abundances were significantly correlated with AO and, N_2O production from AO (Figure S3). N_2O concentrations did not correlate with any of the measured variables (Figure S3).

3.3 Influence of O_2 concentration on N_2O production

N_2O production along the *in situ* O_2 gradient for the substrates NO_2^- and NO_3^- decreased exponentially with increasing O_2 concentrations (Figure 4b, c) while for NH_4^+ , the N_2O production was highest at highest sampled O_2 concentration (Figure 4a). At *in situ* O_2 levels above $8.4 \mu\text{mol L}^{-1}$ N_2O production decreased by 100% and 98% from NO_3^- and NO_2^- , respectively (Figure 4b, c).

In the manipulated O_2 treatments from the oxic - anoxic interface (S11, S19) a unimodal response of N_2O production from NH_4^+ and NO_2^- to O_2 is apparent (Figure 4d, e). Increasing and decreasing O_2 concentrations inhibited N_2O production from NH_4^+ and NO_2^- with the highest N_2O production rate between $1.4 - 6 \mu\text{mol O}_2 \text{ L}^{-1}$. However, this response was only significant in sample S11 (Figure 4d, e). There was no significant response to O_2 concentration of N_2O production from NO_3^- . O_2 did not inhibit N_2O production from NO_3^- up to $23 \mu\text{mol L}^{-1}$ (Figure 4f).

The proportion of hybrid N_2O produced during AO, i.e., the formation of N_2O from one ^{15}N from the labelled NH_4^+ and one ^{14}N from a non - labelled N compound (excluding NH_4^+) such as NO_2^- , NH_2OH or NO , was consistently between 70 – 85 % across different O_2 concentrations for manipulated and natural O_2 concentrations (Figure 5a, c). Hybrid formation during N_2O production from NO_2^- varied between 0 and 95% along the natural O_2 gradient (Figure 5b). In manipulated O_2 treatments hybrid formation from NO_2^- did not change across different O_2 treatments but with respect to the original depth, 0% in sample S11 which originated from 145 m of station 892 or 78% in sample S19 from 120m of station 894 (Figure 5d).

Highest N_2O yields during AO (over 1%) occurred between 1.4 and $2 \mu\text{mol O}_2 \text{ L}^{-1}$, and decreased at both higher and lower O_2 concentrations (Figure 6a). However, only the increase in yield from nmol O_2 to $1.4 - 2 \mu\text{mol L}^{-1} \text{ O}_2$ was significant (t-test, $p < 0.05$) and the following decrease in yield was not (t-test, $p > 0.05$). In the manipulated O_2 treatment of sample S19 (Figure 6c) the same significant pattern was observed, whereas in S11 highest yield was found at $12 \mu\text{mol L}^{-1} \text{ O}_2$. N_2O yield during nitrate reduction to NO_2^- decreased to zero at $8.4 \mu\text{mol L}^{-1} \text{ O}_2$ along the natural O_2 gradient (Figure 6b) while no significant response occurred in the manipulated O_2 treatments (Figure 6d). There, nitrate reduction was decreasing with increasing O_2 but N_2O production was steady with increasing O_2 leading to high yields between $38.8 \pm 9 \%$ - $91.2 \pm 47 \%$ at $23 \mu\text{mol L}^{-1} \text{ O}_2$.

3.4 Effect of large particulate organic matter on N₂O production

The autoclaving of the concentrated POM solution liberated NH₄⁺, reducing the N/C ratio of the particles compared to non-autoclaved particles (Table 2). The highest NH₄⁺ accumulation is found in samples with the largest difference in N/C ratios (Table 2, 904-20m, 898-100 m). Addition of 0.17 – 1.37 μmol C L⁻¹ of autoclaved particles > 50 μm (Table 2) produced a significant increase in N₂O production by up to 5.2- and 4.8-fold in 10 and 7 out of 19 additions for NO₂⁻ and NO₃⁻ respectively (Figure 7a, b). There was no linear correlation of the origin (mixed layer depth, oxycline or anoxic zone), the quality (N/C ratio) or the quantity of the organic matter on the magnitude of the increase. Only samples S20 and S17 were not stimulated by particle addition and N₂O production from denitrification did not significantly differ from the control (Figure 7b).

3.5 Diversity and community composition of total and active nirS and amoA assemblages and its correlation with environmental parameters

nFR values from functional gene microarrays were used to describe the nitrifier and denitrifier community composition of AOA and *nirS* assemblages, respectively. nFR was averaged from duplicate microarrays, which replicated well (R² = 0.89 - 0.99). Alpha- diversities of *nirS* and archaeal *amoA* were not statistically different for total and active communities (students t-test, p > 0.05), but were overall lower for RNA (3.2 ± 0.3) than DNA (3.8 ± 0.4) (Table S1). Principle Coordinate Analysis of Bray–Curtis similarity for each probe group on the microarray indicated that the community structure of archaeal *amoA* genes was significantly different from that of archaeal *amoA* transcripts whereas community structure of *nirS* genes and transcripts did not differ significantly (Figure S2). To identify which archetypes were important in explaining differences in community structure of key nitrification and denitrification genes, we identified archetypes that accounted for more than 1% of the total fluorescence for their probe set and that were significantly different with respect to ambient O₂ using a lefse analysis (Table S2). Furthermore, we used CCA to test whether the community composition, or even single archetypes, could explain the N₂O production rates.

The nFR distribution showed greater variability in the active (cDNA) AOA community than in the total community (DNA) among depths, stations and O₂ concentrations (Figure 8a, b). Archetypes over 1% made up between 76% (DNA) - 83% (cDNA) of the *amoA* assemblage and only 61% (DNA) - 68% (cDNA) of the *nirS* assemblage. The 4 most abundant AOA archetypes AOA55, AOA3, AOA21 and AOA32 made up 20% - 65% of the total and active community (Figure 8a, b). DNA of archetypes AOA55 and AOA79, both related to uncultured AOA in soils, significantly correlated with *in situ* NH₄⁺ concentrations (Figure S3). DNA and cDNA from AOA3 and AOA83 were significantly enriched in oxic waters and AOA7, closely related with crenarchaeote SCGC AAA288-M23 isolated from station ALOHA near Hawaii (Swan et al. 2011), was significantly enriched in anoxic and hypoxic waters for DNA and cDNA respectively (Table S2). All other archetypes did not vary with O₂ levels. DNA of AOA 3, closely related to *Nitrosopelagicus brevis* (CN25), identified as the only archetype to be significantly correlated with N₂O production and yield from AO (Figure S3).

The total and active denitrifier communities were dominated by Nir7, derived from an uncultured clone from the ODZ in the ETSP (Lam et al. 2009), and Nir7 was significantly more enriched in the active community (Figure 8c, d). DNA from ODZ depths of the eddy, S15 (907, 130 m) and S17 (912, 90 m), diverged most obviously from the rest and from each other (Figure 8c, d). Interestingly, these two samples were not divergent among the active *nirS* community (Figure 8c, d; Figure S2). DNA of Nir35, belonging to the Flavobacteriaceae derived from coastal waters of the Arabian Sea (Goréguès et al., 2004), was most abundant (12.3 %) at the eddy edge (S15) as

opposed to the eddy center (S17) where nir167, representing Anammox sequences from Peru, was most abundant (12.0 %). Interestingly, Nir4 and Nir14, among the top 5 abundant archetypes, were significantly enriched in oxic water masses (Table S2). nFR signal of nir166, belonging to Scalindua, and Nir23 were among the top 5 abundant archetypes and significantly enriched in anoxic depths.

CCA is a direct gradient analysis, where the gradient in environmental variables is known a priori and the archetypes are considered to be a response to this gradient. Composition from total and active AOA community did not differ between stations and all samples cluster close together (Figure S4a, b). S18 (912, 5 m) is a surface sample with lowest NO₃⁻ concentration (8 μmol L⁻¹), highest temperature and salinity of the data set and the DNA is positively related with O₂ and driven by AOA55, AOA32 and AOA79. RNA of S17 (912, 90 m) clusters with AOA70. AOA55 was abundant and its distribution is driven by O₂ and NH₄⁺ (Figure S3).

CCA clustered the denitrifier community DNA into one main group with a few exceptions (Figure S4 c). Two surface samples (S16, S18) clustered separate and were positively correlated with Nir4 and Nir14 and O₂. Two anoxic samples from the eddy core (S17) and eddy edge (S15) clustered separate with S17 being driven by 3 nirS archetypes – Nir54, Nir10 and Nir167 and S15 by Nir23, Nir35 and Nir133 (Figure S4 c). Total and active nirS community composition did not differ as a function of O₂. Although, composition of active and total nirS communities were not significantly different, the active community clustered slightly differently. For nirS RNA, surface and oxycline samples (S16 and S10) grouped together and were correlated positively with O₂, temperature and salinity, whereas the anoxic eddy samples did not differ from the rest (Figure S4d). N₂O production from NO₂⁻ significantly correlated with nirS gene and transcript abundance but both reductive N₂O production pathways were not linked with a single dominant nirS archetype (Figure S3)

4. Discussion

Most samples originated from Peru Coastal Water (PCW) characterized by supersaturated N₂O concentrations (Kock et al. 2016, Bourbonnais et al. 2017). Only the deepest sample (S1, 882 - 350m) saw the presence of a different water mass, the equatorial subsurface waters. Thus, our findings about regulation of N₂O production at different stations probably apply to the region as a whole. Several studies indicate that water mass hydrography plays an important role in shaping microbial community diversity (Biller et al. 2012, Hamdan et al. 2012) and a coupling of amoA alpha diversity to physical conditions such as salinity, temperature and depth has been shown in coastal waters off Chile (Bertagnolli and Ulloa 2017). While salinity, temperature and depth were prominent factors in shaping the community compositions of nitrifiers and denitrifiers (Figure S4), for N₂O production rates correlations with physical and chemical parameters were not consistent. On one hand, oxidative N₂O production from NH₄⁺ positively correlated with temperature, salinity, oxygen and negatively with depth and PO₄³⁻ concentration, on the other hand, reductive N₂O production from NO₂⁻ positively correlated with NH₄⁺ and NO₂⁻ concentrations, but negatively with NO₃⁻ concentrations (Figure S3). Both oxidative (AO) and reductive (NO₂⁻ and NO₃⁻ reduction) N cycling processes produced N₂O with differential effects of O₂ on them. Measured N₂O production rates were always highest from NO₃⁻, followed by NO₂⁻ and NH₄⁺, which is consistent with previous studies that showed denitrification as a dominant N₂O source in Peruvian coastal waters harboring an ODZ (Ji et al. 2015a, Casciotti et al. 2018). A low contribution of AO to N₂O production in low O₂ waters is in line with a previous study in this area estimating N₂O production based on isotopomer measurements combined with a 3-D Reaction-Advection-Diffusion Box model (Bourbonnais et al. 2017). The low percentage that AO contributed to total N₂O production was between 0.5 – 6%, with one exception in the shallowest sample S5 with

30 $\mu\text{mol L}^{-1}$ O_2 where AO contributed 86% to total N_2O production. We found strong positive effects of decreasing
435 O_2 concentration and increasing particulate matter concentrations on N_2O production in the upper oxycline.

The occurrence of an anticyclonic mode water eddy at 16°S (transect 4, stations 912, 907) at the time of
sampling was not unusual, as such eddies have been reported at a similar position (Stramma et al. 2013). High N
loss, a large SNM with low NO_3^- concentrations and strong N_2O depletion in the core of ODZ of the eddy result
in reduced N_2O inside of this kind of eddies as they age and are advected westward (Cornejo D'Ottone et al. 2016,
440 Arévalo-Martínez et al. 2016). Our study found similar patterns with largest SNM ($5.23 \mu\text{M NO}_2^-$), lowest NO_3^-
($14 \mu\text{mol L}^{-1}$) and N_2O (4 nmol L^{-1}) concentrations in the eddy center. For the first time N_2O production rates were
measured in an eddy, and the rates of up to $120 \text{ nmol L}^{-1} \text{ d}^{-1}$ are the highest N_2O production rates from
denitrification reported in the ETSP. Previously reported maximum rates ranged from $49 \text{ nmol L}^{-1} \text{ d}^{-1}$ (Bourbonnais
et al. 2017) and $50 \text{ nmol L}^{-1} \text{ d}^{-1}$ (Fariás et al. 2009) to $86 \text{ nmol L}^{-1} \text{ d}^{-1}$ (Dalsgaard et al. 2012). N_2 production was
445 not measured, so it cannot be determined whether this high N_2O production represents a high $\text{N}_2\text{O}/\text{N}_2$ yield or if
the N_2 production rates were also 10 times higher than outside of the eddy. Considering that at some depths only
incomplete denitrification (also known as “stop- and go” denitrification) to N_2O is at work, it would not be
surprising that N_2O production can reach the same order of magnitude as N_2 production from complete
denitrification. Aged eddies also show lower N_2O concentration maxima at the upper oxycline (Arévalo-Martínez
450 et al. 2016), which was not the case in this study where a young eddy was just about to detach from the coast. In
fact, the eddy stations show the highest N_2O peak in the upper oxycline within this data set. Eddies and their age
imprint mesoscale patchiness and heterogeneity in biogeochemical cycling. It appears that young eddies close to
the coast with high N_2O concentrations and high N_2O production rates have a great potential for high N_2O
emissions compared to aged eddies or waters surrounding eddies.

455

4.1 Effect of O_2 on reductive and oxidative N_2O production

The relationship between O_2 concentrations and N_2O production by nitrification and denitrification is
very complex in ODZs. While poorly constrained, the reported O_2 threshold level ($1.7 \mu\text{mol L}^{-1} \text{O}_2$) for reductive
 N_2O production is lower (Dalsgaard et al. 2014) than the reported O_2 threshold level ($8 \mu\text{mol L}^{-1}$) for N_2O
460 consumption in the ETSP (Cornejo and Fariás 2012). Nevertheless, the suboxic zone between $1 - 8 \mu\text{mol L}^{-1} \text{O}_2$
carries high N_2O concentrations indicating higher N_2O production than consumption. In this study, we focused on
this suboxic water masses above the ODZ and determined bulk kinetics of O_2 sensitivity in batch experiments,
which reflect the metabolism of the microbial community. The effect of O_2 on N_2O production differed between
natural O_2 concentrations with varying communities vs. manipulated O_2 concentrations within a community. While
465 N_2O production from NO_2^- and NO_3^- decreased exponentially along the natural O_2 gradient, it did not always
decrease for the manipulated O_2 treatments. Unchanged N_2O production with higher O_2 levels in NO_3^- treatments
showed that at least a portion of the community can respond very differently to a sudden increase in O_2 than
predicted from natural O_2 gradients with communities acclimated to a certain O_2 concentration. In the ETNP, this
pattern has been observed before (Ji et al. 2018a) but the mechanism behind it is unknown. Off the Chilean coast,
470 active N_2O production by denitrification was found at up to $50 \mu\text{mol L}^{-1} \text{O}_2$ (Fariás et al. 2009). These results
reinforce prior studies showing that distinct steps of multistep metabolic pathways, such as denitrification, can
differ in O_2 sensitivity (Dalsgaard et al. 2014). In various bacterial strains and natural communities, the NO_3^-
reductase enzyme (*Nar*) which catalyzes the first step in denitrification, is reportedly the most O_2 tolerant, followed
by the more O_2 sensitive steps of NO_2^- reduction (*Nir*) and N_2O reduction (Körner und Zumft 1989, McKenney et

475 al. 1994, Kalvelage et al. 2011). The fact, that we see this pattern only in the NO_3^- treatments and not in the NO_2^-
treatments is evidence that it is not due to inhibition of the reduction of N_2O to N_2 at higher O_2 . We suggest a
stimulation of incomplete denitrification, which leads to the accumulation of N_2O in our serum bottles rather than
a stimulation of overall denitrification rates to N_2 . While nitrate reduction was inhibited by higher O_2
concentrations, N_2O production was not, leading to very high yields of N_2O production per nitrite produced. We
480 hypothesize that there is a direct channeling of reduced NO_3^- to N_2O without exchange of an internal nitrite pool
with the surrounding nitrite. If NO_2^- does not exchange, our rate estimates for NO_3^- reduction based on produced
 $^{15}\text{N}\text{-NO}_2^-$ are underestimated resulting in high yields. A low NO_2^- exchange rate has been shown before (Ji et al.
2018b). Based on the assumption that all labelled N_2O from $^{15}\text{NO}_3^-$ has gone through the NO_2^- pool, we include
the NO_2^- pool into calculating f . In $^{15}\text{NO}_3^-$ incubations the enrichment of the substrate pool was low ($f = 0.05 -$
485 0.1) and including NO_2^- resulted in an underestimation of no more than 5 % depending on the *in situ* NO_2^-
concentration, and thus does not explain the high rates.

One N_2O producing process not considered in this study is fungal denitrification, but it deserves
mentioning because in soils and coastal sediments it contributes substantially to N_2O production (Wankel et al.
2017, Shoun et al. 2012). With ^{15}N -labelling experiments it is not possible to distinguish between bacterial and
490 fungal denitrification. In ODZs, marine fungal communities show a wide diversity (Jebaraj et al. 2012) and a high
adaptive capability is suggested (Richards et al. 2012). Most fungal denitrifiers lack the capability to reduce N_2O
to N_2 , hence all nitrate reduction results in N_2O production (Richards et al. 2012). In a culture study, the fungus,
Fusarium oxysporum, needed O_2 exposure before it started to denitrify (Zhou et al. 2001). To what extent marine
fungi play a role in denitrification in open ocean ODZs and their O_2 sensitivity remains to be investigated.

495 N_2O production from NH_4^+ did not decrease exponentially with increasing O_2 as shown previously for
the ETSP (Qin et al. 2017, Ji et al. 2018a, Santoro et al. 2011). N_2O production rather increased with increasing *in*
situ oxygen and had an optimum between $1.4 - 6 \mu\text{mol O}_2 \text{ L}^{-1}$ in manipulated O_2 treatments. A similar optimum
curve was observed in cultures of the marine AOA *Nitrosopumilus maritimus*, where N_2O production reached
maxima at O_2 concentrations between $2 - 10 \mu\text{mol L}^{-1}$ (Hink et al. 2017). Furthermore, N_2O production by *N.*
500 *viennensis* and *N. maritimus* was not affected by O_2 but instead by the rate of AO (Stieglmeier et al. 2014, Hink et
al. 2017). To find out if this is the case in our study, we plotted AO rate against N_2O production from NH_4^+ for
natural and manipulated O_2 samples (Figure S5). The resulting significant linear fit ($R^2 = 0.75$, $p < 0.0001$) implies
that the rate of AO was the main driver for the intensity of N_2O production from NH_4^+ and oxygen had a secondary
effect.

505 Discrepancies in estimates of the O_2 sensitivity of N_2O production by nitrification and denitrification are
likely due to a combination of taxonomic variation as well as differences in sensitivity among the various enzymes
of each pathway.

4.2 N_2O yields and hybrid N_2O formation from NH_4^+

510 N_2O yields of AO were $0.15 - 2.07 \%$ ($\text{N}_2\text{O-N mol} / \text{NO}_2^- \text{-N mol} = 1.5 \times 10^{-3} - 20.7 \times 10^{-3}$) which are at
the higher end of most marine AOA culture or field studies (Hink et al 2017, Qin et al. 2017, Santoro et al. 2011,
Stieglmeier et al. 2014). Only in 2015 off the coast of Peru a higher maximum yield of 3.14% was reported (Ji et
al. 2018a). In the ETSP high N_2O yields from AO may be more common than previously thought. Not only high
 N_2O yields in low O_2 waters ($< 6 \mu\text{mol L}^{-1}$), but also higher yields at higher O_2 concentrations, 0.9 % at $30 \mu\text{mol}$
515 $\text{L}^{-1} \text{O}_2$ compared to 0.06% at $> 50 \mu\text{mol L}^{-1}$ (Ji et al. 2018a) were found. In near coastal regions, higher N_2O yield

at higher O₂ concentrations expands the overall water volume where N₂O production by AO contributes to high N₂O concentration, which is more likely to be emitted to the atmosphere.

Insights into the production mechanism of N₂O is gained from hybrid-N₂O formation based on differentiating between production of single (⁴⁵N₂O) and double (⁴⁶N₂O) - labelled N₂O. If the production of ⁴⁵N₂O is higher than what is expected based on the binomial distribution, then an additional source of ¹⁴N can be assumed. *In situ* NH₄⁺ is below detection in almost all water depths, hence in our incubations this pool is 99% labelled. As potential ¹⁴N substrates, NO₂⁻, NH₂OH and HNO are most likely. Whether hybrid N₂O formation is purely abiotic, a mix of biotic and abiotic or biotic reactions, is debatable (Stieglmeier et al. 2014, Kozłowski et al. 2016, Carini et al. 2018, Lancaster et al. 2018, Stein 2019). Hybrid N₂O production from NO₂⁻ was variable with depth and oxygen, which can be explained by the different proportions of nitrifier versus denitrifier NO₂⁻ reduction to N₂O. For example, in the interface sample S19 (892, 144 m, 3.69 μmol L⁻¹ NO₂⁻) N₂O production from NO₂⁻ (0.72 ± 0.19 nmol L⁻¹ d⁻¹) was 20 times higher than from NH₄⁺ (0.033 ± 0.0004 nmol L⁻¹ d⁻¹) and no hybrid N₂O formation from NO₂⁻ was found (Figure 5d). There, the major N₂O production mechanism seems to be by denitrification rather than nitrification, and even if there was a hybrid production we were not able to detect it within the given error ranges. Hybrid N₂O production from NH₄⁺ was independent of the rate at which N₂O production took place and independent of the O₂ concentration and varied little (70–86% of total N₂O production) during AO. Therefore, a purely abiotic reaction outside and without the vicinity of the cell can be excluded because concentrations of potential substrates for abiotic N₂O production like Fe(II), Mn, NO, NH₂OH vary with depth and O₂ concentration (Zhu-Barker et al. 2015, Kondo and Moffet 2015, Lutterbeck et al. 2018, Korth et al. 2019). Hence, any ¹⁴N which is integrated into N₂O to produce a hybrid/single labelled N₂O has to be passively or actively taken up by the cell first (Figure 9). There, it reacts with an intermediate product (¹⁵NO or ¹⁵NH₂OH) of AO inside the cell. With this set of experiments, it is not possible to disentangle if hybrid production is based on an enzymatic reaction or an abiotic reaction inside the cell. Caranto et al. (2017) showed that the main substrate of NH₂OH oxidation is NO, making NO an obligate intermediate of AO in AOB and suggested the existence of an unknown enzyme that catalyzes NO oxidation to NO₂⁻ (further details also in Stein 2019). If NO is an obligate intermediate of AO in AOA (Lancaster et al. 2018), a constant rate of spontaneous abiotic or enzymatic N₂O production is very likely, which always depends on the amount of NO produced in the first place. This could explain why we consistently find ~80% hybrid formation at high as well as at low AO rates. Further studies are needed to investigate the full mechanisms.

4.3 Effect of particulate organic matter on N₂O production

A positive stimulation of N₂O production from denitrification by particulate organic matter was found, indicating carbon limitation of denitrification in the ETSP. The experimental POM amendments simulated a low POC export flux and represented a flux that happens over 2 - 15 days, assuming an export flux of 3.8 mmol m⁻² d⁻¹ and that 8% of the total POC pool is >50 μm (Boyd et al. 1999, Martin et al. 1987, Haskell et al. 2015). We are aware that the POM collected by *in situ* pumps is a mix of suspended and sinking particles and hence the flux should be considered a rough estimate. However, the particle size (>50 μm) used in the experiments is indicative of sinking particles. The stimulation of N₂ production from denitrification by particulate organic matter has been shown in ODZs before (Ward et al. 2008, Chang et al. 2014), with quantity and quality of organic matter influencing the degree of stimulation (Babbin et al. 2014). In this study, amendments of POM at different degradation stages resulted in variable magnitudes of N₂O production from nitrite and nitrate with no significant

correlations between magnitude of the rates and amount, origin or quality of POM added. The processing of the particles has reduced the original N/C ratios of POM from the mixed layer more than of the POM from the ODZ, resulting in similar N/C ratios of particles from different depths. This could be one possible explanation for a lack of correlation of N₂O production with origin of the POM. Furthermore, N₂ production was not quantified and hence it is not possible to evaluate potential relationships between overall N loss and POM additions or whether the partitioning between N₂O and N₂ varied among treatments and depths. N₂O/N₂ production ratio can vary from 0 - 100% (Dalsgaard et al. 2014, Bonaglia et al. 2016). A temporary accumulation of N₂O before further reduction to N₂ in the incubations can be ruled out as N₂O accumulated linearly over time. The only station, where POM additions did not stimulate N₂O production was in the center of the young eddy (912-S17). There, the highest rates of N₂O production from NO₃⁻ (118 nmol L⁻¹ d⁻¹) were found, indicating that denitrification was not carbon limited. This is consistent with previous studies on anti-cyclonic eddies, which have shown high N loss in the core of a young eddy that weakened with aging of the eddy (Stramma et al. 2013, Bourbonnais et al. 2015, Löscher et al. 2016). A direct link between the freshly produced POM fueling N loss on one hand, and decreased N loss with aging due to POM export out of the eddy on the other hand, was proposed (Bourbonnais et al. 2015, Löscher et al. 2016). In this study, the young eddy is a hot spot for N₂O production.

Besides carbon availability as electron donor for denitrification, copper limitation and high NO₃⁻ availability may play a role. Copper limitation has been argued to lead to N₂O accumulation by inhibiting the copper-dependent N₂O reductase (Granger and Ward 2003, Bonaglia et al. 2016), but it was not a limiting factor for denitrification in the three major ODZs previously (Ward et al. 2008). Water sampling from Niskin bottles in our study was not trace metal clean and could be contaminated with Copper from the sampling system, making a limitation of trace metals in our incubations unlikely. However, OM fueled N₂O production may have become limited by the availability of copper during the incubation.

High NO₃⁻ availability increases N₂O production from denitrification in salt marshes (Ji et al. 2015b) and in soils (Weier et al. 1993), systems which are generally not carbon limited. Also, at the oxic - anoxic interface of Chesapeake Bay, the ratio of NO₂⁻ to NO₃⁻ concentration was identified as a driver for high N₂O production from NO₃⁻ (Ji et al. 2018b). This study also found higher N₂O production rates from NO₃⁻ than NO₂⁻, which linearly correlated with the ratio of NO₂⁻/NO₃⁻ concentrations (Figure S6). Intracellularly produced NO₂⁻ does not seem to exchange with the surrounding pool, but ambient NO₃⁻ is directly converted to N₂O, a process identified as “nitrite shunting” in N₂ production studies (de Brabandere et al. 2014, Chang et al. 2014). POM as electron donor is an important regulator for reductive N₂O production.

4.4 Effect of abundance of total and active community composition on N₂O production rates

The abundances of both *amoA* and *nirS* genes found in the ETSP are similar to those reported in earlier studies in the ETSP (Peng et al. 2013, Ji et al. 2015a, Jayakumar et al. 2013). The *amoA* gene abundances were similar to those reported for the coastal ETSP by Lam et al. (2009), but *nirS* abundances reported here were higher than the *nirS* abundances in that study, probably due to the use of different PCR primers. The community composition of AOA did not significantly differ along the O₂ gradient as shown previously (Peng et al. 2013), but a significant correlation between archaeal *amoA* transcript abundance and N₂O production was shown in this study. The combination of qPCR and microarray analysis offered a great advantage to relate the total abundances to the production rates and additionally link particular community components to biogeochemical activities. To determine whether a particular archetype drives the correlation of N₂O production by AO, a Bray-Curtis

dissimilarity matrix revealed archetype AOA3 related to *Nitrosopelagicus brevis* (CN25) to be significantly correlated with the N₂O production by AO. This clade is abundant in the surface ocean and typically found in high abundances in the lower euphotic zone (Santoro et al. 2011, 2015). With the demonstration of high abundances of AOA3 coincident with high nitrification rates and high N₂O production rates, we suggest that *Nitrosopelagicus brevis* related AOA likely play an important role in N₂O production in near surface waters in the Eastern Tropical South Pacific.

The lack of significant correlation between community composition or single members of the community and reductive N₂O production is consistent with the fact that *nirS* is not the enzyme directly synthesizing N₂O and *nirS* communities are sources as well as sinks for N₂O. Taxonomic analysis of the *nirS* gene and transcripts suggested that there is high taxonomic diversity among the denitrifiers, which is likely linked to a high variability of the total denitrification gene assembly (including *nos*, *nor*, *nir*). In particular the abundance and diversity of nitric oxide reductase (*nor*), the enzyme directly synthesizing N₂O, would be of interest, but it is present in nitrifiers and denitrifiers (Casciotti and Ward 2005) and one goal of this study was to differentiate among N₂O produced by nitrifiers and denitrifiers. However, *nirS* gene and transcript abundance correlated with N₂O production from NO₂⁻ making it a possible indicator for one part of reductive N₂O production. It is also worth noting that anammox related *nirS* genes and transcripts (*nirS* 166, 167) contribute up to 12% of the total copy numbers putting a wrinkle on *nirS* abundance as marker gene for denitrifiers only. The subtraction of the anammox related *nirS* genes from total copy numbers did not change the results from Bray-Curtis Analysis. These data indicate that the extent to which gene or transcript abundance patterns or community composition of marker genes of processes can be used as proxies for process rate measurements is variable, likely due to complex factors, including the relative dominance of different community members, the modular nature of denitrification, differences in the level of metabolic regulation (transcriptional, translational, and enzymatic), and the range of environmental conditions being observed.

4.5 Summary and conclusion

In this study we used a combined approach of ¹⁵N tracer techniques and molecular techniques in order to investigate the factors that control N₂O production within the upper oxycline of the ODZ in the ETSP. Our results suggest that denitrification is a major N₂O source along the oxic - anoxic interface of the upper oxycline. Highest N₂O production rates from NO₂⁻ and NO₃⁻ were found at or below the oxic-anoxic interface, whereas highest N₂O production from AO was slightly shallower in the oxycline. Overall, *in situ* O₂ threshold below 8 μmol L⁻¹ favored nitrate and nitrite reduction to N₂O and high N₂O yields from AO up to 2.2%. A different pattern was observed for the community response to increasing oxygen, with highest N₂O production from NH₄⁺ and NO₂⁻ between 1.4 – 6 μmol L⁻¹ O₂ and high N₂O production from NO₃⁻ even at O₂ concentrations up to 22 μmol L⁻¹. This study highlights the diversity of N₂O production regulation and the need to conduct further experiments where single community members can be better constrained. Our experiments provide the first insights into N₂O regulation by particulate organic matter in the ETSP with particles greatly enhancing N₂O production (up to 5fold). Furthermore, the significant positive correlation between *Nitrosopelagicus brevis* (CN25) and N₂O produced from AO could indicate its importance in N₂O production and points out the great value of combining biogeochemical rate measurements with molecular analysis to investigate multifaceted N₂O cycling. This study shows that short term oxygen increase can lead to high N₂O production even from denitrification and extends the existing O₂ thresholds for high reductive N₂O production up to 22 μmol L⁻¹ O₂. Together with high N₂O yields from AO up to O₂ levels

640 of 30 $\mu\text{mol L}^{-1}$, an expansion of low oxygenated waters around ODZs predicted for the future can significantly increase marine N_2O production.

Regardless of which processes are responsible for N_2O production in the ODZ, high N_2O production at the oxic-anoxic interface of the upper oxycline sustains high N_2O concentration peaks with a potential for intense N_2O emission to the atmosphere. An average total N_2O production rate of 3.1 $\text{nmol N}_2\text{O L}^{-1} \text{d}^{-1}$ in a 50 m thick suboxic layer with 0 – 20 $\mu\text{mol L}^{-1} \text{O}_2$ leads to an annual N_2O efflux of 0.5 Tg N y^{-1} in the Peruvian upwelling
645 (2.22 $\times 10^5 \text{ km}^2$, Arévalo-Martínez et al. 2015), which is within the estimates based on surface N_2O concentration measurements from 2012-2013 (Arévalo-Martínez et al. 2015, Bourbonnais et al. 2017). The importance of the Peru upwelling system for global N_2O emissions (5 – 22% of global marine N_2O emissions) is directly linked to the extreme N_2O accumulations in coastal waters. Coastal N_2O hotspots are well known (Bakker et al. 2014) and this study shows that they can be explained by considering denitrification as a major N_2O source. With the further
650 parametrization of POM export as a driver for N_2O production from denitrification, models may be able to better predict N_2O emissions in highly productive coastal upwelling regions and to evaluate how fluxes might change with changing stratification and deoxygenation.

Data availability: The data presented here were archived in the SFB754 database (www.sfb754.de). The N_2O data are also available from the Marine Methane and Nitrous Oxide (MEMENTO) database (<https://memento.geomar.de/de/n2o>).

Author contributions: CF, HWB and BW conceptualized the study. CF and MS performed experiment. CF and ELP analyzed samples. RX and EA collected POM. DLAM sampled and measured N_2O concentrations. AJ performed qPCR. SO supported mass spectrometer analysis. CF analyzed data and led the writing effort, with
660 substantial contributions from all co-authors.

Competing interests: Authors declare no competing interests.

Figure Legends:

- 1050 **Figure 1:** Study site, showing transect and station numbers, in the Eastern Tropical South Pacific during cruise M138.
- Figure 2:** Depth profiles of O₂, nutrients and N₂O in the upper 400 m for all stations. Panel numbers 1 - 4) refer to the transect numbers.
- 1055 **Figure 3:** (I) Profiles of AO, (a, e, I), N₂O production rates from NH₄⁺ (b, f, j), archaeal *amoA* gene (c, g, k) and transcript copy numbers mL⁻¹ (d, h, l). (II) Profiles of nitrate reduction rates (a, f, k, o), N₂O production rates from NO₃⁻ (b, g, l, p) and NO₂⁻ (c, h, m, q) and *nirS* gene (d, I, n, r) and transcript copy numbers mL⁻¹ (e, j, m, s). In (I) and (II), the panel numbers 1 – 4 correspond to transect numbers. Negative values on the y-axis represent shallower, oxic depths and the positive values represent deeper, anoxic depth (0 = interface). Shaded area indicates the anoxic zone. Note different scale for N₂O production rates.
- 1060 **Figure 4:** O₂ dependence of N₂O production rates from NH₄⁺ (a, d), NO₂⁻ (b, e) and NO₃⁻ (c, f). Upper panel (a-c) is N₂O production along natural O₂ gradient from all stations. Lower panel (d-f) is N₂O production in manipulated O₂ experiments with water from oxic - anoxic interface from slope station 892 (S11, 0 μmol L⁻¹ O₂, 145m) and shelf station 894 (S19, 0 μmol L⁻¹, 120 m). Note different scale for N₂O production rates from NH₄⁺. Vertical error bars represent ± Standard error (n = 5 per time course). Horizontal error bars represent ± Standard error of measured
- 1065 O₂ over the time of incubations (n = 6).
- Figure 5:** O₂ dependency of hybrid N₂O formation from NH₄⁺ (a, c) and NO₂⁻ (b, d) along the natural O₂ gradient (a, b) and for the O₂ manipulations (c, d) from sample S11 (0 μmol L⁻¹ O₂, 145m) and S19 (894, 0 μmol L⁻¹, 120 m)
- 1070 **Figure 6:** Yields (%) of N₂O production during NH₄⁺ oxidation (a, c) and during nitrate reduction (b, d) along the natural O₂ gradient (a, b) and for the O₂ manipulations (c, d) from sample S11 (892, 0 μmol L⁻¹ O₂, 145m) and S19 (894, 0 μmol L⁻¹, 120 m). Error bars present ± SD calculated as error propagation.
- Figure 7:** Bar plots of additions of autoclaved suspended and sinking particles >50 μm (See Table 2). POM1 = mixed layer depth, POM2 = oxycline, POM3 = ODZ. Error Bars represent ± SE of linear regression. * indicates significant difference to control rate (p < 0.05)
- 1075 **Figure 8:** Stacked bar plot of community composition of AOA *amoA* archetypes (a, b) and *nirS* archetypes (c, d). Only archetypes over 1% contribution are shown. (a, c) total community composition (DNA). (b, d) active community composition (cDNA).
- Figure 9:** Scheme illustrating the possible reactions for hybrid N₂O formation. The ellipse represents an AOA cell.
